Anatina subrostrata.

a, Inside view of valve, showing the hinge, &c.; b, external view; valves closed.

Mya.—Animal oblong, a little compressed, enveloped in a rather delicate mantle adhering by its borders, closed by a membranous lamina, and forming backwards round the tubes a loose envelope in which they are withdrawn; tubes united, of moderate length, a little separated at their summit and radiated at their orifices; foot very small, conical, coming out of the mantle by a small slit situated at its antero-inferior border, in the median line; branchiæ moderate, not much elongated, unequal on the same side; mouth small, having triangular appendages striated like the branchiæ. Shell enveloped with an epidermis prolonged upon the tubes and mantle of the animal, rather solid, gaping at both extremities, equivalve; umbones projecting but little; hinge composed of one or two oblique folds, diverging backwards from a horizontal, compressed, spoon-shaped process, belonging to the left valve and corresponding to an equally horizontal fosset in the right valve; ligament internal, inserting itself between the fosset and the spoon-shaped process; muscular impressions distant, the anterior elongated, the posterior rounded; pallial impression narrow and deeply excavated. (Rang.)

There are ten species. They are found in the northern seas, west Africa, the Philippines, Australia, and California.

The *Myæ* live buried in sandy beaches, wherein they often lie with the tube just projecting; they are also found in the silt of estuaries.

M. arenaria has the shell ovate, rounded anteriorly. The subjoined cut shows the hinge, muscular impressions, markings, and general form of the shell.

Mya arenaria.

It is found in the British Channel and European seas. It burrows a foot deep. It is eaten in Zetland and America, and is regarded as excellent food.

Lutricola.—Body oval, very much compressed or subcylindrical, the mantle only closed in the half of its lower border; foot small, projecting but little beyond the abdominal mass; tubes long, distinct or united. Shell oval or elongated, regular, equivalve, more or less inequilateral, sometimes scarcely gaping, the edges constantly simple and trenchant, the umbones but little marked; hinge subsimilar, formed of two very small diverging cardinal teeth, sometimes effaced before a large triangular fosset; ligament double, the external posterior rather small, the internal much thicker, and inserted in the fossets; two distinct muscular impressions united by a pallial impression, which is deeply sinuous backwards. (De Blainville.)

M. De Blainville divides the genus *Lutricola* into the two following sections:—

A. Oval or orbicular species nearly equilateral, very much compressed, gaping but little; hinge similar; internal ligament inserted in the fosset of a vertical spoon-shaped process; two distinct tubes. Genus *Ligula*, Leach.

* Without longitudinal striae.

L. compressa has the shell somewhat thin, compressed, rounded-trigonal, aqualid, transversely striated, dirty gray, sometimes yellowish or reddish. It is found in the British Channel.

Lutricola compressa.

** Striae from the umbo to the base.

L. rugosa (*Macra rugosa*, Gm.). It is found in the European seas.

B. Oblong species, subcylindrical, gaping very much; two very strong hinge-teeth; spoon-shaped process of the ligament vertical. Genus *Lutraria*, Lam.

L. solenoides (*Mya oblonga*, Gm.; *Macra hians*, Dilw.) has the shell oblong, with transverse rugiform striae, anterior end very long, apex rounded, gaping much; dirty white or reddish. It is found in the European seas.

Lutraria solenoides.

a, Internal view of valve; b, external view.

The genera above collected under the name of *Lutricola* by M. De Blainville belong to the genus *Lutraria* of Lamarck. [CONCHACEA.]

There are 18 species of *Lutraria* found in the United States, Brazil, the Mediterranean, Senegal, Cape of Good Hope, India, New Zealand, Sitka, and the British Islands.

Section 2. (Ligament external and convex.)

Psammocola.—Of the genera, or rather sub-genera, enumerated by M. De Blainville, of this genus, M. Deshayes is of opinion that the genus *Psammobia* should be retained. It comes near to the *Tellina*, differing from them more in the shell, which has not the irregular posterior bend, than in the animal, if reference be made only to the figure of Poli. The species figured by Messrs. Quoy and Gaimard, in the 'Voyage of the Astrolabe,' presents particular characters, observes M. Deshayes, different from those which *Tellina* have hitherto shown. *Psammotea*, he thinks, should not be continued as a genus. (Edit. Lam.)

The species are numerous. In his 'Tables,' M. Deshayes gives eighteen as the number of recent *Psammobia*, and notices four as fossil (tertiary). *Psammobia vespertina* and *P. muricata* he notes as

both living and fossil (tertiary). The number of species of *Psammotea* recorded is eight recent and one fossil.

The species of *Psammobia* have been found in sands at depths varying from near the surface to thirteen fathoms.

There are 40 species of *Psammobia*. They are found in Norway, the British Islands, New Zealand, and the Pacific. *P. gari* is eaten in the Pacific.

Soletellina.—Shell oval oblong, compressed, with sharp edges, both curved; equivalve, subequilateral, much more wide and rounded at the cephalic extremity than at the other, which is more or less attenuated and sub-carinated; the umbones sub-medial, not projecting much; hinge formed of one or two very small cardinal teeth; ligament thick, convex, and supported on very elevated nymphal callosities; two rounded, distant, muscular impressions; pallial impression very sinuous backwards. (Blainv.)

M. De Blainville observes that this genus, which he instituted for four or five species of Lamarck's *Solens*, differs very little from *Psammocola*.

S. radiata (*Solen rostratus*, Lam.). Shell transversely oblong, violaceous, with many obscure rays; anterior side attenuated and rostrated. It is found in Oriental seas.

Soletellina radiata.

Sanguinolaria.—Animal very like that of *Psammobia florida*. (Garner, 'Zool. Trans.,' vol. ii., pl. 18, figs. 1, 2.) Shell oval, a little elongated, very much compressed, hardly gaping, equivalve, sub-equilateral, equally rounded at both extremities, without any posterior carination; umbones slightly indicated; hinge formed of one or two approximated cardinal teeth in each valve; ligament projecting, convex; two rounded muscular impressions, which are distant and united by a narrow pallial impression, which is very sinuous backwards. (Blainv.)

Both M. De Blainville and M. Rang state that the animal of *Sanguinolaria* is unknown.

S. occidens. Shell radiated and spotted with whitish and red. Found in the Mediterranean.

Animal of *Sanguinolaria occidens* in the shell. (Poll.)

S. rugosa.—Shell semiorbicate, slightly convex, white, with rosy umbones; the striae transverse and arcuate. It is found at Jamaica. (Lamarck.)

Shell of *Sanguinolaria rosea*. (*Psammobia rosea*, Desh.)

The *Sanguinolariae* have been found in sands and sandy mud, at depths varying from five to thirteen fathoms.

There are 20 recent and 30 fossil species. The former are found in the West Indies, Red Sea, India, Madagascar, Japan, Australia, Tasmania, and Peru. The latter are found in the tertiary beds.

Solecuretus.—Animal much too large for the shell; lobes of the

mantle thick forward, soldered together on their posterior moiety, and prolonged on this side into two great unequal siphons united near their summit; foot linguiform, large, very thick; labial palps very long and narrow; branchiae narrow and very long, extending throughout the length of the branchial siphon. Shell oval-oblong, transverse, covered with undulating oblique and longitudinal striae, gaping at both extremities. Hinge median, two cardinal teeth in one valve, one, rarely two, on the other, non-lustrant; nymphæ callous, thick, supporting an external and convex ligament; pallial impression very deeply sinuous. (Desh.)

M. De Blainville separates his *Solecuretus* into the following sections:—

A. Flat delicate species with an interior har running obliquely from the umbo to the abdominal edge.

Ex. *S. radiatus*.

B. More cylindrical species, without an internal har.

Ex. *S. strigilatus*.

C. Species still more elongated and sub-cylindrical.

Ex. *S. Legumen*.

M. Deshayes confines the genus to those species which have all the same character with *S. strigilatus*.

S. strigilatus. Shell oval oblong, very convex, rosy, with two white rays, sculptured with oblique striae. It is a native of the Mediterranean and Atlantic ocean.

Solecuretus (Solen) strigilatus.

There are 25 recent and 30 fossil species. The former occur in the United States, the British Islands, the Mediterranean, West Africa, and Madeira.

Solen.—Animal very much elongated, more or less cylindrical or compressed; mantle closed throughout its length, adhering by its borders, and bound to the lower edge of the shell by a double membrane, which folds back upon itself to form the epidermis, presenting backwards a single tube, double in the interior, conical, annulated, susceptible of much elongation, with two simple orifices, that of the siphon being greater than that of the anus; open entirely in front for the passage of a stout foot, which is conical, convex in its middle, pointed at its extremity, and which terminates the body of the animal in a straight line; branchiae long, narrow, pointed backwards, nearly of equal size, adhering to two lines forward, one on each side of the body, uniting at last at a certain distance backwards on a single line, and then free and floating up to the entry of the siphon; labial appendages not striated like the branchiae, elongated, triangular, recurved, and directing their point backwards; mouth small, anus at the extremity of a very small tube floating in the cavity above the free part of the branchiae. Shell rather delicate generally, translucent, equivalve, extremely inequilateral, elongated, gaping, truncated at both extremities, and with nearly parallel edges; umbones entirely anterior, hardly distinct; hinge composed of one or two teeth; ligament convex, slightly elongated; muscular impressions very distant, the anterior oblong, elongated, rather narrow, the posterior rather rounded; pallial impression straight, very long, terminated backwards by a short bifurcation. (Rang.)

Razor-Fish (*Solen vagina*). Shell and soft parts.

The species of *Solen*, which are popularly called Razor Fishes, live in sandy beaches, wherein they often lie buried in a vertical position 2 feet deep, though their ordinary habit is to go only so low in the sand or silt (for they are found also in estuaries) as to leave the tube just projecting. They may be said to have regular burrows, which leave a mark in the sand like a key-hole. When the animal is undisturbed and the tide is in, it lies with the tubes at the entrance of its perpendicular hole; if it be disturbed, down it goes: in short its life is spent in descending to the depth of its burrow and ascending from

it again to the surface by means of the extension and contraction of its great muscular foot, which is situated at that part of the shell which is lowest. Although with difficulty obtained by digging, they are easily induced to come forth from their hiding places by putting a little salt over their holes. They may then be easily captured. Some of the species make an excellent soup.

They are found in the seas of the whole world. There are 25 recent species.

Solen Legumen. Shell and soft parts.

M. De Blainville thus divides the genus:—

A. Species somewhat curved longitudinally; umbo not terminal.

Ex. *Solen cultellus*.

B. Species straight, or hardly curved; umbo terminal.

Ex. *S. Vagina*.

The British species of *Solen* recorded by Messrs. Forbes and Hanley are *S. Ensis*, *S. marginatus*, *S. pellucidus*, and *S. siliqua*.

Shell of *Solen Ensis*.

a, External view of valves closed; b, internal view of valve.

Solemya.—Animal oval, transverse; lobes of the mantle united for their posterior half, terminated by two short and unequal siphons; foot probosciform, truncated anteriorly by a disc, or kind of sucker, the borders of which are fringed; a single branchia on each side in form of a plume, the barbs of which are isolated up to the base; arms terminal, not floating. (Deshayes.) Shell very delicate, fragile, compressed, elongated, rounded at its extremities; the borders straight and parallel, gaping a little backwards, regular, equivalve, very inequilateral, covered with a shining epidermis, which invests it on all sides, except in front and behind; anterior side much longer than the posterior; umbones but little distinct; hinge composed of a cardinal, dilated, compressed tooth, which is very oblique, a little curved above, serving for the insertion of the ligament in each valve; ligament almost entirely posterior; muscular impressions small, rounded, distant; some traces of a pallial impression. (Rang.)

Sands are the localities in which the genus has been found.

Panopæa.—Shell thick, solid, convex, oblique, elongated, gaping at both extremities, equivalve, inequilateral, rather irregular; umbones well marked, contiguous, rather curved forward, and more approximated to the anterior than the posterior part; hinge presenting a conical tooth in each valve in front of a fosset, and of a thick callosity, not projecting outwards, and but little elongated, on which is inserted the external, posterior, and convex ligament; muscular impressions irregularly oval, the anterior the longest, both united by a pallial impression, which is wide, parallel to the border of the shell, and rather deeply excavated backwards. (Rang.)

P. Aldrovandi is noted as both living and fossil (tertiary). Six recent and 140 fossil species are the numbers stated by Woodward in his 'Treatise on Shells.'

The species of *Panopæa* have been found in sands and shallow water.

Glycmeris.—Animal elongated, thick, cylindraceous, having the lobes of the mantle very thick, open only at the anterior extremity for the passage of a small cylindrical foot, and terminated posteriorly by two siphons, united into a single cylindrical very fleshy mass, and never capable of entering the shell; mouth moderate, oval, accompanied on each side by two large equal triangular palps, joined by their base to the anterior adductor muscle. Branchiae long and thick, two on each side nearly equal. (Deshayes, after Audouin.) Shell with a strong epidermis, elongated, rounded, gaping at both extremities, rather irregular, equivalve, very inequilateral; umbones projecting but little, skinned (écorchés); hinge toothless, presenting only a thick and but little elongated callosity; external ligament supported by nymphæ projecting outwards; muscular impressions distinct and very distant; pallial impression well marked, not excavated posteriorly; valves thickened by callosities in the interior. (Rang.)

There is but one species, which is found on sands at moderate depths.

Saxicava. [LITHOPHAGIDÆ.]

Byssomya. [BYSSOMYA.]

Rhomboides.—Animal. Body rhomboidal, elongated, rather compressed, with two distinct tubes backwards; a rather wide slit at the anterior and inferior part of the mantle for the exit of a small conical foot, with a byssus the filaments of which are enlarged at the extremity. Shell rhomboidal, rather irregular, striated longitudinally, very inequilateral; umbones very distinct and very antero-dorsal; hinge formed by two small cardinal teeth; ligament external, posterior, rather projecting; two rounded muscular impressions.

Ex. *Rhomboides rugosus*.

Hiatella.—Animal unknown. Shell delicate, elongated, sub-rhomboidal, equivalve, very inequilateral, gaping at its inferior border and posterior extremity; umbo very anterior and curved forwards; hinge dorsal, formed of a single tooth in one valve corresponding with a notch on the opposite valve, or of a small tooth with a cardinal fosset on each valve; ligament probably anterior and dorsal; muscular and pallial impressions unknown. (De Blainville.)

M. De Blainville divides the genus into the following sections:—

A. Species with a tooth in one valve only.

Ex. *Hiatella biaperta*.

B. Species with a small tooth on each valve. Genus *Biapholius*, Leach.

Ex. *Hiatella Arctica* (*Mya Arctica*, Oth.; Fahr.)

Gastrochana. [GASTROCHENA.]

Clavagella. [CLAVAGELLA.]

Aspergillum. [ASPEROILLUS; TUBICOLIDÆ.]

PYLORUS. [DIOESTION; STOMACH.]

PYRALLOLITE, a Mineral occurring crystallised and massive. Primary form, according to Levy, an oblique-angled parallelepiped. Cleavage parallel to the two lateral faces of the primary form, and to one of the diagonal planes. Fracture earthy. Hardness, scratches carbonate of lime, and is scratched by felspar. Colour white and greenish; transparent on the edges; lustre resinous. Specific gravity 2.55 to 2.60.

Before the blow-pipe it becomes at first black, and afterwards white; swells and fuses on the edges into a glass, and with borax gives a transparent glass.

A massive variety, yellowish, in small laminar masses, with white carbonate of lime, red phosphate of lime, and green pyroxene. It occurs at Storgard, Pargas, Finland.

Its analysis by M. Nordenskiöld gives—

Silica	56.62
Magnesia	23.38
Alumina	5.38
Lime	5.53
Oxide of Iron	0.99
Oxide of Manganese	0.99
Water	3.53

—96.52

PYRAMIDELLIDÆ, a family of Gasteropodous *Mollusca*. The shell is spiral, turreted; the nucleus minute, sinistral; aperture small; columella sometimes with one or more prominent plaits. Operculum horny, imbricated, nucleus internal. The animal has broad ear-shaped tentacles, often connate; eyes behind their tentacles, at their bases; proboscis retractile; foot truncated in front; tongue unarmed. The species of this genus are all marine. Messrs. Forbes and Hanley speak of this family as presenting "subjects of much interest to the student of extinct *Mollusca*, numerous forms having all the aspect of being members of this family occurring among the fossils of even the oldest stratified rocks. Many of them are gigantic compared with existing species, and the group, as a whole, may be regarded rather as appertaining to past ages than to the present epoch."

The genera embraced in this order are—*Pyramidella*, *Oidostomia*, *Achis*, *Stylifer*, *Chemnitzia*, *Eulima*, *Eulimella*, *Stylina*, *Loxonemta*, *Macrochelus*, *Truncatella*, *Olima*.

Pyramidella has 11 recent and 12 fossil species. The recent species are found in the West Indies, Mauritius, and Australia. The fossil in the chalk.

Sylina has 6 recent species. They are found in the West Indies, the Philippines, and the Galapagos.

Lezonema is a fossil genus with 75 species. Principally from the Lower Silurian of North America and Europe.

Macrocheilus is fossil, and has 12 species. They are found in the Devonian and Carboniferous Rocks.

For the other genera see CHEMNITZIA, OIDOSTOMIA, ECLIMA.

PYRAMIS, a genus of Gasteropodous Mollusca; also of Acalepha. [ACALEPHÆ.]

PYRARGILLITE, a Mineral occurring in four-sided prisms, with bevelled edges and massive; frequently traversed by chlorite. Colour black or blue; in the former case shining, in the latter dull. Emits an argillaceous odour when heated. It dissolves entirely in nitric acid. It is found in granite near Helsingfors in Finland.

Its analysis by Nordenskiöld gives—

Silica	43.93
Alumina	28.93
Oxide of Iron	5.30
Magnesia	2.90
Potash	1.05
Soda	1.83
Water	15.47

—99.41

PYRENEITE. [GARNET.]

PYRENESTES. [FRINGILLIDÆ.]

PYRENOMYCETES. [FUNGI.]

PYRETHRUM (from *πύρ*, fire, because of the hot taste of the root), a genus of Composite Plants belonging to the tribe *Asteraceæ*. It has a hemispherical involucre, the receptacle flat or convex. The fruit angular and not winged. The pappus an elevated membranous border.

P. Parthenium, Feverfew, has stalked pinnate leaves, with ovate or oblong segments, and pinnatifid; they are of a hoary green, the leaflets incline to ovate decurrent and cut. The flower-heads are erect, about half an inch broad, with a convex yellow disc, and numerous short broad abrupt 2-ribbed white rays, often wanting, sometimes multiplied, and the disc being obliterated constituting a double flower. The whole plant is bitter and strong scented, reckoned tonic, stimulating, and anti-hysterical. It was once a popular remedy in ague. It is said that the odour is peculiarly disagreeable to bees, and that these insects may be easily kept at a distance by carrying a handful of the flower-heads. It is common in many parts of Europe and in England.

P. inodorum has sessile pinnatifid leaves, in numerous capillary-pointed segments. A branched stem, solitary beads, the involucre scales lanceolate obtuse; the fruit rugose with two round glandular dots on the external face just below the elevated entire border. It is found in fields and waste places in Great Britain.

P. maritimum has sessile doubly pinnate leaves, with fleshy segments, convex above, keeled beneath. The stem diffuse and branched, the heads solitary; the fruit rugose, and with two elongated glandular spots on the external face, just below the elevated lobed border. It is found on sea-shores in Great Britain.

P. officinale is the Pellitory of Spain, once much esteemed as a sialagogue, and resorted to for relief in toothache. Grew says that "when the root of Pyrethrum is chewed, it makes a sensible impression on the lips, which continues like the flame of a coal betwixt in and out for nine or ten minutes." When extracted, the acrid oil contained in the root is said to be serviceable in cases of palsy, and when cutaneous action is required, as a liniment. Ainslie says it is administered in typhus fever by the Indian practitioners.

(Lindley, *Flora Medica*; Babington, *Manual of British Botany*.)

PYRGITA. [PASSER.]

PYRGOM. [PYROXENE.]

PYRGOMA. [CIRRIPEDIA.]

PYRINA, a genus of Fossil Echinodermata.

PYRITES. [COPPER; IRON.]

PYROCHLORE, a Mineral which occurs in octohedral crystals. Primary form a cube. Cleavage parallel to the faces of a regular octohedron, but not easily to be obtained. Fracture conchoidal, with a lustre between vitreous and resinous. Hardness 5.0. Colour reddish brown or black. Streak pale. Translucent, opaque. Specific gravity 4.206 to 4.216. Infusible by the blow-pipe; becomes greenish-yellow by calcination. Found at Fredrichawærn in Norway, and in Siberia. The analysis by Wöhler gives—

Titanic Acid	62.75
Lime	12.85
Oxide of Cerium	6.80
Oxide of Uranium	6.18
Oxide of Manganese	2.75
Oxide of Iron	2.16
Oxide of Tin	0.61
Water	4.20

—98.3

PYROLA, a genus of Plants, the type of the order *Pyrolaceæ*. It has the calyx 5-cleft, or 5-parted; 5 petals; 10 stamens, slightly adhering at the base; style exserted; stigma 5-lobed; capsule 5-celled, dehiscing near the base, and the margins of the valves connected by tomentum.

P. rotundifolia, Round-Leaved Winter-Green, has the stamens

curved upwards; the style declinate, arcuate at the apex; the petals obovate; the segments of the calyx lanceolate-acute, recurved at the apex, half the length of the corolla, and with equal racemes. This plant is a native of Asia, Europe, and North America. It is found in Great Britain, in the North of England, and the Highlands of Scotland, but it is a rare plant. It has milk-white flowers and numerous leaves, and is the largest plant of the genus. There are four other species of *Pyrola* natives of Great Britain; one of these, *P. uniflora*, is only found in Scotland.

P. aphylla, Leafless Winter-Green, has no leaves, the scape is angular, and furnished with numerous scales at the base; the racemes are many-flowered; the petals are roundish, and the disc of the stigma is elongated. This plant is a native of Nootka Island, on the north-west coast of America, where it was collected by Mr. Meuzies. It is remarkable as indicating the approach of the genus to the characters of *Monotropaceæ*. It has globose pendulous milk-white flowers, and the scales upon the scape are of a greenish colour.

Chimaphila corymbosa is the *Pyrola umbellata* of Linnæus. [CHIMAPHILA.]

PYROLACEÆ, Winter-Greens, a natural order of Exogenous Plants. It has the following characters:—Calyx 5-leaved, persistent, inferior. Corolla monopetalous hypogynous, regular, deciduous, 4- or 5-toothed, with an imbricated aestivation. Stamens hypogynous, twice as numerous as the divisions of the corolla; anthers 2-celled, opening by pores. Ovary superior, 4- or 5-celled, many-seeded, with a hypogynous disc; style 1, declinate; stigma slightly indusiate. Fruit capsular, 4- or 5-celled, dehiscent, with central placenta. Seeds indefinite, minute, winged; embryo minute, at the base of a fleshy albumen. (Lindley.) The species are herbaceous plants, rarely under-shrubs. The stem is round, and in the frutescent species leafy. The leaves are simple, and are either entire or toothed. The flowers are either solitary or disposed in terminal racemes. Although often placed with *Ericaceæ*, the habit of these plants is very different from that order; they have also winged seeds, a minute embryo, and declinate styles, all marks of difference which have induced Dr. Lindley to place them in an order separate from *Ericaceæ*. *Monotropaceæ* are distinguished from this order by their leafless scaly stems and parasitical habit. The embryo also is at the apex of the albumen in *Monotropaceæ*, while it is at its base in *Pyrolaceæ*. *Pyrola aphylla* forms a passing link from *Pyrolaceæ* to *Monotropaceæ*; whilst *Tolmiea*, in the latter order, is a link in the other direction. There is an approach to an indusiate stigma in some of the species of *Pyrolaceæ*, which indicate an affinity with *Goodeniaceæ*.

The following genera belong to this order:—*Pyrola*, *Chimaphila*, *Moneses*, *Cladanthamnus*, *Galax*.

The species of these genera are natives of Europe, North America, and the northern parts of Asia.

Moneses and *Cladanthamnus* have each one species. *M. grandifolia* is a native of Europe, Asia, and North America, in alpine woods. *C. pyroliflorus* is a native of the north-west coast of America, and of the island of Sitcha.

Galax is a genus of doubtful position.

PYROLUSITE. [MANGANESE.]

PYROMORPHITE. [LEAD.]

PYROPE. [GARNET.]

PYROPHYLLITE (*Radiated Tale*), a Mineral which occurs in fibrous radiating masses and small prisms of indeterminate form. Hardness 1.5. Colour light green. Lustre pearly, transparent in thin laminae. Specific gravity 2.8. Before the blow-pipe it exfoliates into white leaves, but does not fuse. With borax it gives a green glass, which becomes colourless when cold; with soda it gives a transparent yellow glass. It occurs near Beresof, in the Uralian Mountains, Siberia. Its analysis by Hermann gives—

Silica	59.79
Alumina	29.46
Magnesia	4.00
Oxide of Iron	1.80
Water	5.62

—100.67

PYRORTHITE, a Mineral, which occurs imbedded in granite or quartz, in single or aggregated slender columnar masses. Fracture conchoidal, uneven, earthy. Hardness 2.5. Colour blackish-brown. Lustre resinous. Opaque. Specific gravity 2.19. When cautiously heated by the blow-pipe it takes fire and burns without either flame or smoke; it afterwards becomes white, and eventually fuses into a black enamel. With borax it gives a transparent glass. It dissolves in acids when heated, except a black powder. It is found near Fahlun, in Sweden. The analysis by Berzelius gives—

Silica	10.43
Oxide of Cerium	13.92
Oxide of Iron	6.08
Yttria	4.87
Alumina	3.59
Lime	1.81
Oxide of Manganese	1.39
Water	26.50
Carbon and Loss	31.41

—100

PYROSIDERITE. [IRON.]

PYROSKLERITE, a Mineral. Its primary form is a rhombic prism, with one perfect cleavage, and another at right angles with this imperfect. Colour emerald-green and apple-green; streak white. Fracture uneven and splintery. Hardness 3·0. Lustre dull. Translucent. Specific gravity 2·74. It is found in the island of Elba, and at Aker in Südermanland. Its analysis by Von Kobell gives—

Silica	37·03
Alumina	13·50
Magnesia	31·62
Protoxide of Iron	3·52
Oxide of Chromium	1·43
Water	11·00

—98·10

PYROSMALITE. [IRON.]

PYROXENE, a Mineral, which has received various names, probably because it has been found in different countries, and under slightly varying circumstances and properties. The different names by which it has been known are *Alalite*, *Augite*, *Baikalite*, *Coccolite*, *Diopside*, *Passaite*, *Jeffersonite*, *Malacolite*, *Mussite*, *Pyrgom*, and *Sahlite*. [AUOITE.]

PYRRHITE, a Mineral, occurring crystallised in regular octohedrons. It has no cleavage observable. Colour deep orange-yellow. Hardness equal to that of Felspar. Lustre vitreous, brilliant. Transparent on the edges. It is found at Alabashka, near Mursinsk, and at the Azores.

PYRRHOCERAS. [CORVIDÆ.]

PYRRHOCORAX. [CORVIDÆ.]

PYRRHODES. [PITTACIDÆ.]

PYRRHULA. [BULLFINCH.]

PYRRHULAUDA, a genus of Birds.

PYRULA. [SIPHONOSTOMATA.]

PYRUS, the Latin word for Pear-Tree, is the name of a genus of Plants belonging to the natural order *Rosaceæ*. This genus is characterised by having a superior calyx with a 5-lobed limb; roundish petals; five styles; the fruit a closed 5-celled pome with a cartilaginous putamen called the core; two seeds in each cell; the testa cartilaginous. The species are trees or shrubs with simple or pinnate leaves, and the flowers placed on terminal many-flowered cymes. The species of this genus have obtained various names, as Apples and Pears, Crabs, Beam-Trees, and Mountain-Ashes.

P. communis, the Pear, has ovate serrated leaves, glabrous on both surfaces, with umbellate peduncles. It is a native of Europe in woods and hedges. In its wild state it is thorny, but always unarmed when cultivated. It is the Pear-Tree of our orchards. It is easily distinguished from the apple-tree by the shape of its fruit. [PEAR, in ARTS AND SC. DIV.]

P. Malus, the Apple, has acute serrate ovate-acute leaves; flowers in a sessile umbel; the fruit globose, and the styles combined below. This is the Crab-Tree of our hedges when wild, and the Apple-Tree of our orchards. [APPLE, in ARTS AND SC. DIV.]

Other species of *Pyrus* besides the above yield edible fruits.

On Mount Sinai grows a species called *P. Sinaica*, whose fruit is hard, gritty, and austere, and whose leaves are gray with down; in Germany a similar kind, the *P. nivalis*, is by no means uncommon, with a considerable resemblance to the last; Siberia and Persia produce another, called *P. salicifolia*, with very narrow hoary leaves; and in the former country are found the Siberian Crab, *P. prunifolia*, and the Berry-Fruited Crab, *P. baccata*, whose fruit is too small for ordinary consumption, but is often seen in the form of a sweetmeat.

Besides these, the Chinese Crab, *P. spectabilis*, and also *P. coronaria*, are cultivated for their flowers.

P. domestica, the Service-Tree, has serrated pinnated leaves, downy below; the flowers in panicles, and the fruit obovate. This tree, though not uncommon in Great Britain, is a doubtful native. Its wood is very compact, and is said to be the hardest and heaviest of any indigenous in Europe.

P. Aria, the White Beam-Tree, has the leaves oval or oblong, unequally and doubly serrate or slightly lobed towards the end, nearly entire below; flowers corymbose. It inhabits rocks in the West and North of England. Its scarlet fruit renders it very ornamental in the autumn.

P. aucuparia, the Rowan-Tree, or Roan-Tree, known also under the names of the Fowler's Service-Tree and Mountain-Ash. Its Latin name, *P. aucuparia*, and its various modern designations, have been given to it on account of the general use made of its fruit for the purpose of decoying birds into traps. It is much cultivated, both on account of its valuable wood and rapid growth. It is known from the other species of *Pyrus* by its slightly glabrous serrated leaflets and its globose fruit. It is found in most parts of Europe, in the north-west of Asia, in Nova Scotia, and other regions of the northern parts of North America, and in the island of Japan. It does not however attain equal magnitude in all climates. In its most northern localities and alpine situations it is a low shrubby bush; whilst in southern districts it forms a handsome tree, growing to the height of 20 or 30 feet. The finest trees in this island are found in the Western Highlands and on the west coast of Scotland. This tree has enjoyed from remote times a distinguished reputation. A belief in its power against witchcraft and evil spirits of all kinds seems to have been prevalent at a very early date; and, according to Lightfoot, in his 'Flora Scotica,' it was till a late period held in high reputation in Scotland as a charm against evil influence. It is through a hoop of this wood that sheep are made to pass night and morning as a preservative against evil spirits.

The Rowan-Tree is a graceful tree, with an erect stem and orbicular head. It grows very rapidly for the first three or four years of its existence, and on this account it is well adapted for planting with young oaks, which it protects till they grow above it, when it is destroyed by their shade. It also forms excellent coppice-wood, the shoots being adapted for poles and for making hoops. The bark is used by tanners. The leaves, when dried, have been sometimes used in the north of Europe as a substitute for wheat in times of scarcity. It is prized next to yew for making the how. In Wales it is as religiously planted in churchyards as the yew is in England.

P. fennica is a species also called a Service-Tree, and found in the north of Europe and Scotland. It has scarlet fruit. The leaves are oblong, doubly serrate near the apex, pinnatifid below; the pinnæ lanceolate-oblong, serrated, the two lowermost distinct, under side white and downy. Flowers corymbose.

P. torminalis, the Wild Service-Tree, is a native of England. It has cordate or ovate-lobed glabrous leaves, the lobes triangular acute, serrated, the lower ones larger and spreading, the flowers corymbose. It has brown oval fruit.

P. scandica is another British species; at one time supposed to be a hybrid, but distinguished by the lobes of its leaves being triangular-oval, toothed, deepest towards the middle. Flowers corymbose.

These species are all natives of Great Britain. A number of others have been introduced into our shrubberies and parks. Of these a full account is given in Loudon's 'Arboretum et Fruticetum Britannicum.'

PYTHON. [BOA.]

PYXIS. [CHELONIA.]

Q

QUADRUMANA, Cuvier's name for his second order of Mammiferous Animals, an order which must be always viewed by the zoologist with great interest, inasmuch as it contains those forms among which will be found the nearest approach—though the distance is still great—to Man. [CHIMPANZEE; ORANG-UTAN; APE; CHEIROPODA.]

The order *Primates* of Linnæus consisted of the genera *Homo*, *Simia*, *Lemur*, and *Vespertilio*. [PRIMATES.]

Cuvier placed *Homo* aloof in his order *Bimana*, of which it is the only genus. His order *Quadrumania* embraced the Singes (*Simia*, Linn., including the Orangs) and the Makis (*Lemur*, Linn.); between these two extremes came the *Ouititis*, or *Arctopithecii*. [JACCHUS.]

Of his *Quadrumania*, Cuvier remarks that, independently of the anatomical details which distinguish them from man, they differ from him in the very striking character arising from their hind-feet having free thumbs, which are opposable to the other fingers, whilst those fingers are long and flexible, like those of the hand. They therefore climb trees with facility; but they do not hold themselves or walk erect except with difficulty, their foot in such case not resting on the sole, but on its external edge, and their narrow pelvis not favouring equilibrium in that posture. Their intestines, he observes, are suf-

ficiently similar to ours, their eyes are directed forward, they have mammae on the breast, et penem pendentem. The cerebrum has three lobes on each side, the posterior of which covers the cerebellum, and the temporal fossa is separated from the orbit by a bony partition; but for the rest, they recede gradually from the form of man, assuming a more elongated muzzle, a tail, and a progression more and more exclusively quadruped. Nevertheless, adds Cuvier, the liberty of their fore arms and the complication of their hauds permit among them all many actions and gestures similar to those of man.

Illiger's first order, *Erecta*, like Cuvier's *Bimana*, included man alone. His second order, *Pollicata*, consisted of the *Quadrumania*, the *Prosimii*, the *Macrotrarsi*, the *Leptodactyla*, and the *Marsupiatia*.

The *Quadrumania* embraced the Orangs and *Simie* generally, including *Hapale* (the *Jacchus*).

Dr. J. E. Gray divides the *Primates* into the Anthropomorphous and Quadrupedoid.

The first family of the first division, *Hominide*, is thus subdivided:—

+ Tail none.

1. HOMININA, *Homo*. 2. SIMIINA, *Troglodytes*, Geoff.; *Simia*, Linn. *Hylobates*, Ill.

†† Tail long or short.

3. PRESBYTINA, *Presbyter*, Esch. 4. CERCOPIITHECINA, *Lasiopyga*, Ill.; *Cercopithecus*, Linn.; *Cercocebus*, Geoff.; *Macacus*. 5. CYNOCEPHALINA, *Cynocephalus*, Brisson; *Papio*, Brisson.

The second family, *Sariguidæ*, is thus subdivided:—

† Tail end naked.

1. MYCETINA, *Mycetes*, Ill. 2. ATELINA, *Ateles*, Geoff.; *Brachyteles*, Spix; *Gastromargus*, Spix; *Lagothrix*, Geoff.

†† Tail end hairy.

3. CALLITHRICINA, *Cebus*, Erxleben. 4. SAGUININA, *Saguinus*, Lacépède; *Nyctipithecus*, Spix; *Pithecia*, Geoff.; *Brachypus*, Spix. 5. HAPALINA (*Hapalina* ?), *Jacchus*, Geoff.

Under the Quadrupedoid division, Dr. Gray arranges the *Lemuridæ*, the *Galeopithecidæ*, and the *Vespertilionidæ*.

Under the *Quadrumanæ*, or Tetracheirs (his second order), M. Lesson arranges the *Simiæ* and *Lemuridæ* generally, together with *Loris*, *Nycticebus*, *Galago*, *Tarsius*, *Cheiromys*, and *Cheirogalenus*.

His first order, *Bimana*, includes man only.

The *Quadrumanæ* form the first order of the system of Mr. Swainson, who excludes man from the zoological circle. His *Quadrumanæ* consist of the following families and genera:—

1. SIMIADÆ.—*Simia* (including *Troglodytes*, *Hylobates*, *Presbytes*, and *Pithecia*, as sub-genera).

Cercopithecus (including *Lasiopyga*, *Semnopithecus*, *Colobus*, *Cercopithecus*, *Cercocebus*, and *Nasalis*, as sub-genera).

Imuna.

Macacus.

Papio (including *Papio* and *Cynocephalus* (*Cynocephalus* ?) as sub-genera).

2. CEBIDÆ.—*Mycetes*, *Lagothrix*, *Ateles*, *Cebus*, *Callithrix*, *Hapales* (including *Midas* as a sub-genus), and *Pithecia*.

3. LEMURIDÆ; and 4. VESPERTILIONIDÆ. [SIMIADÆ; LEMURIDÆ; GALEOPITHECIDÆ; CHEIROPTERA.]

QUAGGA. [EQUIDÆ.]

QUAIL. [PERDIDÆ.]

QUAKING GRASS. [BRIZA.]

QUAMASH is the North American name of an eatable Bulb, found in the plains of the Missouri, and called *Camassia esculenta* by botanists. It is a plant of the Liliaceous order, and is nearly allied to the European Squill.

QUAMOCLIT, a genus of climbing Plants of the natural family of *Convolvulaceæ*, chiefly found in the hot parts of America, but species are indigenous both in India and China. The genus is characterised by having a 5-leaved calyx. Corolla somewhat salver-shaped, plicate, and 5-lobed. Stamens 5, inserted into the base of the corolla. Ovary 4-celled. Cells with single ovules. Style simple. Stigma capitate and bilobed. Capsule 4-celled, 4-valved. Seeds 4, erect. Climbing plants with the leaves alternate, cordate, entire, lobed, or pinnatifid; peduncles axillary; one or many flowers of a red colour. *Q. vulgaris* is common in every part of India, and, being a beautiful plant, has been cultivated in this country as a tender annual. The name of the genus has been taken from that of this species, which was *Iponaea Quamoelit*, the latter name signifying Dwarf-Bean, because, though smaller, it resembles the kidney-bean in its habit.

QUARTZ, the Mineralogical name of numerous varieties of Rock Crystal, the Native Oxide of Silicon [SILICON], called also Siliceous or Flint Earth, and Silicic Acid. It is remarked by Mr. Brooke ('Mineralogy') that the "differences of structure, hardness, specific gravity, mixture with foreign matter, and other characters belonging to this species, are so numerous as to render any single description inapplicable to all its varieties." Some of the varieties of quartz have been already described; these we shall presently refer to.

Quartz occurs crystallised and massive, and in both states it is widely diffused throughout nature, and is especially one of the constituents of granite and the older rocks. The primary form of the crystal is a rhomboid, but this is of rare occurrence; it is generally met with in hexagonal prisms terminated by hexagonal pyramids, and when the prism is entirely wanting and both pyramids are present the crystal is a dodecahedron with triangular planes. Cleavage parallel to the planes and pyramids of the ordinary crystal. Fracture conchoidal. Hardness 7-8. Scratches glass readily, and gives fire with steel. Becomes positively electrical by friction, and two pieces, when rubbed together, become luminous in the dark. Transparent; translucent; opaque. Lustre vitreous, resinous. Specific gravity 2.65 to 2.81. Colourless when pure, but exhibiting a vast variety of colours, of which those mentioned below are the more remarkable.

Quartz is infusible; insoluble in acids in general, but acted on by hydrofluoric acid. It combines, by fusion with the alkalies, potash and soda, and thus with them acts the part of an acid, and also in many natural compounds. The acid is termed Silicic Acid, and its compounds Silicates.

The finest specimens of crystallised quartz occur in Dauphiné, Madagascar, &c.; they are found also in Cornwall and near Bristol of great brilliancy, and are known by the name of Cornish and Bristol diamonds. To enumerate the different places in which this substance

occurs would be almost endless. Quartz is composed of one equivalent of silicon = 14, and one equivalent of oxygen = 8; its equivalent is therefore 22.

Hornstone and *Chert* are varieties of compact quartz. Cavernous quartz is termed Spongiform Quartz or Swimming Stone, and other scarlet varieties have also been described.

Quartz possessing different colours has received various names; some of these we shall briefly notice.

Brown or Smoky Quartz occurs in fine crystals near Cairngorm in Aberdeenshire. It is used for seals and ornaments when cut and polished. The nature of the colouring-matter is not known, but is probably carbonaceous matter.

Purple Quartz, or *Amethyst*, is found both crystallised and massive. It is of every shade of purplish-violet, and the colour in the perfect amethyst is pretty equal throughout the crystal or mass; frequently however the summits of the crystals only are coloured. It is used for ornaments. According to Rose, amethyst consists of—

Silica	97.50
Alumina	0.25
Oxide of Iron	0.75

—98.5

Amethysts of the finest quality are found in India, Ceylon, Persia, and Siberia. Amethystine Quartz of inferior quality is met with in most countries. In Cornwall it occurs in some tin-mines.

Blue Quartz (*Siderite*) occurs crystallised and massive. It is compact, of a grayish or greenish-blue colour. Lustre resinous, waxy. Translucent on the edges. It is found near Salzburg.

Green Quartz is found in Peru, in translucent hexagonal prisms. Opaque massive green quartz is called Prase; the colour appears to be owing to actinodite. It is found in Saxony. *Chrysoprase* is light green amorphous quartz; it is coloured by oxide of nickel. It is found near Silosia and North America.

Yellow Quartz is transparent; of various shades of colour. It is found in Cornwall, Scotland, Bohemia, &c. It is probably coloured by oxide of iron. It has been called Scottish and Bohemian Topaz.

Yellow Quartz is opaque. Ferruginous Quartz occurs of various shades of yellow and reddish-yellow. According to Bucholz, it contains 5 per cent of oxide of iron, to which its colour is owing. It is found near Bristol, in Scotland, &c.

Red Quartz (*Compostella*), Hyacinthine Quartz. Colour yellowish or reddish-brown. It is found in Spain and North America.

Amorphous Quartz. The following varieties of quartz will be found under their articles, AGATE, AVANTURINE, FLINT, FLINTY SLATE, OPAL, and BLOODSTONE.

In addition to these, which may be considered as among the purer varieties of quartz, it occurs mixed with variously-coloured clays and other extraneous matter, forming different kinds of Jasper.

Jasper occurs opaque, which constitutes one of the most prominent differences between it and agate. Its colours are green, yellow, and red, of various shades, rarely blue; these colours are occasionally mixed in spots and irregular veins. Jasper is massive, has often a resinous lustre, but is sometimes dull. It is found on many parts of the continent, in Cornwall, and in Scotland.

Striped or Riband Jasper presents green, yellow, and red colours of various shades, sometimes in spots; but the most beautiful variety is composed of equal and parallel stripes of these colours. In occurs in Siberia, the Harz, and Saxony.

Egyptian Jasper, or Egyptian Pebble, occurs in rough roundish masses, and is generally of a brown colour. Internally it is usually of a light colour. It is found on the surface to the eastward of Grand Cairo, and on the borders of the Red Sea.

It is well known that siliceous earth assumes other forms besides that of quartz and the varieties of it which have now been described; one of the most useful of these is Common Sand.

QUASSIA, a name formed in remembrance of a negro named Quass, who first made known the medicinal virtues of one of the species, is a genus of Plants belonging to the natural order *Simarubaceæ*. It consists of trees inhabiting the tropical parts of South America, particularly Surinam and the adjoining countries. They have leaves pinnated like those of the common ash; flowers with a small 5-parted calyx, 5 petals, a definite number of hypogynous stamens, and a fruit consisting of 5 dry or fleshy drupes.

Q. amara, the true Quassia of modern botanists, is a small tree, with its leaflets in two pairs, with an odd one, and a winged jointed leafstalk. Its flowers are scarlet, large, like those of the Red American Horse-Chestnut, and arranged in narrow racemes. It inhabits the woods of Surinam, Demarara, and probably the greater part of Central America. The wood of the root of this plant was formerly in great repute as a stomachic and as a remedy for the malignant endemic fevers of Surinam. The flowers also were, and still are in that country, infused in wine or spirits, and form a bitter beverage; but the wood is out of use, in consequence partly of its being less easily procured than that of the next species, and partly from an opinion being entertained of some bad properties existing in connection with the intense bitter.

Q. excelsa (*Picramnia excelsa*, Lindley) is a large tree inhabiting Jamaica. It has oblong acuminate obtuse leaflets, in from four to eight pairs, and paniced corymbose small pale yellowish-green flowers.

This tree yields the Quassia chips now so extensively employed in Europe as a bitter substance. The wood is imported from Jamaica in billets of various sizes, is white, scentless, but most intensely bitter. It is one of the ingredients employed by fraudulent brewers in adulterating beer.

Q. Simaruba (*Simaruba amara*, Aublet) is the plant which furnishes the bark called Simarouba, which comes from Jamaica in bales, and is used as a tonic, although it also appears to act as an emetic. It is a large tree, found in the West India Islands and on the mainland of America. Its leaflets are 2 to 9 on each side, oval, smooth, firm, and sharp-pointed. The flowers are very small, whitish, and arranged in branching scattered panicles.

The three genera, *Quassia*, *Picræna*, and *Simaruba*, may be distinguished thus:—

Quassia.—Petals forming a tube; stamens 10. Flowers hermaphrodite; ovaries 5.

Picræna.—Petals quite distinct; stamens 5. Flowers polygamous; ovaries 3.

Simaruba.—Petals quite distinct; stamens 10. Flowers unisexual; ovaries 5.

QUATA. [ATELES.]

QUEEN'S GILLIFLOWER. [HESPERIS.]

QUERCUS, the Latin word for an oak-tree, which is of frequent occurrence in the Roman writers. It is now, as then, applied to the oak and all the other species associated with it by botanists in one common genus. *Quercus* differs essentially from *Castanea*, the Chestnut, in having short obtuse stigmata, and from both it and *Fagus*, the Beech, in the cells of its ovary containing two ovules instead of four. It is also distinguished by its acorn or nut being seated in a cup, and not in a close husk; but there are intermediate conditions of this part, technically called the cupule, which render it of less value as a mark of distinction than would at first sight appear. Many of the oaks of the hotter parts of Asia have the acorn completely inclosed within the cupule. Still however the prickly husk of the beech and the chestnut, splitting into valves, may in general be distinguished from the closed-up cup of the Indian oaks.

Oaks, like roses, are scarcely known in a wild state in the southern hemisphere. In the islands of the Indian Archipelago they reach their most southern limits, especially in Java; thence they pass upwards beyond the equinoctial line, and following the eastern parts of Asia, they spread to the westward along the Himalaya Mountains, and reaching Europe, are only arrested by the Atlantic Ocean. On the other hand they find their way to the eastward of their Asiatic origin, and overrun America from Canada and Oregon through California and Mexico, till their progress to the south is stopped by the Isthmus of Darien.

While however the genus is thus extensively distributed, the species are confined within comparatively narrow territorial limits. Many of the Javanese kinds appear to be peculiar to the Indian Archipelago, or only occur near the south-eastern angle of Asia. Those of the Himalayas are perfectly distinct from the oaks of the Trans-Himalayan regions, and have not even been found on the mountains of Persia. Several of the Oriental kinds are known nowhere else, and the American species are quite peculiar to that country.

The species are very numerous, and we propose to give some of the more remarkable according to their geographical distribution.

I. Oaks of Europe, Northern Asia, and Barbary.

Under this head we include all the more common species of the genus, the greater part of which exist in cultivation in this country. They may be divided into three groups: the Forest Oaks, or *Robora*; the European Oaks, or *Ilices*; and the Mossy-Cupped Oaks, or *Cerres*.

a. The Forest Oaks (*Robora*).

The species comprehended under this head have deciduous thin leaves, whose lobes are never lengthened into a bristle, and whose acorns are seated in shallow cups, the scales of which are so short and closely pressed to the sides as not to form visible extensions. The wild oaks of England may be taken as the representatives of the others, which differ from them chiefly in the quantity of down upon their leaves, the size of the acorns, and the quality of their timber.

Q. pedunculata, Common British Oak. Leaves sessile or nearly so, with numerous deep sinuities and a thin texture, with but little polish on the upper side. Acorns arranged in long stalked spikes. This, which is our commonest oak in England at the present day, appears not to be confined to the colder parts of Europe, as has by some been supposed, for we have specimens before us both from Spain and Hungary, but it is certainly much more common in the north than in the south, where its place is usurped by the next species. It has the reputation of being the True British Oak, whose timber is alone suited for naval purposes on account of its durability and hardness; but this is a mere fable, the wood of the next species being as suitable in all respects under equal circumstances. But the timber of the oak, like all other wood, is materially affected by the nature of the soil in which it grows, and this has probably given rise to the often repeated assertion that Sussex oak, which chiefly consists of *Q. pedunculata*, is the best kind that can be employed in ship

building. The species is readily known by its leaves having very short stalks, or none at all, while the acorns are placed on very long stalks. In consequence of the importance of distinguishing it from *Q. sessiliflora*, we have thought it desirable to introduce a wood-cut of the plant, common as it is.

1, Common British Oak (*Quercus pedunculata*); 2, Manna-Oak (*Q. mannifera*); 3, Sessile-Cupped Oak (*Q. sessiliflora*).

The *Q. fastigiata* of the gardens is a singular variety, with the branches rising close to the stem, like those of a Lombardy poplar.

Q. sessiliflora, Sessile-Cupped Oak. Leaves on long yellowish stalks, with numerous sinuities, and a firm texture; much polished on the upper side. Acorns either altogether sessile or arranged in very short stalked spikes. We have already stated that the timber of this has been supposed, although erroneously, to be inferior to that of *Q. pedunculata*. Experiments as to strength and toughness have shown that there is no material difference between the two in those respects, and the durability of the wood of the Sessile-Cupped Oak is attested by the well-known fact, that the roof of Westminster Hall is constructed of it, and not of chestnut, as has been sometimes said. It has been found to be the timber of some of the most ancient of buildings in this country and elsewhere; an immense beam in an old Shropshire building, now called Stone House, was *Q. sessiliflora*, and the oak usually obtained from bogs, where it must have lain for centuries, has often proved to be the same.

The wood may be easily known by its medullary rays, or silver grain, being so far apart that it cannot be rent, and this gives it quite a peculiar aspect. *Q. sessiliflora* is found all over England now, but nowhere in much quantity. It however is more abundant in the west than elsewhere, and constitutes the greater part of the oak of North Wales. It is a much handsomer plant than the last, and grows considerably faster, and therefore is by far the most advantageous kind for the planter. Its comparative scarcity at the present day may perhaps have arisen from its having been felled in preference as long as any of it remained in the ancient forests, which its superiority in size to the other species would render probable, and not having been replaced, it would thus become gradually exterminated. It appears to be still common over all the south of Europe, where however it is not uncommonly mistaken for the last. The supposed species called *Q. apennina* and *Q. microcarpa* are probably varieties of it. What is called the Durmast Oak, which has been regarded as a species by some botanists under the name of *Q. atrovinosa*, or *Q. intermedia*, seems to us a slight variety of *Q. sessiliflora*, with the leaves pubescent on the under side. It is here in all probability that the classical *Esculus* of Virgil belongs, for, according to Professor Tenore, a

broad-leaved variety, which he calls *Q. robur Virgiliana*, answers in all respects to the language of the poet, and its acorns are sweet, and eaten like chestnuts at this day in Italy, where they are called *Quercia Castagnara*. ('Osserv. sull. Flor. Virgiliana,' p. 12.)

Q. pubescens, a native of the southern parts of Europe, has most of the characters of *Q. sessiflora*, but its leaves are smaller, often quite woolly on the under side, and the lobes are themselves much sinuated. It has been injudiciously confounded with that species, to which it is said to be in all respects inferior in the quality of its timber. It forms a majestic tree, with much the habit of *Q. Cerris*.

The *Q. Esculus* of Loudon is, no doubt, the same as the last; but what the plant was to which Linnaeus applied the name, and which has been supposed by some to be the *Esculus* of Virgil, is altogether doubtful. Another oak related to the sessile-cupped is the *Q. pyrenaica*, or Tauzin, a small scrubby tree inhabiting poor sandy soil in the south of France, and throwing up an abundance of eucers. Its wood is of little value except for the staves of casks. This species is readily known by its gray leaves, the hair of which is remarkably coarse.

b. The Evergreen Oaks (*Ilex*).

All the European oaks with leaves truly evergreen belong to this section, which however in some respects approaches the Mossy-Cupped Oaks when the latter acquire a semi-European habit. In such cases they are known by the scales of their cups being very short, and the toothings of their leaves not bristle-pointed.

Q. rotundifolia, Round-Leaved Oak. Leaves nearly orbicular, with spinous teeth, a little heart-shaped at the base, smoothish above, downy beneath. Very little is known of this plant, except that it is allied to *Q. Ilex*. Smith and others say it is a Spanish plant, and if so, they probably meant *Ballota*; but we have before us a Turkish specimen, of which a cut is given, to which the name is very applicable, and which is quite different from that species.

1, *Quercus Brantii*; 2, Round-Leaved Oak (*Q. rotundifolia*).

Q. Ilex, Common Evergreen Oak, or Holm-Oak. Leaves ovate-oblong, acute, coriaceous, entire, or serrated, hoary beneath. Bark even. Acorns ovate, on short stalks. A most variable plant, common all over the south of Europe, where it may be found with leaves varying from being as prickly as a holly to being as even at the edge as an olive, and from the size of a shoe-leaf to that of a beech. It loves the neighbourhood of the sea, and in its wild state generally grows singly or in small clusters, not forming forests. Its wood is very hard and heavy, tough, and in all respects of excellent quality, where its weight is not against it. Its acorns are bitter, and unfit for food.

Q. Ballota, Sweet Acorn-Oak. Leaves elliptical, coriaceous, entire

or serrated, very obtuse, white, and downy beneath. Bark even. Acorns cylindrical, elongated. "This evergreen oak," says Captain Cooke, "is one of the leading vegetable features of nearly all Spain. The native woods are formed of it in a great measure. A species, it is quite distinct from the *Q. Ilex*: the leaves are thicker, more rounded at the point, of a dull glaucous green, and the tree is altogether more compact and of a less graceful form. The great and essential difference however is in the acorns, which are eatable, and when in perfection are as good as or superior to a chestnut. To give this sweetness they must be kept, as at first they have a considerable taste of tannin, which however disappears in a few days. These are the edible acorns of the ancients, which they believed fattened the tunny-fish on the passage from the ocean to the Mediterranean; a fable only proving that the species grew on the delicious shores and rocks of Andalusia, which unhappily is no longer the case."

Q. Suber, Cork-Tree. Leaves ovate-oblong, bluntish, coriaceous, entire or sharply serrated, downy beneath. Bark cracked, fungous. The Cork-Tree is spread through all the warm parts of Spain, but is most abundant in Catalonia and Valencia, whence the principal exports have been made. In the property of forming a spongy soft substance on its bark, it surpasses all other European trees, and hence is of the greatest value for corks and for similar purposes. The form of the tree is said to be much more beautiful than that of the common evergreen oak, and in the districts suited to it attains a great height. The species bears the climate of London, but acquires little of its natural beauty in this country.

Q. faginea, Beech-Oak. Leaves on short stalks, obovate, with numerous uniform shallow lobes; downy beneath; when young somewhat heart-shaped and unequal at the base. Fruit sessile. Cup with downy close-pressed somewhat ciliated scales. Acorn conical or somewhat cylindrical. A native of Portugal, Spain, and Tangiers, and apparently unknown in our gardens. Mr. Barker Webb however, who has studied some of the European species with great care, regards it as identical with *Q. Turneri*, or *Q. Australis*, and if so, we possess it. The same learned botanist reduces to this the Aleppo Gall-Nut Oak, *Q. infectoria*, and he is probably right.

1, *Quercus regia*; 2, Beech-Oak (*Q. faginea*).

Q. coccifera, Kermes Oak. Leaves elliptic-oblong, rigid, smooth on both sides, with spreading, bristly, spinous teeth. Acorns ovate. Cup with spreading pointed scales. A native of the south-easterly parts of Europe, where it forms a small bush, resembling a dwarf holly. It is celebrated as being the haunt of the Kermes insect.

c. Mossy-Cupped Oaks (*Cerris*).

The species of this section are remarkable for their thin deeply

pinnatifid leaves, the long narrow loose scales of their cup, and their equally long deciduous stipules. In this as in other parts of the genus, there is much confusion and uncertainty regarding both the limits of species and the quality of their timber.

Q. Cerris, Turkey Oak. Leaves deciduous, on very short stalks, oblong, deeply and unequally pinnatifid; hairy beneath; lobes lanceolate acute, somewhat angular. Stipules longer than the footstalks. Cup hemispherical, with long loose hairy scales. An exceedingly common plant all over the south-east of Europe, where it seems to form some of the finest specimens of oak. It has an open, straight, graceful mode of growth, very different from the gnarled and tortuous appearance of native British oaks, than which it also grows much faster. It would seem to be unknown in Spain, where its place appears to be taken by the *Q. Hispanica* of Lamarck.

Q. Hispanica, the Spanish Oak. Trunk corky. Branches rather erect. Leaves nearly evergreen, lanceolate acute, with fine serratures or crenatures, which are sharp-pointed, coriaceous, deep-green, glaucous, and downy on the under side. Cups top-shaped, somewhat sessile, with shaggy, prickly, spreading scales. According to Mr. Barker Webb, this plant grows in Spain and by the Algerine river Monchique, and he reduces to it as synonyms the *Q. crenata* of Lamarck, *Q. pseudosuber* of Desfontaines, *Q. Agilopifolia* of Persoon, and the Lucombe Oak of the English nurseries.

Q. Austriaca, the Austrian Oak. Leaves on longish stalks, ovate-oblong, slightly but copiously sinuated, downy and hoary beneath; lobes short, ovate-acute, entire. Stipules shorter than the footstalks. Cup hemispherical, bristly. It is found in Austria and Hungary.

Q. Agilops, Great Prickly-Cupped Oak, or Valonia. Leaves ovate-oblong, with bristle-pointed tooth-like lobes, hoary beneath. Cup very large, hemispherical, with lanceolate, elongated, spreading scales. The Morea and adjacent countries produce this valuable tree, which yields the acorns called Velani, or Valonia, in commerce, of which nearly 150,000 cwt. are imported yearly for the use of tanners, and sold at from 12*l.* to 15*l.* a ton. The tree is reported to be handsome in its own country; but with us, although it has long been cultivated, it is an inelegant tree, of a stunted mode of growth. What has been said of its elegant appearance and so forth, seems to belong to *Q. Cerris*.

specimens were examined by Lamarck, who called them *Q. crinita*, but little more is known about the species. Another plant, under the name of *Q. rigida*, has been published from Caramania, where the oaks are said to arrive at a great size and beauty; and *Q. infectoria*, the Common Gall-Oak, has long been known. But there can be no doubt that the mountainous regions intervening between the Turkish empire and India produce oaks that require investigation, and three perfectly distinct species have in fact been sent from Kurdistan. Of all that have yet been found in the countries of the East, we shall give a short account.

Q. crinita, Hairy-Cupped Oak. Leaves on long stalks, oblong, deeply pinnatifid, downy beneath, lobes lanceolate, bluntish, nearly entire. Cup hemispherical, downy, bristly. A tree of Asia Minor, found by Olivier, and figured in his 'Travels,' t. 12, and said to be the same as an Armenian species met with by Tournefort, and after him called *Q. Tournefortii*; but this is doubtful. It is described as a large tree yielding excellent timber, employed extensively by the Turks in naval constructions. There is however very little in the accounts hitherto given of the plant to distinguish it from the Common Turkey Oak, *Q. Cerris*, with which Mr. Loudon combines it, but not upon satisfactory evidence.

Q. infectoria, Oriental Gall-Oak. Leaves ovate-oblong, very smooth on both sides, deeply toothed, somewhat sinuated, deciduous. Fruit sessile. Cup tessellated. Acorn elongated, nearly cylindrical. A very common plant in Asia Minor, where its branches are attacked by an insect, the *Cynips scriptorum*, which punctures them, and causes the formation of the oak-galls so well known in commerce. It forms a scrubby bush rather than tree, and is of no value except for its galls. Its branches occasionally produce large brownish-red tubercles, spongy within, which are by some supposed to be the apples of the Dead Sea, whose appearance was tempting, but which contained only dust and ashes.

Great Prickly-Cupped Oak (*Quercus Agilops*).

II. Oaks of the Levant.

Little has hitherto been ascertained regarding the species of this part of the world. The French traveller Olivier brought home with him a plant very near *Q. Cerris*, the Mossy-Cupped Oak, which he reported to be met with throughout great part of Asia Minor, and to furnish the wood employed in the arsenal of Constantinople. His

1, Stiff-Leaved Oak (*Quercus rigida*); 2, Sweet Acorn-Oak (*Q. Ballota*); 3, Oriental Gall-Oak (*Q. infectoria*).

Q. rigida, Stiff-Leaved Oak. Leaves oblong, undivided, with spinous serratures, smooth, glaucous beneath, heart-shaped at the base. Footstalks bearded at the summit. Scales of the cup rigid, spreading. A native of Caramania, of Kurdistan, and, according to Sibthorpe, of the Morea, but the last is doubtful. It is a handsome-looking plant, so far as can be judged from dried specimens, but nothing is known of its uses.

Q. Brantii, Brant's Oak. Branches, footstalks, and leaves underneath covered all over with thick short wool. Leaves heart-shaped, ovate-acute, with bristle-pointed teeth, ash-coloured, with starry down

on the upper side. This is described in the 'Botanical Register' as being a most remarkable plant; the full-grown leaves being six inches long, including the footstalk, and three inches and a half across at the widest part, which is near the base. They are as downy as those of a young plane-tree. The species appears allied to *Q. Balloia*, a Spanish species.

Q. castaneaefolia, the Chestnut-Leaved Oak. Leaves oblong-lanceolate, rather downy on the under side, coarsely serrated, with bristle-pointed lobes. Acorns nearly sessile, oblong, with the cups, when old, covered by reversed scales. A tree from the province of Mazanderan, reported to be very beautiful. The leaves are often from 4 to 5 inches long. Mr. Barker Webb states that it is the same as what has been called *Q. Libani*, and that it is remarkable for having large depressed fruit, with wide lozenge-shaped scales turned back at the point.

1, Chinese Oak (*Quercus Chinensis*); 2, Chestnut-Leaved Oak (*Q. castaneaefolia*).

Q. regia, the Royal Oak. Leaves stalked, ovate-lanceolate, heart-shaped, wavy, with coarse sharp unequal serratures, on each side green, shining, and smooth. The lobes of the leaves terminated by a conspicuous bristle. From Kurdistan. It is a noble species, with leaves as large as those of a Spanish chestnut, and very like them.

Q. mannifera, the Manna Oak. Leaves stalked, oblong, somewhat heart-shaped, cut; the lobes blunt, smooth above, downy beneath. Young acorns oval, stalkless, smooth. An inhabitant of the Kurd Mountains, where it was discovered by Mr. Brant, the British consul at Erzerum, who found that the Kurds obtain a sweet mucilaginous substance from its branches and leaves by steeping them in boiling water at the hottest season of the year, and afterwards evaporating the water. This substance is made into cakes, and sold in the markets of the town of Van under the name of *Obiok-Helvahée*, 'the Sweetmeat of Heaven.' The species is very near *Q. semilifera*, especially a form of it which has been named *Q. Mongolica*.

Q. Iberica, the Georgian Oak. Leaves ovate-oblong, downy beneath, sinuated, with short blunt somewhat emarginate lobes. Acorns nearly sessile. Cups hairy, with sharp-pointed scales. A native of Georgia.

III. Oaks of the Himalayas, China, &c.

All travellers in the Himalayas testify to the abundance of oaks. The people employed by Dr. Wallich gathered a considerable number of species, and Dr. Royle assures us that they are found from moderate elevations up to the limits of trees. Among these, all from the lower regions are, no doubt, too tender for cultivation in

Great Britain; but of the alpine species some may be expected to prove hardy.

Q. semicarpifolia, Marking-Nut-Leaved Oak. Leaves obovate, obtuse, coriaceous, entire; heart-shaped at the base; downy beneath; the young ones with spinous teeth. Acorns solitary or in pairs, on short downy stalks, depressed at the point, about twice as long as the shallow scaly cups. As this species occurs in the Himalayas at the upper limits of the forests, at even greater elevations than the Pines, it would, no doubt, suit the climate of England; and if so, its introduction would be very desirable, for it is stated to form a magnificent tree, whose timber is much esteemed by the natives.

Q. incana, the Himalayan Ilex. Leaves coriaceous, ovate-lanceolate, shining and smooth on the upper side, densely downy beneath, with coarse serratures which are not bristle-pointed. Acorns solitary, sessile, acute, but little protruded beyond the hemispherical downy cup, the scales of which are small and closely pressed. A beautiful tree, very like the evergreen oak of Europe. Its leaves are much more woolly on the under side. Dr. Wallich found it in Kumaon, where the people called it 'Munroo'; Dr. Royle states it to be the 'Ban' of the hill people, where he saw it, and that it occurs at moderate elevations. It is therefore in all probability tender.

Q. lanata, Woolly-Leaved Nepal Oak. Leaves elliptic-oblong, deep green, sharply serrated, coriaceous; densely woolly beneath. Fruit in very short axillary solitary spikes. Cup scaly, without prickles. This is one of the handsomest oaks yet discovered. It is found wild in the Himalayas.

Q. annulata, Ring-Cupped Oak. Leaves obovate, taper-pointed, serrated in their upper half; somewhat glaucous and silky beneath. Acorns axillary, sessile, ovate, with the cup furrowed concentrically. Found in the Himalayas.

Q. Chinensis, the Chinese Oak. Leaves ovate-lanceolate, taper-pointed, with bristly shallow serratures, and very long footstalks; slightly downy on the under side. Acorns globose, sessile, in pairs. Cups with hoary lanceolate scales, the exterior of which are reflexed, and longer than the acorn. A beautiful Chinese species, found (by the botanists attached to the Russian mission to Peking) in mountainous places. It is said to have exactly the habit and appearance of a Spanish chestnut. We give a figure of it from specimens communicated by Dr. Bunge; its discoverer.

IV. Oaks of the United States of North America.

In general these are cultivated in England, where they are found tolerably hardy. They however evidently suffer from want of summer heat, and are by no means of the same value to us as the species of the continent of Europe; and it may be doubted whether any of them are ever, in their own country such noble trees as the finest specimens of *Q. pedunculata* and *Q. sessilifera*. We shall only mention the kinds common in the plantations of Great Britain.

Q. alba, White Oak. Leaves oblong, deeply pinnatifid, glaucous beneath, lobes linear-oblong, obtuse, entire, dilated upwards. Fruit stalked. Cup depressed, warty. A very fine species, producing sweet acorns and excellent timber, and approaching nearer to the European forms than any other American species. Specimens of it in the American forests are often from 70 to 80 feet high.

Q. Prinus, Chestnut-Leaved White Oak. Leaves on longish stalks, obovate-acute, somewhat downy beneath, with nearly equal dilated callous-tipped tooth-like serratures. Cup contracted at the base. Acorn ovate. A tree of considerable beauty, varying considerably according to soil and situation, and hence divided by some writers into many species, called *Q. palustris*, *Q. montana*, *Q. monticola*, *Q. acuminata*, *Q. Castanea*, *Q. pumila*, *Q. Chinquapin*, *Q. prinoides*, *Q. tomentosa*, *Q. discolor*, &c., under all which names it is propagated in the nurseries. The wood is porous, and not of very good quality, but the broad bright green foliage is handsome.

Q. coccinea, Scarlet Oak. Leaves smooth, oblong, deeply and widely sinuated, on long stalks, lobes divaricated, acute, sharply toothed, bristle-pointed. Cup turbinate, half as long as the acorn. The middle States of North America abound in this and the following species, which derive their name from their leaves becoming in the autumn of a rich crimson colour. It forms a large and graceful tree, but the head wants massiveness. The wood is of very little value, and perishable; it is only employed for fuel, and for staves for casks intended to hold dry goods. It grows fast, and stands the climate of even the colder counties of England.

Q. rubra, Mountain Red Oak. Leaves smooth, oblong, sinuated, on long stalks, lobes acute, sharply toothed, bristle-pointed. Cup flat underneath. Acorn ovate. A specimen of this is said by Mr. Loudon to exist at Strathfieldsay 100 feet high; it is very like the last species, but its leaves become more purple in the autumn. Its wood is of bad quality.

Q. tinctoria, Dyer's Oak, Black Oak, or Quercitron. Leaves downy beneath, obovate-oblong, dilated, widely sinuated; lobes short, obtuse, slightly toothed, bristle-pointed. Cup flat underneath. Acorn globose. A native of Pennsylvania and of the mountains of the Carolinas and Georgia, where it becomes a very large tree, with a bark so dark-coloured as to have gained for it the name of Black Oak. The leaves are large and very handsome, becoming dull red or yellow in the autumn. Its wood is strong, but very coarse. The inner bark

abounds in a yellow dye of great brilliancy, which is known in trade under the name of Quercitron. Large quantities of it are annually imported from Philadelphia.

Q. Phellos, Willow Oak. Leaves membranous, linear-lanceolate, tapering to each end, entire, smooth, with a small point. Acorn roundish. Low swampy forests on the sea-coast of the southern states of North America. A large tree with something the aspect of a willow, whence its name. Its timber is stated to be strong, but very coarse. *Q. laurifolia* and *Q. imbricaria* are nearly related to it.

Q. virens, Live Oak. Leaves coriaceous, elliptic-oblong, revolute, entire, pointless; obtuse at the base, clothed with starry down beneath. Fruit stalked. Acorn oblong. A very valuable species, confined to the southern states of the North American Union, where it is most abundant upon the shores of creeks and bays. It is also abundant in Texas. The Live Oak yields the best oak of America, the timber being heavy, compact, and fine-grained; and is extensively employed in the American dockyards, although it does not usually acquire a large size. The acorns are stated to be remarkably sweet. It is much too tender to suit this climate; and consequently specimens are to be found only in curious collections in sheltered warm situations.

V. Oaks of Mexico.

These are extremely numerous, and must in many cases form highly ornamental trees. Several species have been introduced by the Horticultural Society, but we at present know nothing of their habits. It is to be feared that they will in general prove too tender for England.

Q. acutifolia, Sharp-Leaved Oak. Leaves heart-shaped, lanceolate, tapering to a very sharp point, with coarse pointed teeth, covered with rusty down on the under side, especially along the principal veins. Young acorns in spikes, which have a short footstalk. Forests of this tree occur on the road from Acapulco to Mexico, where it is called 'Aguatle.' It is described as a large tree producing timber of excellent quality.

Q. sideroxylla, the Iron-Wood Oak. Leaves oblong, somewhat wedge-shaped, obtuse at the base, armed towards the upper end with sharp-pointed teeth; hoary on the under side. Acorns sessile, ovate, seated in a roundish cup. Found in Mexico, near Guanajuato, and in other places, in dry barren places 6000 or 7000 feet above the sea. It forms a large tree of great beauty. Its timber is very hard, takes a fine polish, and is extremely durable when used under ground or when sunk under water.

Q. lanceolata, the Lance-Leaved Oak. Leaves lance-shaped, entire, wavy, shining on the upper side, strongly bearded beneath at the principal angles of the veins. Acorns oval, sessile, in goblet-shaped cups. Common in Mexico at the height of 5000 or 6000 feet. It is a large tree, producing a very hard wood, very durable when used under ground, and extensively consumed in mining operations.

Q. glaucescens, Blue-Leaved Oak. Leaves on very short stalks, wedge-shaped, obovate, entire near the base, slightly toothed and indented at the edge, glaucous, very smooth. Acorns in racemes. Common in Mexico at the height of 2000 feet above the sea. Its wood furnishes the greater part of the charcoal used in that country.

Q. obtusata, the Blunted Oak. Leaves oblong, blunt at each end, unequal at the base, bent inwards near the middle, on the under side strongly veined, and covered with a powdery down. Acorns spherical, in axillary racemes, almost entirely covered by a scaly cup. A fine tree, native of the Mexican mountains 6000 feet above the sea. Wood very compact and strong, and capable of taking a fine polish.

Q. macrophylla, Large-Leaved Mexican Oak. Leaves obovate, crenate, tapering and heart-shaped at the base, downy beneath. Fruit spiked. This is doubtless the finest oak in the world. It inhabits the southern parts of Mexico and Guatemala, and has leaves 12 to 18 inches long, and broad in proportion. Its acorns are as large as French walnuts. They have been received in this country by the Horticultural Society, but unfortunately would not vegetate.

For detailed information concerning the species of oaks, the reader is referred to Blume's *Flora Javae*; the article 'Quercus' in Rees's *Cyclopædia*; Webb's *Iter Hispanicum*; Humboldt and Bonpland's *Plante Aigüinoctiales*; and Loudon's *Arboretum Britannicum*, vol. iv.

QUERULINÆ. [MUSCIPIDÆ.]

QUICKSILVER. [MERCURY.]

QUILLWORT. [ISOETES.]

QUINCE. [CYDONIA.]

QUINCITE. [MEERSCHAUM.]

QUINQUINA, or QUINA, names given to the species of Plants which are now generally referred to the genus *Cinchona*. In the article CINCHONA will be found an account of the species of *Cinchona*, as recognised by botanists previous to the investigations of M. Weddell. This traveller dwelt in the Cinchona districts of the Andes during the years 1845-6-7, and has since published a work on this subject, entitled 'Histoire Naturelle des Quinquinas.' In addition to a highly interesting account of the districts, M. Weddell gives a full description of the methods of preparing the Cinchona Barks by the natives, who live in the forests. By dwelling on the spot he was enabled to correct much that was erroneous with regard to the nature

and character of the species used in medicine. He also discovered the real plant which yields the yellow-bark, that furnishes the largest quantity of quinine. The following table from M. Weddell's work exhibits the names of Commercial Cinchona Barks, and the species from which they are believed to be obtained:—

I.—GRAY CINCHONA BARKS.

§ 1. Loxa Cinchona Barks. (Crown Bark, Angl.—China-Loxa, Kron China, Germ.)

Loxa Cinchona Bark, gray compact	<i>Cinchona Condaminca</i> , H. et B.
Loxa Cinchona Bark, brown compact (Dunkele Ten China, Germ.—China pseudo-Loxa, Bergen)	<i>C. scrobiculata</i> , H. et B.
Loxa Cinchona Bark, red chestnut.—Light Calisaya	
Loxa Cinchona Bark, red fibrous of the King of Spain. (Quina Estoposa, Pav. in collect., Lamh. Mus. Brit.)	

Loxa Cinchona Bark, yellow fibrous *C. macrocalyx*, Pav.

§ 2. Lima or Huanuco Cinchona Barks. (Silver Bark, Gray Bark, Angl.—China-Huanuco, Graue China, Germ.)

Lima Cinchona Bark, gray-brown. (Casarilla Provinciana, Peruv.)	<i>C. micrantha</i> , Ruiz et Pav. or
Lima Cinchona Bark, gray ordinary	<i>C. lanceolata</i> , Ruiz et Pav.
Lima Cinchona Bark, white	(?) <i>C. purpurea</i> , Ruiz et Pav.
Lima Cinchona Bark, very rugous, resembling the Calisaya Bark.—Casarilla Negrilla, Peruv. (Casarilla Lagartijada, Laubert)	<i>C. glandulifera</i> , Ruiz et Pav.
Cinchona Bark, red of Jaen or of Loxa	(?)

II.—RED CINCHONA BARKS.

(Red Bark, Angl.—Rotho China, Germ.)

Red Cinchona Bark, becoming white in the air	(?)
Red Cinchona Bark of Lima	
Red Cinchona Bark true, non-verrucous (Casarilla Roja Verdadera, Laubert)	<i>C. nitida</i> , Ruiz et Pav.
Red Cinchona Bark, officinal	
Red Cinchona Bark true, verrucous	
Orange-Red Cinchona Bark, verrucous	
Pale-red Cinchona Bark, with a white surface	(?)
Brown Carthagena Bark	
Red Carthagena Bark	

III.—YELLOW CINCHONA BARKS.

Yellow Cinchona Bark of the King of Spain (Casarilla Amarilla del Rey, Laubert)	<i>C. Calisaya</i> , Wedd.
Calisaya Cinchona Bark, or Royal Yellow Bark (Königs China, Germ.—Yellow Bark, Angl.—China Regia, Bergen)	
Orange-Yellow Cinchona Bark; Cinnamon Cinchona Bark (Quinquina—Cannelle), Light Calisaya (Casarilla Claro-Amarilla, Lauh.)	<i>C. micrantha</i> , Ruiz et Pav.
Pitaya Cinchona Bark (Quinquina de la Colombie ou d'Antioquia, Guib., 'Hist. Nat. des Drog.'—Casarilla Parecida à la Calisaya, Laubert)	<i>C. Candaminea</i> , Humb. et Bonp.
Woody Carthagena Bark (Quinquina de Colombie Ligneux)	
Orange Cinchona Bark of Mutis (Spongy Carthagena Bark; New Spurious Yellow Bark, Pereira)	<i>C. lancifolia</i> , Mutis.

§ 3. Huamalis Cinchona Bark. (Rusty Bark, Angl.—China Huamalis, Braune Chiua, Germ.)

Huamalis Cinchona Bark, dull gray	<i>C. hirsuta</i> , Ruiz et Pav.
Huamalis Cinchona Bark, thin reddish	(?) <i>C. purpurea</i> , Ruiz et Pav.
Huamalis Cinchona Bark, white	(?)
Huamalis Cinchona Bark, ferruginous	<i>C. micrantha</i> , Ruiz et Pav.
Yellow Cinchona Bark of Cuenca	<i>C. ovalifolia</i> , H. et B.

IV.—WHITE CINCHONA BARKS.

Ash-coloured Loxa Cinchona Bark (Ash-Bark, Angl.—Blasse Ten-China, Germ.—China Jaen, Berg.)	<i>C. ovata</i> , Ruiz et Pav.
Gray Cinchona Bark, pale ditto	
White Loxa Cinchona Bark	
White Fibrous Jaen Cinchona Bark	
Cuzco Cinchona Bark	<i>C. pubescens</i> , Vahl., or
Arica Cinchona Bark	<i>C. cordifolia</i> , Mutis.

Pale-Yellow Carthagena Cinchona Bark (Hard Carthagena Bark, Angl. —Quina Amarilla, Mutis.—China Flava Dura, Bergen) } *C. pubescens*, Vahl., or *C. cordifolia*, Mutis.
 Orange-Yellow Carthagena Cinchona Bark (Quinquina de Maracalibo.—China Flava Fibrosa, Bergen) }
 Pitayon Cinchona Bark, or False Pitaya Cinchona Bark } (1)

The following, according to M. Guibourt, are the most active barks:—

1. Calisaya Cinchona Bark.
2. Yellow Orange Bark.
3. Pitaya Bark.
4. Verrucous True Red Bark.
5. Non-Verrucous True Red Cinchona Bark.
6. Red Lima Bark.
7. Gray Lima Bark.
8. Verrucous White Huamalies Bark.

On the subject of distinguishing the various barks of commerce, M. Weddell points out the fallacy of the present method of distinguishing the sorts of bark by the colours red, yellow, and gray, as frequently the same barks at different ages have different colours. Having shown also the impossibility of a chemical classification, he proceeds to make the following remarks:—

"If a classification be absolutely needed, one which should be based on the anatomical structure of the bark would be found to be of far greater utility than either of the preceding, inasmuch as we shall find existing, even in the Cinchonas, a certain relation between the structural and chemical characters.

"The following are the data which my researches on the subject have furnished me with:—

"1. If a large piece of the *Cinchona Calisaya* met with in commerce be attentively examined, it will be found that the exterior surface is entirely deprived of its peridermis, and presents broad superficial furrows, short, more or less confluent, and divided by projecting ridges, the bases of which are of a fibrous texture, similar to the inner surface of the bark or of the layer which is immediately in contact with the wood. The examination of a transverse section shows that the texture of the bark is homogenous, and composed of ligneous fibres of almost equal thickness, uniformly distributed in the midst of cellular tissue gorged with resinous matter, tissue which may be said to isolate each fibre, being interposed in thin layers between them. Finally, when these fibres are examined longitudinally, we find that they are short and fusiform, and that their cut extremities are but loosely attached to each other, and are sometimes completely separate, and appear to float in the midst of the cellular tissue which surrounds them.

"2. If we take a similar piece of the bark of *C. scrobiculata*, we shall find that instead of these furrows of fibrous texture, which so well characterise the *C. Calisaya*, the exterior almost presents a smooth surface of a cellular texture, traversed here and there by slight linear indentations, the inner surface being, as in the preceding bark, of a fibrous texture. In the transverse section the fibres are more numerous than in the *C. Calisaya*, especially towards the inner surface; but they lessen in numbers rapidly near the exterior, and the outermost layer is entirely without them. These fibres, if examined in a longitudinal section, will be found to be of nearly double the length of those of the *C. Calisaya*, and their extremities are invariably attached one to the other, their ends being by this means more elongated.

"3. If we study with equal attention the bark of *C. pubescens*, we shall there find a peculiar structure. The external surface somewhat resembles the preceding bark, with the exception of a slight whitish marbling, formed by the continuity of the peridermis, and sclosures which may result from desiccation. The internal surface is fibrous, as in the preceding barks; but a transverse section shows us that it is principally composed of cellular tissue, in which the fibres form but a small number of irregular and concentric series in the interior half of the bark; and that which draws attention at the first glance is the size of these fibres, each one being three or four times as large as those of either of the former varieties; the result being that several of them are attached and united together in bundles, which may be fully proved by the examination of a longitudinal section of this bark.

"As may be perceived, we have only spoken of Cinchonas which have been deprived of their peridermis, because it is in this state that they are now usually met with in commerce. If perchance they were again to be used with their natural coating, it would afford additional means whereby to distinguish them, but would not in any way affect those of which we have just treated; for nothing would be easier than to remove the peridermis and to expose the surface beneath. Be this as it may, the structure of all the Cinchona barks more or less resemble one or other of the three types we have spoken of, and on this plan there might be formed, without much difficulty, a series of groups comprehending all the known Cinchonas. The purpose however in noticing these peculiarities, has been to facilitate the comprehension of a very important fact in the diagnostics of the different kinds of Cinchonas; that of the vast difference they present in their mode of fracture. However singular it may in the first instance appear to be, it is easy to prove that, to a certain extent, the chemical composition of the bark operated upon may be determined by its mode of fracture; or, more properly speaking, there exists a relation between the chemical and the anatomical characters of the Cinchonas, this being constantly proved by a particular form of fracture: smooth or corky where it divides the tunic or cellular covering of the bark; fibrous, stringy, or woody in those cases where it has affected one or other of the three forms of liber before described. Another fact which is now fully proved is, that the bark containing the largest proportion of quinine is that of the *C. Calisaya*; and experience has shown us, that after the *C. Calisaya*, the barks possessing it in the greatest quantities are precisely those the structure of which most resembles this bark; for instance, those in which the dermis is reduced to a single liber by the successive exfoliation of the outer tunics, or at least by their adjunction to the peridermis. On the other hand, experience seems to have shown, to a certain extent, that the Gray Cinchonas (which we have generally found to be the young barks of other species) contain a larger proportion of cinchonine than of quinine; we also know that many old barks, which have retained the cellular coating they had when young, yield a proportionably larger quantity of cinchonine; from which circumstance we may conclude that quinine is contained in the liber, or, more correctly speaking, in the cellular tissue interposed between the fibres of the liber, and that the cinchonine is principally found in the tunic or cellular coating. As to the tannin, it is found in larger quantities in this latter part than in the fibrous tunic—a fact which is easily determined with reference to the fresh bark where the exterior layers of the derm are more stypitic than the internal layers." (*Pharmaceutical Journal*, vol. ix.)

The following are the specific characters of the *Cinchona Calisaya*:—Leaves oblong or lanceolate, obovate, obtuse, attenuated at the base, rarely acute on both sides; smooth, polished, or pubescent beneath; scrobiculate in the axils of the veins; filaments usually shorter than one half the length of the anthers; capsule ovate, scarcely equal in length to the flowers. Seeds frequently frimbriate, denticulated at the margin. Of this there are two varieties:—

C. C. vera. A tree with obtuse oblong-ovate or oblong-lanceolate leaves.

C. C. Josephiana. A shrub with somewhat acute oblong-lanceolate or ovate-lanceolate leaves.

Both varieties are natives of Bolivia and Southern Peru.

(*Pharmaceutical Journal*, vol. ix.)

QUINSEY-WORT. [ASPERULA.]

QUISCALUS, a genus of Birds. [STURNIDÆ.]

QUISQUALIS, a genus of Plants of the natural family of *Combretaceæ*, which is indigenous in Amboyna, Java, and the Malayan Peninsula, and extends into India. The genus is characterised by having a very long slender tube of the calyx, which is 5-fid at the mouth. Petals 5, oval, oblong, larger than the teeth of the calyx. Stamens 10, exserted, inserted into the faux of the calyx; the alternate ones shorter. Ovary ovate, oblong, 4-valved. Style filiform, obtuse. Drupe dry, 5-angled, 1-seeded. Shrubs with climbing branches. Leaves opposite, seldom alternate, entire, ovate. Spikes axillary and terminal. (Flowers change in colour from white to red. The few plants of the genus are cultivated in this country with great ease in moist stove-houses in a mixture of loam and peat.

Q. Indica is the most common species; its fruit is reckoned a vernifuge.

QUITCH. [TRITICUM; AGROSTIS.]

R

RABBIT. [LEPORIDÆ.]

RACAMINÆ. [VULTURIDÆ.]

RACCOON. [URSIDÆ.]

RACE-HORSE, a Bird. [MICROPTERUS.]

RADIATA. [RAYED or RADIATE ANIMALA.]

RADIOLA (from *Radiolus*, little ray, in allusion to the rayed cap-

sules), a genus of Plants belonging to the natural order *Linaceæ*. It has a calyx of 4 sepals connected below, deeply trifid. There are 4 petals, 4 stamens, 4 capsules, with 8 cells and 8 valves.

R. milligrana is the only species of this genus. It is the *R. linoides* of some botanists, and is a British plant. The stem is from one to two feet high, repeatedly forked, with solitary flowers in the axils as

well as at the extremities of the branches. The flowers are small and white; the capsules light brown, and slightly depressed; the sepals deeply and acutely 3-cleft, connected below into a tube.

(Bahington, *Manual of British Botany*.)

RADISH. [RAPHANUS.]

RADIUS. [SKELETON.]

RAFFLESIA is the name of a plant found in the hot damp jungle of Sumatra, growing parasitically on a kind of vine, and discovered by the late Sir T. S. Raffles, whose name it bears. It consists of a number of scales investing a fleshy calyx measuring a yard in diameter, and containing the organs of fructification within or beneath the rim of a huge fleshy central column. [RAFFLESACEÆ.]

RAFFLESACEÆ, *Patma-Worts*, a natural order of stemless leafless Parasitical Plants, consisting of flowers growing immediately from the surface of branches, and immersed among scales. The perianth is superior, with a 5-parted limb, thickened processes or calli either distinct or united into a ring being attached to the throat of the tube. The essential organs are combined in a column which adheres to the tube of the perianth. Anthers 2-celled, either distinct and opening by vertical apertures, or combined together so as to become a multicellular mass opening by a common pore. Ovary 1-celled; placentas parietal. Fruit indehiscent. The species are East Indian and South American plants, parasitic on the species of *Cissus* and on some *Leguminosæ*. There are 16 species. Some of them are said to be styptic. Their perianth has a fungoid appearance.

Rafflesia Arnoldi, a Sumatra parasite, is capable of containing 12 pints of fluid in its cup. The flower is said sometimes to have a weight of 14 lbs.

R. Patma is employed as an astringent and styptic in Java. *R. Horsfieldi*, *R. Cumingi*, and *R. Rochussenii* have similar properties.

The genera are *Rafflesia*, *Sapria*, *Brugmansia*, *Apodanthes*, and *Pilosyles*.

(Balfour, *Classbook of Botany*; Lindley, *Vegetable Kingdom*.)

RAGGED ROBIN. [LYCHNIS.]

RAGWORT. [SENECIO.]

RAIANIA, a genus of Plants so-called in honour of the great naturalist John Ray, is known by the stamiferous flowers having a bell-shaped perianth in six deep oblong pointed segments, most spreading in their upper part. Corolla none; stamens with six filaments, bristle-shaped, shorter than the calyx; anthers simple. Pistilliferous flowers, the perianth superior, of one leaf, bell-shaped, in six deep segments, permanent, withering; corolla none; pistil with the germen inferior, compressed, with a prominent border at one side, 3-celled; styles 3, the length of the calyx; stigmas obtuse; capsule membranous, of three cells without valves, crowned by the calyx; two of the cells barren, almost obliterated, without wings; the third fertile, compressed, extended into a very large half-ovate membranous wing; seed solitary, nearly elliptical, compressed.

R. hastata, Halberd-Leaved Raiania, is found in the island of St. Domingo. The root is perennial, sometimes large and ovate, sometimes 4 or 5 inches long and 2 inches thick, round at each end. Its substance resembles that of a radish without any internal fibres; the bark thin, ash-coloured, a little rugged and warty, the flesh very white, tasting like a bean. The flowers small, whitish, in simple axillary drooping clusters.

R. cordata, Heart-Leaved Raiania, has ovate leaves somewhat heart-shaped at the base, 7-ribbed. It is a native of the West Indies, from whence it was sent to Kew Gardens in 1786, by Mr. Alexander Anderson. Plumier represents the habit of the root, stem, &c., much like the foregoing; but the leaves are regularly ovate, pointed, more or less heart-shaped at their base, and furnished with seven ribs continued from that part to the point. These ribs are connected by numerous transverse veins.

R. ovata, Ovate-Leaved Raiania, has ovate-pointed 3-ribbed leaves. It is a native of the hills of St. Domingo, and has a shrubby stem, turning thread shaped, sub-divided with slender smooth leafy branches. The leaves rather distant, stalked, smooth on both sides, pointed, entire, 3-ribbed, being ovate at the base. The flowers dioecious, the males in compound clusters, females in simple ones; all stalked and turned toward one side. Corolla very minute, yellowish-green in the male, reddish in the female blossoms.

R. angustifolia, Narrow-Leaved Raiania, is a native of the west part of St. Domingo, where it climbs upon high trees, flowering in May.

R. quinata, Five-Leaved Umbellate Raiania, has five leaves on a common stalk. It was observed by Thunberg about Nagasaki, and in Japan, flowering in April and May. The stem is twining, round, smooth, ash-coloured, and branched. Leaves several together, axillary, stalked, smooth. Flowers in umbels from the same buds as the leaves, on slender stalks, as long as the footstalks.

R. hexaphylla, Six-Leaved Clustered Raiania. Leaves six, on a common stalk, oblong-acute. Flowers racemose. It is a native of the country of Fokonia, in Japan, among bushes, flowering in April. The stem is round, striated, smooth, climbing. The flowers in axillary racemes, clusters snow-white. It differs from *R. quinata* in having mostly six leaflets on a stalk, which are acute, reticulated, with veins at the back, and larger than in that species. The flowers moreover grow in clusters, not in umbels.

RAIIDEÆ, or RAIINÆ, a sub-order, or family of Plagiostomous

Cartilaginous Fishes, of which the Common Ray is the type. The body of these fishes is horizontally flattened, and more or less discous; the dorsal fins are mostly placed on the tail; a peculiar cartilage, called naso-pectoral, arises from the nasal part of the skull, and extends towards or meets the anterior part of the crest or pectoral fin; the branchial openings are inferior.

This sub-order is divided into the following families or tribes:—

1. *Cephalopteridæ*, Horned Rays.—They have a muzzle distinguished by two horn-like processes; the mouth before or beneath very broad; teeth very small, in some wanting in upper jaw; tail as long or longer than body, with a back-fin and spine. The genus *Cephaloptera* has large lateral eyes and a transverse mouth, with small teeth like a file.

C. Giorna is the only species known in the European seas. A specimen of this fish was once taken on the southern coast of Ireland. It has been described by M. Risso as frequent on the coast of Nice. It approaches the shore, and is most frequently taken in the month of July. In Italy the small ones are called Vachetta, and the larger ones Vacha. It dies immediately on being taken out of the water. It is eaten by the poorer classes at Nice, but is not tender. They grow to a prodigious size. Risso records a male weighing 800 lbs. and a female weighing 1200 lbs.

2. *Myliobatidæ*, Eagle Rays.—The head is partially disengaged from pectorals; mouth transverse; teeth large, mosaic-like; eyelids wanting; tail long, with a back-fin on root and a serrated sting behind. The genus *Myliobatis* has flat teeth; the central plates much longer than those which are lateral; pectoral fins wing-like; the tail armed with one fin upon the root, behind that a serrated spine.

M. aquila, the Whip Ray, the Eagle Ray, and the Mullen. This fish, though rare, has been found on the British coasts. Dr. Johnston has described a specimen found at Berwick-upon-Tweed. It inhabits the Mediterranean, and has been taken as far south as the Cape.

3. *Trygonidæ*, the Sting Rays.—The head is laterally inclosed by the pectorals; the teeth transversely elliptical; the tail without any fin, or merely a low vertical cuticular hair, and with one or more sharp serrated spines.

The genus *Trygon* has the characters of the family.

T. pastinaca, the Common Trygon, the Sting-Ray, the Fire Flaire, La Pastinaque of the French, is an example of this family. It was well-known to the ancients, who entertained many fictions with regard to the venom of the spines of these fish. It is not unfrequent on the British coasts. The powerful serrated spine on its tail is used as an organ of defence.

4. *Anacanthidæ*, Stingless Rays.

5. *Raiidæ*, the Skates.—The body is rhomboidal; tail depressed, slender, generally with a low terminal fin, and frequently with rows of small spines; skin smooth or with small curved prickles; teeth flat, pavement-like, and pointed in males in spawning time. The genus *Raia* has two small fins near the end of the tail; the eyes and temporal orifices are on the upper surface of the head; the nostrils, mouth, and branchial apertures beneath.

The Skates are very numerous on the British coasts, and some of the species are used as food. The young are deposited in a similar manner to the sharks, in their bony cases of a square form, with four projecting horns, giving them the form of a butcher's tray. These cases are very frequently picked up on the sea-shore, and are sometimes called sea-purses. In Cumberland they are called Skate-Barrows, on account of their form. As the young fish increases in size it at last separates the edges of the bony layers in which it is inclosed, and escapes into the ocean. The following are the British species of this genus:—

R. mucronata, the Long-Nosed Skate, remarkable for its long pointed nose.

R. oxyrhynchus, the Sharp-Nosed Ray, the White Skate, the Burton Skate.

R. intermedia, the Flapper-Skate.—This species was first taken in the Frith of Forth by Dr. Parnell, and first described by him.

R. batis, the Skate, the Blue Skate, the Gray Skate, the Tiuker, La Raie Cendrée of the French. This is one of the commonest species on our coast. The preceding species as well as this, the Thornback, and the Homelyn, are all commonly called Skate.

R. marginata, the Bordered Ray. It has been only occasionally taken in Great Britain.

R. microcellata, the Small-Eyed, or Painted Ray. This is a rare species.

R. miraletus, the Homelyn, the Home, the Sand Ray, and Spotted Ray. It is one of the commonest species along the line of our southern coast. With the Thornback it is the most common species found in the London market.

R. spinosa, the Sandy Ray, Raie Râpe of the French. It has been only occasionally taken in the British Islands.

R. fullonica, the Shagreen Ray. This species is known by its rough back. It is only occasionally taken in the British Islands.

R. clavata, the Thornback, the Rough Ray. This Ray is easily distinguished by the spiny plates with which it is covered. Its flesh is regarded as the finest of all the Rays. It is in the best condition for the table about November.

R. radiata, Starry Ray. A rare species.

6. *Torpedinidæ*, the Torpedoeæ.—The head is very large and surrounded by pectorals, so as to form a circular disc; the tail is short, fleshy, depressed at the base, cylindrical at the extremity; mouth beneath; teeth pointed or flat. These fish are many of them remarkable for their power of giving electric shocks. [ELECTRICITY IN ORGANIC BEINGS.] There are two species of *Torpedo* found on the British coasts.

Torpedo vulgaris, the Old British Torpedo, the Common Cramp-Fish, the Numb-Fish, the Electric Ray, and the Cramp-Ray. This fish is only occasionally found on our coasts.

T. nobiliana, the New British Torpedo. This is identical with the *Torpedo* of the Mediterranean.

7. *Rhinobatidæ*, the Beaked Rays, have the muzzle generally beaked and pointed; the mouth undulated; the teeth rounded or elliptical, in some broader than long, and longer on summit of undulations; body smooth; caudal fin bilobular, or cut obliquely, forming one lobe. These fishes connect the Sharks and Rays. The species inhabit the Mediterranean, the Atlantic, and the coasts of Brazil. They are not found on the coasts of Britain.

8. *Pristidæ*, Saw Fishes.—The snout is produced into a long flat oaceous saw-shaped blade, with teeth on the lateral edges; body flattened before, somewhat elongated posteriorly; skin with very small, flat, roundish, or 6-cornered scales; mouth beneath.

(Adams, Baillie, and Barron, *Manual of Natural History*; Yarrell, *History of British Fishes*.)

RAIL. [RALLIDÆ.]

RAIN, FOSSIL. Singular as may appear the notion that the impressions of rain should be recognisable and be recognised on the surfaces of stratified rocks, the opinion is held by some eminent geologists, on the evidence of specimens of New Red-Sandstone taken from the Storeton Quarries near Liverpool. In March, 1839, Mr. Cunningham, to whose researches in the Storeton Quarries we are indebted for much of our knowledge of the foot-prints of *Cheirotheria* and other ancient animals, communicated a paper on the subject to the Geological Society of London. "In examining some of the slabs of stone extracted at the depth of above 30 feet, Mr. Cunningham observed that their under surface was thickly covered with minute hemispherical projections, or casts in relief, of circular pits in the immediately subjacent layers of clay. The origin of these marks, he is of opinion, must be ascribed to showers of rain, which fell upon an argillaceous beach exposed by the retiring tide, and their preservation to the filling up of the indentations by sand. On the same slabs are impressions of the feet of small reptiles, which appear to have passed over the clay previously to the shower, since the foot-marks are also indented with circular pits, but to a less degree, and the difference Mr. Cunningham explains by the pressure of the animal having rendered these portions less easily acted upon." If these impressions on the clay be really the marks of rain or hail (a specimen is before us, and it certainly resembles such impressions on clay), perhaps the easiest way of comprehending the preservation of them is to suppose dry sand drifted by the wind to have swept over and filled up the foot-prints, rain-pits, and hollows of every kind which the soft argillaceous surface had received. (*Geological Proceedings*, 1839.)

RAISINS, Dried Grapes. [Vitis.]

RA'LLIDÆ, a family of Birds belonging to the *Grallæ* of Linnæus, *Grallatores* of Illiger. The species are commonly called Rails.

Brisson placed the Rails in the first section of his 17th order, with the Lapwings, the Jacana, the Pratincole, &c.

The genus *Rallus* of Linnæus consisted of Rails properly so called; and the species in the last edition of the 'Systema Nature,' as left by him, were *Crex aquaticus*, *C. Porzana*, *C. fuscus*, *C. striatus*, *C. torquatus*, *C. Philippensis*, *C. Benghalensis*, *C. Carolinus*, and *C. Virginianus*. The genus is placed in the order *Grallæ* (the fourth), between *Parra* and *Peopha*.

Latham also gave it a place among the *Grallæ* (his seventh order), between the Pratincole and the Jacana.

Lacépède arranged *Rallus* among his Oiseaux de Rivage, in his thirty-third order (birds with a straight and compressed bill), between the *Hians* and *Scopus*.

In M. Duméril's system *Rallus* is placed in the first family (Pressirostres or Ramphostœus) of his fifth order, Echassiers, between the Jacanas and Oystercatchers (*Macrotopus*).

Illiger's *Macrodyctylæ*, belonging to his sixth order, *Grallatores*, include the genera *Parra*, *Rallus*, and *Crex*.

In Cuvier's fifth order, Echassiers, *Rallus* appears in its fifth family, *Macrodyctyles*, between the *Kamichis* (*Palamedea*) and the *Fulica*.

M. Vieillot's second tribe (*Tritradactylæ*) of his fourth order (Echassiers) includes, among many other families, the *Macrodyctyles*, including the genera *Rallus*, *Porzana*, *Porphyrio*, and *Gallinula*. The *Macrodyctyles* are placed between the *Macronychea* (*Jacana*) and the *Pinnatipèdes* (*Fulica*, *Phalaropus*, &c.).

M. Temminck places *Rallus* between *Scolopax* and *Gallinula*, in his thirteenth order (*Grallæ*).

In M. De Blainville's system *Rallus* is also placed among the *Macrodyctyles*, in the order *Grallatores*.

The *Macrodyctyles* of M. Latreille form the sixth family of his fourth order, Echassiers, and consist of the *Jacana*, *Kamichil*, and *Chauna*.

M. Lesson makes the *Rallusines*, the fourth family, according to him, of the Echassiers, consist of the genera *Jacana* (*Parra*), *Pa-*

medea, *Chauna*, *Glareola*, *Rallus*, *Crex*, *Gallinula*, *Porphyrio*, *Podoa*, and *Fulica*. The *Rallusines* are placed between the *Scolopacidae* and the *Charadriada*.

In Mr. Swainson's 'Sylopsis' the *Rallidæ* are placed between the *Tantalidæ* and *Scolopacidae*, and consist of the following genera: *Parra*, *Porphyrio*, *Fulica*, *Rallus*, *Gallinula* (with the sub-genus *Alecthelia*).

The genera of *Rallidæ* (which family he places between the *Scolopacidae* and the *Phalaropodidae*), enumerated by Prince Bonaparte in his 'Birds of Europe and North America,' consist of *Aramus*, Vieill., *Rallus*, Linn., *Ortygometra*, Leach, *Gallinula*, Brisson (*Stagnicola*, Brisson), *Fulica*, Linn., and *Porphyrio*, Ray.

The *Rallidæ*, in Mr. G. R. Gray's 'List of the Genera of Birds,' are the fifth and last family of the *Grallatores*, and immediately preceded by the *Palamedeidae* (which embrace the genera *Parra*, *Chauna*, *Palamedea*, and *Alecthelia*). The order *Natatores* follows.

The following are the sub-families and genera of Mr. G. R. Gray's *Rallidæ* :—

Sub-Family I. *Rallinæ*.

Genera. *Ortygometra*, Ray (*Rallus*, Linn., *Porphyrio*, Brisson, *Crex*, Bechstein, *Gallinula*, Lath.).

Porzana, Vieill. (*Rallus*, Linn., *Gallinula*, Lath., *Zapornia*, Leach).

Rallus, Linn. (*Gallina* (*Gallinula* ?), Ray).

Ocydromus, Wagler. (*Rallus*, Forster.).

Sub-Family II.

Porphyrio, Brisson. (*Fulica*, Linn., *Gallinula*, Lath.).

Gallinula, Ray (*Fulica*, Linn., *Hydrogallina*, Lacépède, *Stagnicola*, Brehm.).

Fulica, Linn.

Sub-Family III. *Helioninæ*.

Helionis, Bonn. (*Plotus*, Gmelin, *Podoa*, Ill., *Colymbus*, Bodd.).

Podica, Less. (*Helionis*, Vieill., *Podoa*, Boie, *Rhigolura*, Wagler.).

We proceed to notice some of the leading forms of this family :—

Rallidæ.—Feet very large; bill in general short, and greatly compressed; tail excessively short, nearly hidden by the covers; hinder toe elevated. (Swainson.)

Parra.—Bill straight, slender, moderate; feet very long; toes and claws of enormous length; the latter straight or recurved; carpus generally armed with acute spurs. (Swainson.)

Parra Africana.

Mr. Swainson remarks that the Jacanas or *Parrae* are wading birds, somewhat analogous, both in structure and habits, to the European Water-Hen; but in their native haunts from not being disturbed, they are less shy. "The number of these birds," says Mr. Swainson, "on the lakes of Brazil, the elegance of their movements, and their fearlessness of man, excite an interest in the traveller who journeys through regions ornamented alone by nature. They are very light birds, and their long toes spreading over a wide surface enable them to walk on the floating leaves of aquatic plants with as much facility as if they were on land. In such situations their appearance is really delusive; for their pressure being sufficient to sink the surrounding leaf just below the surface, the birds actually appear to walk upon the water." ('Zool. Ill.,' second series).

The species are numerous in South America; some in India; and a few in Africa.

P. Africana. Deep cinnamon above; crown of the head naked; throat white; breast fulvous; neck and quills black; spur on the wing obsolete.

It has been found in Africa, Abyssinia (Bruce), Mozambique (Salt), Western Africa (Swainson, on the authority of Ward), South Africa (Smith).

The strong bony spur with which the wing is armed in the typical species, becomes so small in *P. Africana*, that it is hardly perceptible when the wing is closed. In another African species, *P. Capensis*, the spur or spine has become a small tubercle. The African Jacanas may therefore be referred to the aberrant group of this genus. Dr. Smith only met with one individual of *P. Capensis*, and he strongly suspects that it was in immature plumage. It was killed while seeking for its food upon some water-plants which coated the surface of a small river near Algoa Bay, and he has figured the bird standing on a leaf of a water-lily. He notices *P. Africana* as the only other species of the group which has yet been found in Southern Africa, and states that it never ranges so far to the westward as the Cape Colony, though it is often found to the westward of Port Natal.

Porphyrio.—Bill short, strong, high; the base dilated into a flat plate on the front of the head; the culmen arched. Nostrils large, basal, covered by a membrane, naked; the aperture terminal and oval. Feet very large. Toes without any lateral membrane. Claws large, slightly curved. (Sw.)

These birds live nearly like the Water-Hens, to which they are most closely approximated: like them, their habitual haunts are the fresh-waters; but the immense rice-fields and marshes of the south equally serve them for an asylum and retreat. More inclined by their appetite to cereal grains and plants, than aquatic herbs, the Porphyrios frequent the land more than the Water-Hens; they move with grace on the water, and run with elegance and swiftness on the land or over the plants which grow in the water. Their body is not so compressed nor so slender as that of the water-hens; their formidable bill, composed of a very hard substance, and nearly without a nasal fossa, which is covered by a membrane, serves them as an instrument for cracking the husk of grain and breaking the hardest stems; their feet, which they use to seize their food and convey it to their bill, are provided with very long toes, easily retractile, and with nails which bend also with some facility, which gives them a power of prehension. A brilliant plumage, where blue or a turquoise hue predominates, clothes the greatest number of the known species.

It is not clear what species of this genus was known to the ancients, who held it in high estimation. The *Porphyrio* does not appear to have been sought after for any other purpose than that of keeping it alive; indeed Ælian states that he never heard of one being served at any banquet. Pliny ('Hist. Nat.', x. 46 and 49) speaks of the Porphyrios as 'laudatissimi in Comagene,' and says that their bill and long legs are red; the Balearic Islands are also named by him as a place whence they were sent to Rome. He speaks of their peculiar mode of drinking, their soaking their food in water and raising it to their bills in their claws; "Bihunt aves euctu, ex his quibus longa colla, intermittentes, et capite resupinato velut infundentes sibi. *Porphyrio* solus morsu bibit, idem est proprio genere, omnem cibum aqua subinde tingens, deinde pede ad rostrum veluti manu affert."

But there was another quality which was supposed to reside in the *Porphyrio*, which made it both a highly prized and dangerous inmate. The bird was considered as a kind of guard over the women of the house in which it was domiciled: it was believed that it took notice of adultery, and that if the crime was committed, it would give notice to the master of the house by making signs as if it wished to strangle itself. It is to this that the old quatrains allude in the 'Portraits d'Oyseaux':—

"Porphyrio declare l'adultère
Fait au logis auquel on l'entretient:
Car à ces fins tous les semblans il tient
De se vouloir étrangler et défaire."

P. hyacinthinus (Pollo Sullano, Savi). Bill fine red; legs and feet fleshy red; irides lake-red; cheeks, throat, sides of the neck, and chest turquoise-blue; remainder of the plumage deep dull indigo-blue, having the edges of the greater and lesser coverts of the wings lighter in colour and more brilliant; under tail-coverts white. (Gould.)

Young of the Year.—Belly, till the month of October, white; occiput yellowish-brown; median part of the head whitish; mantle bluish-ash. Feet reddish-olive. At the time of the moult, which takes place towards the end of October, individuals are found in a state of transition from the livery of youth to that of the adult: early in May the rich blue plumage is complete. (Temm.)

"Independently of the southern and eastern parts of Europe, the marshes of which are the places of constant resort for this beautiful bird, its range is extended," says Mr. Gould, "over a great portion of Africa to the south, and as far as the mountains of the Himalaya to the east. In Europe it is especially abundant in the Grecian Archi-

pelago, the Levant, and the Ionian Islands; it is less common in Dalmatia and Sardinia. The southern provinces of Hungary and Russia and the borders of the Caspian Sea may also be enumerated among its European localities." M. Temminck states that it is to be seen in many cities of Sicily (where, according to M. Cantraine, it is very common in the neighbourhood of Lentini), that it is not known in Dalmatia nor Calabria, and is rare in Sardinia; and that it is known in Catania under the name of Gallo-Fagiano.

Porphyrio hyacinthinus.

Mr. Gould states that, like the Water-Hen, or Common Gallinule, this species dwells on the borders of rivers and in all marshy situations. In its food it is partly herbivorous, feeding on various kinds of marine vegetables; still, as the robust and hard character of its bill implies, it prefers hard seeds and grain, to which are added snails, frogs, and other aquatic animals.

"Although its form," continues Mr. Gould, "would seem to deny the fact, its actions and appearance on the land are both elegant and graceful. It is extremely quick in all its movements, running with ease and swiftness; and from the great expansion of its feet, it is enabled to pass with facility over soft oozy mud, aquatic herbage, &c.; but although much agility characterises this species on land, its aerial evolutions are heavy, and apparently performed with considerable difficulty." M. Temminck states that it lives in the marshes where the water is not deep, and that its stupidity is such that when closely pursued it buries its head in the mud. M. Verneuil informed him that solitary individuals are sometimes found in Dauphiné; that of the museum of Grenoble was, he adds, killed in the marshes of Burgundy.

It breeds in marshes, much in the manner of the Common Gallinule, giving preference to the sedge parts of the morass and partly inundated rice-fields, where it constructs a nest of aquatic plants, and lays three or four white and nearly round eggs. (Gould.)

Fulica.—Bill as in the *Porphyrio*, but more slender; the base straight; the gonyx short and angulated. Feet very large; the toes margined with a lateral membrane, which is either narrow and of equal breadth or dilated into lobes. The natatorial type. (Sw.)

F. atra. It is the Foulque, Macroule, or Morrelle, of the French; Schwarzes Wasserhuhn of the Germans; Meir Koet of the Netherlands; Folaga and Folara of the Italians; Blas-Klaeka of the Swedes; Vand-Hoene and Bles-Hoene of the Danes; Jär Ddwfr Foel of the Welsh; and Coot of the English. Some have thought that it is the *Képos* of Aristotle.

The head and neck are of a deep-black; upper parts slaty-black; all the lower parts bluish-ash; frontal plate very wide, pure white; bill white, slightly tinged with rose-colour; iris crimson-red; feet ash-colour, tinged with greenish, but of a yellow or greenish-red above the knee.

The sexes do not differ, excepting that in the female and the young the frontal plate is less developed, and that in the latter, after the autumnal moult, the lower parts are slightly tinged with reddish. Before the moult, the frontal plate of the young is hardly apparent, and that and the bill are greenish-ash; all the lower parts are whitish-ash: in this state it is, according to M. Temminck, *Fulica Athiops*, Sparrm.; Gmel.

It is found throughout Europe, in marshes, lakes, and gulfs; very abundant in Holland and in the lakes of the interior of France; less numerous in Germany and Switzerland. Dr. Von Siebold and M. Bürger saw it in Japan.

"The Coot," says Mr. Gould, "is indigenous to our islands, residing on all large sheets of water, but giving preference to those overgrown with rushes and margined with a belt of thick reeds and luxuriant vegetation." Such is the meer or pond before William of Wykeham's palace at Bishop's Waltham, where they abound. In such haunts it builds, early in the spring, a strong and solid nest of rushes, grasses, and water-plants. The large nest thus constructed rises above the surface of the water, on the bottom of which, when shallow enough, the base of the nest sometimes rests. Its more frequent situation however is in the reedy and rushy tufts and rank vegetation of the water's edge, so as to be concealed. The eggs, which are brownish-white, spotted with dark brown, range from seven to ten in number. The young, when hatched, are clothed in a black down, and take water very soon. As winter approaches the Coot seeks the open waters near the sea, and the mud-flats at Southampton are among the places visited by them in great numbers. The Coot swims and dives admirably, but flies heavily and with effort. Its food consists of worms, slugs, aquatic plants, insects, &c.

The Coot (*Fulica atra*).

Much cannot be said for it as an article of food, except when it is young, and then it requires much perseverance to get off the black down next to the skin.

Gallinula.—Bill short, straight, the margins not inflexed; the cutting edges of the upper mandible folding over the lower. Gonys very short, angulated. Toes simple, without any marginal membrane. The rasorial type. (Sw.)

G. chloropus is the Poule d'Eau of the French; *Gallinella* of the Italians; Wasserhuhn, Grünfüßige Rohrhuhn, and Braune Meerhuhn, of the Germans; Common Gallinule, Water-Hen, or Moor-Hen of the English; and Dwfriar of the Welsh.

Water-Hen (*Gallinula chloropus*).

Old Male.—Head, throat, neck, and all the lower parts slaty-blue; upper parts deep olive-brown; external border of the wings, large longitudinal spots on the sides, and lower coverts of the tail, pure

white; three or four of the feathers placed at the centre of the tail-coverts deep black; base of the bill and large frontal plate bright red, point of the bill yellow; irils red; feet yellowish-green; on the tibia a naked circle of a fine red.

The Old Female differs only in having the tints of the plumage a little less bright.

The Young, till their second autumnal moult, differ much from the old. The top of the head, the nape, the back, and the rump are olive-brown; quills deep brown, terminated by bright brown borders; tail deep brown; throat, front of the neck, and a spot below the eye whitish; rest of the lower parts bright gray; point of the bill olive-green, blending into olive-brown at the base; iris brown; feet olive, but tinged with yellowish on the tibia.

Young of the Year.—More of the whitish around the bill; and the lower parts with the tints less bright. Individuals in a state of transition from one period of age to another have the frontal plate more or less large, coloured with red or yellowish.

"One circumstance," says Mr. Gould, in his 'Birds of Europe,' "respecting this familiar bird appears to have escaped the notice of most ornithologists: we allude to the fact of the female being clothed in a dark and rich plumage, and having the base of the bill and the frontal shield of a bright crimson-red tipped with fine yellow; her superiority in these respects has caused her to be mistaken for the male, which, contrary to the general rule, is at all times clothed in a duller plumage, and has the upper surface more olive than in the female; the bill is also less richly tinted. We were first led to notice this fact in consequence of observing the birds sitting or rising from the nest to be those whose richly-coloured bills had induced us to believe them to be males, and which the dissection of a great number of individuals has now fully proved to us to be the females. Besides this difference, the sexes vary in size, the female being about one-fifth less than her mate."

This species appears to be not only dispersed over the whole of Europe, but extends its range over the greater portion of Africa and India; and, like the Peregrine Falcon and Barn-Owl, may be said to be universally distributed over the globe. "It is even questioned," says Mr. Gould, "whether those from tropical America, China, and the islands of the Pacific, which exhibit the most trifling marks of difference, should not be considered as identically one and the same species." It was seen by Dr. Von Siebold and M. Bürger in Japan; and M. Temminck remarks that the African variety, which is also found in the isles of Sunda, has the anterior border of the wing reddish; the lower tail-coverts, which in European, Asiatic, and Japanese individuals are of pure white or Isabella colour, have a reddish tinge in the variety from Africa and the Sunda Isles, which is also somewhat less than European and Japanese birds, and has the frontal plate larger. The variety from the Sunda Isles is, according to M. Temminck, *Gallinula orientalis* of Horsfield, ('Linn. Trans., vol. xiii.) The only difference between the Japanese bird and that of Europe is the Isabella tint of the lateral under tail-coverts in the former: in the European variety those feathers are white.

In our islands the haunts of the common Gallinule are rivers, meers, ponds, sedgy spots, and marshy places. The nest is formed of interlaced flags, weeds, &c., generally in the most concealed parts of the rushy rivulet or sedgy margined pond, and in it from five to nine pale yellowish-brown eggs spotted with red are deposited. Incubation continues for three weeks. The young are exposed to many enemies, for their parent has not only to guard them against birds of prey and the smaller *Carnivora*, rats, &c., but against the attacks of the pike. The food consists of aquatic insects, molluscs and worms, seeds, and water herbage. The flesh of a water-hen, in good season, after having had the advantage of a neighbouring wheat or barley stubble, is well flavoured, juicy, and sapid. The sportsman who is not well acquainted with their habits, often leaves them behind perched among the boughs of the trees or shrubs that overhang the water or closely adjoin it; for these birds when hard pressed not uncommonly get up into such retreats till the danger is passed. On its feet it is lively and not ungraceful; on wing it is heavy and slow.

Some of the African Gallinules, figured by Dr. Smith (*G. dimidiata* and *G. Jardini* for instance), present certain differences which would appear to warrant subgeneric distinction.

Rallus.—Bill lengthened, slender; both mandibles in general slightly curved, and with their margins considerably inflected beyond the nostrils. The tenuirostral type. (Sw.)

R. aquaticus is the Rale d'Eau of the French; Porciglione, Merla Aquarola, and Merla d'Acqua, of the Italians; Wasser Ralle of the Germans; Water-Rail, Bidecock, Bilcock, Velvet-Runner, Brook-Runner, and Brook-Ousel, of the English; and Cwtair of the Welsh. It is the Rale Noir of Bélen, who gives the following synonyms:—*Ὀρνυγούρα*, *Matrix*, *Cothurnicum*, *Ralla*, *Rasle*, *Ralle*, *Roy* et *Mero* des Cailles, and *Re de Quaglio*.

Throat whitish; sides of the head, neck, breast, and belly, leaden-ash colour; all the feathers of the upper parts red-brown, marked in the middle with deep black; sides deep black transversely striped with white bands; lower coverts of the tail white; bill red but clouded with brown at the point and above; feet brown flesh-colour; iris orange.

The Young of the Year have the middle of the belly of a red-

brown, and the abdomen is blackish-ash without the white bands. (Temminck.)

Mr. Gould remarks that the sexes are alike in plumage, but that the male is generally the largest. M. Temminck observes that they undergo a double moult, but that there is no marked difference between the two liveries.

It is distributed generally all over Europe, but it is more particularly abundant in the low districts of Holland, Germany, and France. In our Islands it is more plentiful than is generally believed from its very shy and retired habits. Dr. Von Siebold and M. Bürger saw the bird in Japan.

Water-Rail (*Rallus aquaticus*).

"Except when closely watched," says Mr. Gould, "the Water-Rail seldom takes to flight, but evades pursuit by quietly yet quickly traversing the bottoms of thick-set reed-beds and banks overgrown with luxuriant vegetation bordering the sides of pools and ditches, where it finds a covert through which its slender and compressed form enables it to pass with the greatest facility; besides which it possesses the power of swimming and diving, both of which materially aid its escape. Without denying the possibility of this bird being migratory, we have the strongest reason to believe that numbers remain with us during the whole of the year, frequenting during the summer season fen-land, morasses, ponds, and ditches, about which it incubates; resorting on the approach of winter to the sides of our large streams and rivers. Its nest is composed of rushes and vegetable fibres closely concealed among herbage, at a little elevation from the water; its nidification in fact closely resembles that of the Moor-Hen. Its eggs are of a yellowish-white colour, marked with spots of red-brown. Its food consists of worms, snails, soft insects, and their larvæ, which abound in swampy places; vegetable substances also form a part. The young, when first excluded from the egg, are covered with black down, and are observed to be in perfect possession of the powers of swimming, and providing for their own safety and subsistence, remaining however under the parent's care and protection."

The Water-Rail is a delicious bird for the table. The writer of the old quatrain in the 'Portraits d'Oyseaux,' thus alludes to its celerity in running:—

"Le Ralle noir par les ruisseaux habite,
Et est cogueu en diverse contrée.
D'un bon coureur la vitesse est monstree,
Quand on le dit, comme un Ralle, aller viste."

Crex.—Bill shorter than the head, thick at the base, subcultrated, compressed; the culmen gradually defecting from the forehead to the point of the bill; lateral furrow of the upper mandible broad, and occupying more than half its length; angle of the under mandible bending upwards; both mandibles of an equal length. Nostrils concave, lateral, linear-ovoid, pierced in a membrane occupying the mandibular furrow in the middle of the bill. Wings armed with a spine, and having the second and third quill-feathers the longest. Plumage soft, thick, and open in texture. Legs strong, of mean length, with the lower part of the tibiae naked. Feet 4-toed, three before and one behind. Toes long, slender, and cleft to their base, without any lateral membrane; hind toe resting on the ground. Claws arcuate, compressed, and pointed. (Selby.)

C. pratensis, Bochst., *Rallus Crex*, Linn., is the Ralle de Genet, or Roi des Cailles of the French; Re di Quaglia of the Italians; Wiessen-Knarrer and Wachtel-Küing of the Germans; Kwartel Koning of the Netherlands; Vagtel-Konge, Aker-Rixe, and Skov-Snarre, of the Danes and Norwegians; Land-Rail, Corn-Crake, Daker-Hen, Bean-Crake, and Corn-Drako of the English; and Rhegen yr yd of

the Welsh. Belon gives the following synonyms:—'Ορνυομήτρα ἄλλη, Ralla, Re de Quaglie, Ralle Rouge, or Ralle de Genet. It has a large ash-coloured eyebrow, prolonged upon the sides of the head; all the feathers of the upper parts blackish-brown in the middle, bordered laterally with ash-colour, and terminated with reddish; the long feathers which extend on the quills entirely bordered by a large band of olive-reddish; coverts of the wings of a rusty-red; quills reddish externally; throat, belly, and abdomen white; breast olive-ash; sides reddish, striped with white; upper mandible brown, lower whitish; iris reddish-brown; eyebrows flesh-colour; feet flesh-colour, or reddish-brown.

The young have the tints less vivid, but brighter, with some white spots.

Land-Rail (*Orex pratensis*).

"The Land-Rail," says Mr. Gould, "appears to be extensively spread over the whole continent of Europe; it is very abundant in Holland, and not uncommon in France and Germany. It is a migratory species, arriving with us about the latter end of April or the beginning of May, when it scatters itself in pairs over the whole of the British Isles."

Worms, snails, insects and their larvæ, seeds, and grain form the food of the Land-Rail. It is very fond of grasshoppers. "Its habits," says Mr. Gould, "are extremely shy and retiring, selecting for its places of abode grassy meadows, fields of young corn, ozier-beds, and marshy grounds, seldom allowing itself to be seen; and were it not for the peculiar note of the male, which consists of a singular grating monotonous—sometimes sounding as if beneath one's feet, and again appearing as if uttered at a distance—its presence would not be betrayed. In these its favourite places of resort and concealment it carries on the process of incubation, constructing its nest on the ground, and occasionally on small hillocks, the nest being composed of slender flags or grasses; the female laying from eight to twelve eggs, rather less than those of the moor-hen, to which, in the markings, they bear some resemblance, of a yellowish-white, covered with dull rust-coloured spots. The young when hatched are covered with a blackish down, and are soon able to follow the parent birds, attaining by the commencement of the shooting-season nearly the adult size and plumage." Its southward migration commences in October, when it passes over to the Continent.

After it is once flushed it is almost impracticable to force the Land-Rail to take wing a second time, until it has run through every part of the cover that holds it. It is easily shot when on wing, though its flight is generally very short, for it flies heavily, and with the legs hanging down. It will run before a dog with the greatest rapidity, and very frequently escapes by trusting to its legs alone.

When dressed on the same day on which it is killed, with the trail in, it is very delicious, and it has always been highly esteemed for the table.

In the old quatrain under the cut of the Land-Rail we read—

"Au Ralle noir est ressemblant ce Ralle,
Sinon de bec, de grandeur et couleur.
A la Perdrix il ne cede en valeur,
Même leur chair est en bonté égale."

In the 'Northumberland Household-Book,' Reys are among the birds admitted to his lordship's table, and are charged at twopence each, the same price as that of a quail, and double that of a teal. Drayton too, in his 'Polyolbiou' (twenty-fifth song), notices—

"The Rayle, which seldom comes but upon rich men's spits."

RAM. [OVEE.]

RAMBEH, the Malay name of a fruit described by Mr. Jack as being common in the peninsula of Malacca, but unknown at Ben-

coolen, while the Choopa, which is nearly allied to it, is abundant at the latter, but is not found at the former place. The fruit is that of a tree called *Pierardia dulcis*, of the natural order of *Sapindaceæ*. Another species of the same genus is called *P. sapida*, from its also yielding an edible fruit. It is found in the district of Tippera, to the eastward of Calcutta, and also in China, where it is cultivated for its agreeable fruit, according to information obtained by Dr. Roxburgh from Chinese gardeners. It is remarkable that it should there be called Lutqua, as it is called Lutco by the Hindoos on the eastern frontier of Bengal.

RAMBOOTAN, a Fruit. [SAPINDACEÆ.]

RAMPHASTIDÆ, a family of Scansorial Birds known by the common name of Toucans.

Bélon, at the end of the 25th chapter of his third book 'De la Nature des Oyseaux vivants le long des Rivières, ayants le Pied plat, nommez en Latin Palmipedes Aves' (A.D. 1555), gives a wood-cut of the bill of a Toucan, which, from the black patch at the end of it, was probably that of *Ramphastos Toco*. He describes the bill as belonging to a bird of the 'terres neuves,' which possesses that organ half a foot long, large as a child's arm, pointed and black at the tip, white elsewhere, and notched some little on the edges, hollow within, and so finely delicate that it is transparent and thin as parchment. Its beauty, he observes, has caused it to be kept in the cabinets of the curious. He further says that he has not seen the bird, but that he suspects that it is 'de pied plat,' and therefore he has placed it with the River Birds.

In the 'Portraits d'Oyseaux' also, the cut of this bill is placed at the end of 'Le Second Ordre des Oyseaux au pied plat.' Above it appears the following description:—

"Bec d'un Oyseau aquatique apporté des terres neuves.

"Si quelqu'un avoit fait un corps d'Oyseau à ce bec sans avoir gros-seur suffisante, qu'on le juge fait à discretion, car nous l'avons mieux aymé laisser ainsi, que luy en feindre un."

Below the cut is the following quetrain:—

"Ce bec est gros comme le bras d'un enfant,
Creux par dedans, transparent comme verre;
Tenue et léger, veu d'estrange terre,
Noir par le bout, et blanc au demeurant."

The birds themselves do not seem to have found their way to England a century after the date of Bélon's works, for, in the Museum Tradescantium, the standard collection of the time, and which, from the list of contributors, appears to have been the great receptacle for all curiosities, we read under the division (No. 2) of Beaks or Heads, "Aracari of Brazil, his beak four inches long, almost two thick, like a Turke's sword" (A.D. 1656). But if the bird itself had not been brought forward, it is probable that Tradescant knew its nature, from the description above given. Petiver (Tab. xlv. f. 13) gives a figure of the bird complete, and though it bears all the marks of the imperfect state of the arts at that time, as far as engravings of subjects of natural history are concerned, it is substantially correct, and the arrangement of the toes right. The description is, 'Toucan Surinamensis niger, ex albo, flavo, rubroque mixta,' taken from a Dutch painting in Mr. Clark's collection: this does not exactly agree with any authors I have yet read. Willughby (Tab. xx.) gives a figure of a Toucan (*Ramphastos Toco*, probably) under the name of "the Brazilian Pie of Aldrovandus, the Toucan of Maregrave and others, the Xochitencatl of the Mexicans: Nieremb." The figure is incorrect about the feet, to which three anterior toes are given, though Willughby, who cites Thevetus, Faber, Dal Pozzo, Leri-us, Oviedo, and John de Laet, was evidently aware of the true organisation, namely two toes before and two behind.

Brisson placed the form in his 13th order, consisting of those birds which have four toes, two before and two behind.

Linnaeus arranged the Toucans (*Ramphastos*) at the head of the second division (*Pedibus scansoriis*) of his second order, *Picæ*.

Latham also assigned to them the same situation.

Laocépède places *Ramphastos* at the head of the second order (Bec Dentelé) of his Grimpeurs, or Climbers.

Duméril arranged the form at the head of the Levlrostres, or Céno-ramphes, the second family of his third order, Grimpeurs.

The *Scansores* form the first order in the method of Illiger, and *Ramphastos* and *Pteroglossus* appear at the head of the second family, *Serrati*.

In Cuvier's system the Toucans are arranged in his third order, Grimpeurs, between the Auis [CROTONHAGA] and the Parrots [PSITTACIDÆ].

The *Zygodactyli* are the first tribe of M. Vieillot's second order, *Sylviolæ*, and the Toucans are placed in the fourth family, *Pteroglosses*, between the Jacamars and Barbets.

M. Temminck arranges the form in the first family of his fifth order, *Zygodactyles*.

The *Grandirostres* form the fifth family of the Grimpeurs, the third order in the system of M. Latreille, and embrace the genera Toucan and Aracari, which are placed between the *Proglusses* (Wryneck, Woodpecker, &c.) and the *Galliformes* (*Mouquhaga*, *Touraco*).

The Toucans appear as the fifteenth family of the Nocturnal Birds of M. De Blainville, and are placed between *Buceros* and *Picus*.

In M. Lesson's 'Projet' the *Ramphastidæ* succeed the *Picidæ*, and are the last family of the first tribe of his *Insectores* or *Grimpeurs* (*Heterodactyles*).

The genera of the *Ramphastidæ*, according to Mr. Swainson, are—*Ramphastos*, *Pteroglossus*, *Aulacorhynchus*, and *Scythrops*.

Mr. G. R. Gray ('List of the Genera of Birds') makes the *Ramphastidæ*, the first family of the *Scansores*, with the following genera:—

Ramphastos, Linn. (*Pica*, Gesn., *Tucana*, Brisson).

Pteroglossus, Ill. (*Ramphastos*, Linn.).

Selenidera, Gould (*Ramphastos*, Linn.; *Pteroglossus*, Wagl.).

Aulacoromphus (*Ramphastos*, Linn.; *Pteroglossus*, Sw.; *Aulacorhynchus*, Gould).

Scythrops, Lath.

Mr. Gould, in his beautiful monograph of the *Ramphastidæ*, divides them into two great sections:—

1. Cauda brevior, quadrata; rostro maximo. Nigri, guttore caudæque tegminibus discoloribus. *Ramphastos*. (The Toucans.)

Of these Mr. Gould records 11 species, arranged in four subdivisions, according to the distribution of their colouring.

2. Cauda longior, graduata; rostro major. Viridescentes; capite, gastrico, tegminibusque caudæ superioribus in plurimis discoloribus. *Pteroglossus*. (The Araçaris.)

Of these Mr. Gould records 22 species, arranged in twelve subsections, also according to the distribution of their colouring.

The Toucans and Araçaris appear to be restricted in their geographical range to tropical America, and there they live retired in deep forests, mostly in small companies. Their flight is straight but laborious, and not graceful; while their movements, as they glide rather than hop from branch to branch, are elegant.

Mr. Vigors gives the following account of a Toucan (*Ramphastos Ariel*, Vig.), which he kept in a state of domestication for many years. After alluding to an account of an individual which ate animal food in domestication by Mr. Broderip, he says, "I have not allowed it to be indulged in that disposition to animal food which so strikingly belongs to this family. I find in fact that it thrives sufficiently well upon a vegetable diet; and I fear that if it should once be allowed any other, it would be difficult to restrain its inclination for it within moderate limits. Eggs are the only animal food with which it has been supplied since it came into my possession. Of these it is particularly fond, and they are generally mixed up in his ordinary food, which consists of bread, rice, potatoes, German paste, and similar substances. He delights in fruits of all kinds. During the period when these were fresh, he fed almost exclusively on them; and even in the present winter months he exhibits great gratification in being offered pieces of apples, oranges, or preserved fruits of any description. These he generally holds for a short time at the extremity of his bill, touching them with apparent delight with his slender and feathered tongue; and then conveying them by a sudden upward jerk to his throat where they are caught and instantly swallowed. His natural propensity to preying upon animals, although not indulged, is still strongly conspicuous. When another bird approaches his cage, or even a skin or preserved specimen is presented to him, he exhibits considerable excitement. He raises himself up, erects his feathers, and utters that 'hollow clattering sound' noticed by Mr. Broderip, which seems to be the usual expression of delight in these birds; the irides of his eyes at the same time expand, and he seems ready to dart upon his prey, if the bars of his cage permitted his approach. On one occasion, when a small bird was placed by chance over his cage at night, he showed great restlessness, as if aware of the neighbourhood of the bird; and he would not be composed until the cause of his anxiety was discovered and removed.

"When in his cage, he is peculiarly gentle and tractable, suffers himself to be played with, and feeds from the hand. Out of his cage, he is wild and timid. In general he is active and lively; and, contrary to what might be expected, from the apparent disproportion of the bill and the seemingly clumsy shape of the birds of this genus, as they are usually set up or represented in figures, his appearance is not only graceful, but his movements, as he glides from perch to perch, are light and sylph-like; so much so as to have suggested to an intelligent friend who witnessed them the specific name which I have ventured to assign him. He keeps himself in beautiful plumage, his lighter colours being strikingly vivid, and the deep black of his upper body in particular being always bright and glossy. For this fine condition he seems to be much indebted to his fondness for bathing. Every day he immerses himself in cold water with apparent pleasure, even in this severe weather; and in no respect indeed does he appear to suffer by the transition from his own warm climate to our uncongenial atmosphere.

"Besides the 'hollow clattering noise,' as my friend Mr. Broderip so expressively terms the usual sounds of these birds, he utters at times a hoarse and somewhat discordant cry when he happens to be hungry, and to see his food about to be presented to him. On such occasions he stands erect, raising his head in the air, and half opening his bill as he emits this cry. These are the only sounds I have heard him utter; and in neither can I say that I have detected any

similarity, or even approach, to the word Toucan, as has sometimes been asserted, and from whence the trivial name of the genus has been supposed to originate. Neither have I been able to verify another observation which has been advanced respecting these birds, that the bill is compressible between the fingers in the living bird. The bill, notwithstanding the lightness of its substance, is firm, and capable of grasping an object with much strength. The mode in which Mr. Broderip describes his Toucan as having broken the limbs of the bird which he was about to devour, by 'a strong lateral wrench,' sufficiently shows that the bill is not deficient in power. Indeed I generally observe that my bird takes what is offered him rather by the sides than by the point of his bill; and I suspect that much of the powers of that member are centred in this lateral motion. The serration of the edges also may be supposed to tend to these peculiar powers. The manner in which he composes himself to rest is represented in the accompanying plates. Since the cold weather has commenced, he has been brought into a room with a fire, and the unusual light seems to have interfered with his general habits; he does not go to rest as early or as regularly as was his custom; and he sometimes even feeds at a late hour. During the warmer months however, when he was more free from interruption, his habits were singularly regular. As the dusk of the evening approached, he finished his last meal for the day; took a few turns, as if for exercise after his meal, round the perches of his cage; and then settled on the highest perch, disposing himself, almost at the moment he alighted on it, in the posture represented, his head drawn in between his shoulders, and his tail turned vertically over his back.

Toucan at roost; first stage.

"In this posture he generally remained about two hours, in a state between sleeping and waking, his eyes for the most part closed, but opening on the slightest interruption. At such times he would allow himself to be handled, and would even take any favourite food that was offered him without altering his posture further than by a gentle turn of the head. He would also suffer his tail to be replaced by the hand in its natural downward posture, and would then immediately return it again to its vertical position. In these movements the tail seemed to turn as if on a hinge that was operated upon by a spring. At the end of about two hours he began gradually to turn his bill over his right shoulder, and to nestle it among the feathers of his back, sometimes concealing it completely within the plumage, at other times having a slight portion of the culmen exposed. At the same time he drooped the feathers of his wings and those of the thigh-coverts, so as to encompass the legs and feet; and thus nearly assuming the appearance of an oval ball of feathers, he secured himself against all exposure to cold."

All are now agreed that in a state of nature the *Ramphastidæ* are omnivorous.

The incubation of most if not all of this family takes place in the holes of trees, a habit that was very early known. We find Willughby, after quoting Faber for proof that in the structure of their feet, &c., the Toucans resemble the Woodpeckers, "to the genus whereof the toucan, as Faber in this place proves, doth undoubtedly belong," continuing thus:—"for it not only hath a like situation of toes, but also in like manner hews holes in trees to build its nest, as Fryer Peter

Alvaysa, and other Indians and Spaniards, who had long lived in America, told Faber for a certain truth; and Oviedus, in the forty-third chapter of his summary of the history of the West Indies, published in Italian, writes, adding that he thinks there is no bird secures her young ones better from the monkeys, which are very noisome to the young of most birds. For when she perceives the approach of those enemies, she so settles herself in her nest as to put her bill out at the hole, and gives the monkeys such a welcome therewith that they presently pack away, and glad they escape so. From this quality of boring the trees, this bird is by the Spaniards called 'carpintero,' and by the Brazilians 'tacataca,' in imitation, I suppose, of the sound it makes." The feathered structure of the tongue is also there noticed.

Toucan at roost; second stage.

Mr. Gould remarks that the true Toucans, unlike many of the *Araçarís*, offer no sexual difference in the colour of the plumage; but the females are rather less than the males in all their proportions. He adds that the young of both genera assume at a very early age the adult colouring; but that their large bills, as might be expected, are not fully developed for a considerable period.

The colours of the bill, which are generally very vivid during life, become, in many instances, greatly changed and deteriorated by death: this should be borne in mind by those who describe species from dead specimens, especially if they have been a long time preserved.

In the 'Monograph' by Mr. Gould, Professor Owen has given an account of the anatomy of these birds, of which we give the following summary.

Professor Owen remarks that the organs of digestion in the Toucan present a general simplicity of structure, which accords with its geographical position and power of assimilating both animal and vegetable food, so abundantly provided by nature in a tropical climate. The size of the oesophagus and general width of the intestinal canal correspond to the magnitude of the beak. There is no lateral dilatation of the crop, nor is the gizzard so encroached upon by its muscular parietes as to render such a reservoir for the alimentary substances necessary. The proventriculus communicates with the gizzard by a wide aperture. The muscular coat of the gizzard does not exceed half a line in thickness; the lateral tendons are small, but very distinct. The lining membrane is of a horny texture, and was stained of a deep yellow colour. The pyloric orifice is remarkably contrasted in its diminutive size with the ample entrance to the gizzard; a structure which facilitates the regurgitation of the alimentary substances. The description then goes on to state that as the regurgitated morsels have been observed to undergo a second mastication, the digestive processes exhibit in this bird an analogy to that of the Ruminants, and that as the thin parietes of the gizzard of this omnivorous bird are sometimes unequal to the comminution of the food, the utility of the extraordinary developed beak becomes apparent, which thus compensates by additional mastication for the absence of the grinding

structure so peculiar to the stomachs of the true vegetable-feeders. ('Cat. Mus. Coll. Chir.')

The length of the tongue, one of the most remarkable among birds, in a full grown *Ramphastos Toco* was six inches. The posterior ridge, or backward-projecting process, was broad and finely notched, and situated about four lines from the glottis. Anterior to this process, Mr. Owen describes the tongue as being soft and minutely papillose for the extent of four lines, and here he thinks most probably the sense of taste resides: the rest of the organ consists of a transparent horny lamina, flattened horizontally, and supported by the anterior process of the os hyoides, which forms a ridge along the middle of its inferior surface. At about four inches from the extremity of the horny lamina the margins become obliquely notched, and these notches, becoming deeper and closer together towards the extremity, occasion the bristled appearance on each side of the tongue: these bristles were applied to the food in the cases of the captive Toucans above recorded. The cornua of the os hyoides are one inch and a half in length.

Upper surface of Tongue of Toucan. (Owen.)

1, The fringed or feathered portion; m, orifice of larynx; n, orifice of pharynx; o, cornua of the os hyoides; p, trachea or windpipe; q, gullet.

Professor Owen observes that the osseous portions of the mandibles of the Toucan are disposed in a manner adapted to combine with the great bulk of those parts a due degree of strength and remarkable lightness, and the bony structure is consequently of a most beautiful and delicate kind. "The external parietes are extremely thin, especially in the upper beak: they are elastic and yield in a slight degree to moderate pressure, but present considerable resistance if a force is applied for the purpose of crushing the beak. At the points of the mandibles, the outer walls are nearly a line in thickness; at other parts in the upper beak they are much thinner, varying from 1-30th to 1-50th part of an inch, and in the lower beak are from 1-20th to 1-30th part of an inch in thickness. On making a longitudinal section of the upper mandible, its base is seen to include a conical cavity, about two inches in length and one inch in diameter, with the apex

A, Section of the cranium and upper mandible of *Ramphastos Toco*. a, The cancellated structure of the beak; b, the cavity at the base; c, branches of the fifth pair of nerves; d, external orifices of the nostrils; e, osseous parietes of the nasal passages; f, osseous tubes protecting the olfactory nerves; g, pituitary membrane exposed, and branches of the olfactory nerves radiating from it; h, superior semicircular canals of the internal ear; i, hemispheres of the cerebrum. (Owen.)

B, Vertical longitudinal section of the head. The same letters indicate the same parts as in the previous figure. k, cerebellum; l, the tongue; m, glottis; n, internal aperture of the nostrils; o, os hyoides; p, trachea; q, oesophagus; r, beginning of the spinal chord; s, articulating surface of occipital bone; t, nasal septum or partition; u, air-cell anterior to the orbit, from which the air passes into the mandible; v, cancellated structure of the lower jaw. (Owen.)

directed forwards. The walls of this cone consist of a most beautiful osseous network, intercepting irregular angular spaces, varying in diameter from half a line to two lines. From the parietes of this cone a network of bony fibres is continued to the outward parietes of the mandible, the fibres which immediately support the latter being

almost invariably implanted at right angles to the part in which they are inserted. The whole of the mandible anterior to the cone is occupied with a similar network, the meshes of which are largest in the centre of the beak, in consequence of the union which takes place between different small fibres as they pass from the circumference inwards. It is remarkable that the principle of the cylinder is introduced into this elaborate structure: the smallest of the supporting pillars of the mandibles are seen to be hollow or tubular, when examined with the microscope. The structure is the same in the lower mandible, but the fibres composing the network are in general stronger than those of the upper mandible." (Owen.)

Professor Owen states that the medullary membrane lining these cavities appears to have but a small degree of vascularity. Processes of the membrane, accompanying vessels and nerves, decussate the conical cavity at the base of the beak. The principal nerves are two branches of the fifth pair, which enter at the lower part of the conical cavity, and diverge and ascend as they pass forward to the end of the bill, giving off branches, which are distributed to the horny covering, and supply it with insensibility. "The air," says Professor Owen, "is admitted to the interior of the upper mandible from a cavity stunted anterior to the orbit, which communicates at its posterior part with the air-cell continued into the orbit, and at its anterior part, with the maxillary cavity. The nasal cavity is closed at every part, except at its external and internal apertures, by the pituitary membrane, and has no communication with the interior of the mandible."

Smell.—"The organ of smell is confined to the base of the upper jaw. The canal, which is traversed by the air and odorous particles in inspiration, forms a sigmoid curve in the vertical direction. The external orifice is on precisely the same perpendicular line as the internal one. It is situated at the posterior surface of the upper mandible, where it is raised above the level of the cranium; the orifice is consequently directed backwards, secure from all injury that might happen to it in the act of penetrating dense or interwoven foliage. The olfactory canal is at first of almost a cylindrical form, and about two lines in diameter. It passes forwards for about half an inch, receiving from the mesial aspect the projection of the first spongy bone; it then bends downwards and backwards, and is dilated to admit the projections of the two other spongy bones: from this point it descends vertically to the palate, at first contracted, and afterwards dilating to form the internal or posterior orifice. The first or outermost spongy bone is almost horizontal, and has its convexity outwards. The second is nearly vertically placed, with its convexity directed backwards: it terminates in a narrow point below. The third or superior spongy bone makes a small projection towards the mesial plans about the size of a pea. These spongy bones are formed by inward projections of the inner and posterior osseous parietes of the nasal passage: they are cellular, and air is continued into them from the cranial diaphragm; but the parietes of the nasal passage are entire and smooth, and lined by a delicate pituitary membrane. The inner table of the skull is continuous with the parietes of the nasal cavity, by means of the bony canal which accompanies and protects the olfactory nerves, and which represents, as it were, a single foramen of the cribriform plate of the *Mammalia*. The communication of the cavity of the cranium with that of the nose is thus similarly formed, and is only obstructed in the recent state by the pituitary membrane, on the posterior cul-de-sac of which the olfactory nerve distributes its branches in a radiated manner. These branches were confined, as Scarpa has observed in other birds, to the pituitary membrane covering the septum narium and the superior spongy bone."

Hearing.—"The external orifice of the meatus auditorius is situated about half an inch behind the lower boundary of the orbit. The membrana tympani closes it so obliquely that its plane is directed almost backwards; its anterior edge is consequently about three lines from the external orifice, while its posterior margin is at least six lines from the same point. It is convex outwardly, as in birds generally. The apparatus of the internal ear is easily exposed, the semicircular canals being lodged in a delicate reticulation of the diaphragm of the cranium. These parts, with the ossiculum of communication and the cochlea, do not present any deviations from the ordinary structure worthy of notice."

Sight.—The sense of sight in the *Ramphastidæ* appears to be sufficiently well developed, but requires no special observation.

Respiratory and Circulating System.—Mr. Owen found the trachea narrow and simple in its structure, the rings somewhat flattened, and decreasing in diameter towards the inferior extremity, from which a single pair of muscles passes off to the sternum. The length of the lower fourth of the tube, and the state of tension in the brouchia are regulated by a pair of small muscles, which, arising from the sides of the tracheal cartilages, are inserted into the bone of divarication at the extremity of the trachea; this part of the tube is subjected to variations in length, as is indicated by the tortuous character of the recurrent nerves attached to the sides of the trachea in this part. The lungs, small in proportion, are of the usual form and structure, and the abdominal air-cells are also small. The heart is more oblong than it is in birds generally; its apex, as it were, truncate; and its length one inch.

Urinary and Genital System.—The kidneys, composed of three

lobes, of which the middle one is smallest, are an inch and a half in length, with a surface convoluted, though in a less marked degree than it is in reptiles. Between the anterior extremities of these glands Mr. Owen found, in a female *Ramphastos Ariel*, the ovary of a triangular shape, and apparently healthy. The ova were like minute granules, and disposed in a convoluted manner. The supra-renal glands were imbedded in the posterior part of the ovary. The oviduct, of the size of a crow-quill, commenced by the usual fimbriated and wide aperture, was slightly tortuous at the commencement, and then continued straight to the cloaca.

Oseous and Muscular Systems.—Certain parts of this system bear upon peculiar functions performed by the Toucans, and are thus described by Professor Owen:—"The pectoral muscles as in the *Psittacidae*, are but feebly developed, and the keel of the sternum is of moderate size, not projecting more than half an inch from the plane of the bone. The sternum has four notches at its posterior margin. The clavicles, or lateral halves of the furcula, are here, as in the *Psittacidae* and *Struthionidae*, separate; they are an inch in length, slender, pointed at their lower ends, and joined to each other and to the sternum by a ligament only."

Foot of Toucan. a, Seen from below.

"The peculiar motions of the tail called for a particular examination of that part. It is difficult to state the precise number of the caudal vertebrae, in consequence of the terminal ones being ankylosed, requiring for this purpose the examination of a young specimen at a period before the ankylosis takes place. In the skeleton of a Black-Billed Toucan which I have examined, it would appear that three vertebrae are thus ankylosed, making the entire number of coccygeal vertebrae nine. The Woodpecker has also nine caudal vertebrae, and this seems to be the greatest number found in birds. The first six of these vertebrae in the Toucan are articulated by ball-and-socket joints, the ball and the socket being most distinct in the last two joints. That between the sixth and the ankylosed vertebrae is provided with a capsule and synovial fluid; the others have a yielding ligamentous mode of connection. The spinous processes of these vertebrae, both superior and inferior, are of moderate size, but smallest in the sixth, where the greatest degree of motion takes place. The transverse processes, on the contrary, are large and broad, so as almost wholly to prevent lateral motion. The first of the ankylosed vertebrae is broad and flat, and of a rounded form, supporting the two coccygeal glands: the last of these processes is compressed laterally, and of the ordinary ploughshare form. The caudal vertebrae can be inflected dorsad till their superior spines are brought into contact with the sacrum; in the opposite direction they can scarcely be bent beyond a straight line; and it is to this structure of the bones and joints that is to be attributed the capability in the Toucan of turning its tail upon its back (as represented in the 'Zoological Journal', vol. ii., pl. xv.), the muscles presenting comparatively few peculiarities, since the motion alluded to is remarkable rather for its extent than the vigour with which it is performed. The principal elevators of the tail are the sacro-coccygei superiores (sacro-suscaudiens of Vicq d'Azyr). They arise from two longitudinal ridges on the inferior and convex part of the sacrum, and are inserted into the superior spines of the first six vertebrae by detached tendons terminating broadly in the ankylosed vertebrae. The principal antagonists of these muscles, the sacro-coccygei inferiores (sacro-souscaudiens of Vicq d'Azyr), pass over the first five vertebrae, and terminate in the sixth and ankylosed vertebrae; their origins are wider apart than in the preceding pair of muscles, coming off from the margin of the sacro-sciatic notches. In the interval are situated small muscles passing from the transverse processes to the inferior spines of the first six vertebrae. From the limited nature of the lateral motions of the tail, the muscles appropriate to these movements are feeble, especially in comparison with those which are observed in the birds that spread their tail-feathers in flight, in order to regulate their course during that vigorous species of locomotion. These muscles are in number two on each side, arising from the posterior extremities of the ischium, and inserted into the expanded ankylosed vertebrae. From the disposition of these muscles it is obvious that after the proper eleva-

NAT. HIST. DIV. VOL. IV.

tors have raised the tail to a certain height, they also become dorsad of the centre of motion, combine their forces with the elevators, and by this addition of power terminate the act of throwing up the tail by a jerk. Mr. Vigors, in his observations on the living animal, observes, that 'in these movements the tail seemed to turn as if on a hinge that was operated on by a spring.' (Owen, in Gould's 'Ramphastidae'.)

We now proceed to give some examples of the Toucans and Araçarís.

Ramphastide.—Bill enormous, vascular within; the margins serrated. Wings short, rounded. Feet with two toes before and two behind. (Sw.)

Ramphastos.—Bill smooth. Nostrils entirely concealed, and placed at the edge of the thickened frontlet of the bill. Wings short, rounded; the four outer quills graduated and abruptly pointed. Tail short, rounded. (Sw.)

R. Toco appears to be one of the largest species, being 27 inches in total length. The bill measures $7\frac{1}{2}$ inches; the wings 10 inches; the tail, 7 inches; and the tarsi are 2 inches in length. A beautiful figure of the bird, by Lear, is given in Mr. Gould's magnificent work. The range of the species is very wide, perhaps wider than that of any other, being distributed throughout the whole of the wooded districts from the river Plata to Guyana.

R. Cuvieri. Beak brownish-black on the sides, with a large basal belt and culmen line of greenish-yellow, the basal belt being bounded behind by a narrow line of black, and before by a broader one of deep black, which is only apparent in certain lights; the top of the head and whole of the upper surface black, with the exception of the upper tail-coverts, which are bright orange-yellow; cheeks, throat, and chest white, with a tinge of greenish-yellow, terminated by a band of scarlet; under surface black; under tail-coverts scarlet. Total length 24 inches; bill, $7\frac{1}{2}$ inches; wings, 9 inches; tail $6\frac{1}{2}$ inches; tarsi, 2 inches. (Gould.)

This is a very rare bird and is found in the densely wooded districts on both sides of the Amazon.

Ramphastos Cuvieri. (Gould.)

Pteroglossus.—Bill smooth, less compressed; nostrils vertical, naked, round, pierced on the upper surface of the bill, on the edge of the frontlet. Wings short, rounded. Tail lengthened, graduated. (Sw.)

P. Humboldtii. Bill large in proportion to the body; a band of black occupies the culmen from the base to the tip; the remainder of the upper mandible of a dull yellowish-orange, with the exception of an indefinite mark of black which springs from each serrature, and a fine line of the same colour surrounding it near the base; lower mandible black, with the exception of the base, which is surrounded with pale yellowish-orange; the head, back of the neck, throat, and chest black; all the upper surface, except a spot of scarlet on the rump, of a dull olive; primaries blackish-brown; under surface pale straw-yellow with a slight tinge of green; thighs chestnut; naked space

Head of Araçari. (Gould.)

round the eyes and tarsi lead colour. Total length about 16 to 17 inches: bill 4, wing 5½, tail 6½, tarsi 1½ inches. (Gould.)

It is a native of Brazil, probably near the Amazon.

*Pteroglossus Humboldtii.* (Gould.)

P. pluricinctus. Male.—A broad band of black advances from the nostrils along the whole of the culmen, and forms a narrow belt down the sides of the upper mandible at its base; the elevated basal margin of the bill is yellow; the sides of the upper mandible beautiful orange-yellow, fading into yellowish-white towards the tip; under mandible wholly black with a yellow basal ridge; head, neck, and chest black; whole of the upper surface, except the rump, which is scarlet, dark olive-green; breast marked with two broad bands of black, the upper separated from the throat by an intervening space of yellow dashed with red; a similar but broader space separates the two bands of black, the lower of which is bounded by scarlet, advancing as far as the thighs, which are brownish-olive; under the tail-coverts light yellow; naked space round the eyes, tarsi, and feet, dark lead-colour.

The female differs from the male in having the ear-coverts brown,

and a narrow belt of scarlet bordering the black of the throat. Total length 20 inches: bill 4½, wings 6½, tail 8½ inches. (Gould.) It is a native of Brazil.

*Pteroglossus pluricinctus.*

Upper figure, female; lower, male. (Gould.)

RAMPHOSTOMA. [CROCODILIDÆ.]

RAMPION. [CAMPANULÆ.]

RAMSON, the common name of the *Allium ursinum*, a species of Garlic found wild in many parts of Great Britain, and formerly cultivated in gardens; but its use is superseded by the *Allium sativum*, a native of Sicily, which is the Garlic now in cultivation. [ALLIUM.]

RAMTILLA, a genus of Plants belonging to the natural order Compositæ and the sub-tribe Heliantheæ, so called from the Indian name Ram-Tilla, by which the oil of its seed is designated. The plant is remarkable for the number of names by which it has been described by botanists. Of these we need only mention the *Verbesina sativa* of Roxburgh, and the *Ramtilla oleifera* of De Candolle. Cassini had however previously formed it into a new genus, and, under the name of *Guizotia*, "dedicated it to the celebrated historian, then minister of public instruction." This name, being prior to that of *Ramtilla* by a year or two, is now retained as that of the genus. De Candolle, having obtained specimens and seeds from various countries, discovered that the Indian plant was identical with one from Abyssinia, which has been mentioned by Bruce under the name of *Pelymnia frondosa*. The fact is interesting in a plant cultivated in both countries for the same purposes, and forming one of the links which indicate the connection which existed in early times between India and Upper Egypt. This plant is cultivated in different parts of India, from October to March, in fields, for the sake of the seed, from which an oil is expressed, and used as a substitute for that of the *Sesamum*, which is considered the best kind. It is used both in dressing food and as a lamp oil.

RANA. [AMPHIBIA.]

RANDIA (named after Isaac Rand, M.D., once a demonstrator of botany at the Chelsea Botanic Gardens), a genus of Plants belonging to the natural order Rubiaceæ.

R. dumetorum, the Bush-Randia, is a thorny branching small shrub or tree, with oval leaves, rather blunt, cuneate at the base, and smooth. The flowers are very sweet-scented, sessile, solitary, mostly terminal; the calyx has oblong lobes, rather shorter than the villous corolla. The fruit is smooth, yellow, resembling a small crab-apple, firm and fleshy. The seeds are oval, numerous, and lying in mucus. The fruit when bruised and thrown into water intoxicates and even kills fish

having the same effect as the *Cocculus Indicus*, which is not however known in the East Indies, where this plant grows. In the form of powder it is a powerful emetic. An infusion of the bark of the root is employed to produce nausea in bowel complaints.

R. uliginosa, the Bog-Randia, has almost terminal opposite thorns, tetragonal branches, oblong leaves somewhat cuneate, glabrous. The flowers solitary, sessile, almost terminal. It is a native of the East Indies, in moist places. The flowers are large, white, and fragrant, and in twos or threes at the top of the branchlets. The berry is about the size of a pullet's egg, ash-coloured or olive-gray, and 2-celled. The seeds are flattish, nestling in the pulp. The flowers of this species render it deserving of a conspicuous place in the hot-house.

(Lindley, *Flora Medica*.)

RANELLA. [SIPHONOSTOMATA.]

RANGIFER. [CERVIDÆ.]

RANICEPS, a genus of Subbrachial Malacopterygious Fishes, belonging to the family *Gadidae*. It has the following characters:—Head depressed; body compressed; two dorsal fins, the first very small, the second dorsal and the anal fins elongated; ventral fins small, the first two rays lengthened and separated.

R. trifurcatus, the Lesser-Forked Beard, the Tadpole-Fish. Pennant describes two species of *Raniceps* as belonging to the British Fauna, *R. Jago* and *R. trifurcatus*. Dr. Johnston, of Berwick, was the first to suspect they might be the same fish; and Mr. Yarrell, after comparing Dr. Johnston's specimens with descriptions by Mr. Couch, of Cornwall, comes to the conclusion that the two species mentioned by Pennant are one and the same. It is a rare fish; but Mr. Thompson records a specimen as taken in Ireland, and Dr. Parnell describes it in his 'History of the Fishes of the Frith of Forth.'

(Yarrell, *History of British Fishes*.)

RANIDÆ. [AMPHIBIA.]

RANINIDÆ, a tribe of the family *Apterura*, belonging to the section of Anomomous Decapod Crustaceans.

This tribe, in its general form and in the conformation of its feet, approaches very closely to the *Hippidae*, and especially to the *Albuncæ*. [HIPPA.]

Ranina dentata.

a, seen from above; b, seen from below.

The carapace is convex laterally, nearly straight from before backwards, wide and truncated anteriorly, and gradually narrowed backwards. The ocular peduncles are lodged in the orbits, but are bent (coudés), and composed of three moveable pieces. The internal antennae have no fossæ, and are not capable of bending themselves back under the front; the external antennae are very short and very stout at their bases. The external jaw-feet are very much elongated, but not pediform, and behind their insertion the pterygostomial regions of the carapace unite themselves to the sternal plastron, without leaving any aperture for the entry of the water into the

branchial cavity. The sternal plastron is very large anteriorly, but becomes linear between the third or fourth last pair of feet. The anterior feet are very much compressed, and their immovable finger projects but very little, so that the moveable finger is bent back against the anterior border of the hand, nearly as in the subcheliform feet.

M. Milne-Edwards makes this tribe consist of three genera, thus characterised:—

Raninians having the sternal plastron.	Linear between the base of the feet of the second pair.	Carrying on the external border a great auriculiform prolongation.	} <i>Ranina</i> .
	Second joint of the external antennae very wide between the base of the second pair of feet, which are widely separated from the third pair.	not enlarged externally	
			} <i>Raninoides</i>

Ranina dentata may be taken as an example of the tribe. It inhabits the Indian Seas; Mauritius.

Rumphius states that it comes to land, and creeps even to the tops of houses.

Cancer dorsipes, figured by Rumphius, and confounded by most modern authors with *Raninoides levis* and *Albunea Symnista*, appears to belong to this genus.

In the neighbourhood of this tribe M. Milne-Edwards places *Eryon Caribensis* of Frémierville.

The fossil designated by Ranzani as *Ranina Aldrovandi* belongs, in the opinion of M. Milne-Edwards, to the tribe of Raninians, and may be referred to the genus *Ranina*.

RANUNCULACEÆ, *Crowfoots*, a natural order of Exogenous Plants. The species are herbs, rarely shrubs, with an acrid watery juice, and generally with much-divided exstipulate leaves, the petioles of which are dilated and sheathing; sepals 3 to 6, usually deciduous, sometimes deformed; petals 3 to 15, sometimes anomalous, at other times suppressed; stamens hypogynous; anthers adnate; carpels numerous, 1-celled, or united into a single many-celled pistil; ovary one- or more-seeded, the ovules sutural, styles simple; ovules anatropal; fruit either consisting of dry achenia, or baccate with one or more seeds, or follicular with one or two valves. Seeds albuminous, when solitary either erect or pendulous; embryo minute; albumen horny. The Buttercup or Crowfoot Family characterise a cold damp climate, and when met with in the tropics, they occur on the sides and summits of mountains. There are about a thousand known species, of which 1-5th is found in Europe and 1-7th in North America. The plants of this order have narcotic acrid properties, and are usually more or less poisonous. The acidity varies at different seasons, and in different parts of the plant; it is frequently volatilised by heat, and destroyed by drying. Some of the species are bitter and tonic. Dr. Wright remarks that notwithstanding the ancient reputation of this order as medicinal agents, nearly the whole have fallen into disuse, owing to the uncertainty of their action.

The illustrative genera are—*Aconitum*, which furnishes Aconite, or Monk's Hood. [ACONITUM.] *Clematis*. [CLEMATIS.] *Coptis*. [COPTIS.] *Delphinium*, the species of which are known as Larkspurs. [DELPHINIUM.] *Helleborus*, the Hellebore of the ancients, famed as a drastic purge. [HELLEBORUS; PEONIA.] *Nigella*. [NIGELLA.] *Ranunculus*, Crowfoot, or Buttercup, whence the order is named. [RANUNCULUS.] (Lindley, *Vegetable Kingdom*; Balfour, *Classbook of Botany*.)

RANUNCULUS (from 'rana,' a frog, because many of the species inhabit humid places frequented by that reptile), a genus of Plants, the type of the natural order *Ranunculaceæ*. It has 5 sepals, occasionally 10, with a nectariferous excavated scale at the base. The stamens and ovaries are numerous, the achenia ovate, somewhat compressed, mucronate, arranged on globose or cylindrical receptacles. The species are mostly acrid, and if applied when fresh to the skin will produce blisters; this quality is destroyed by drying or by heat.

R. aquatilis, Water-Crowfoot, has a floating stem and submersed leaves divided into numerous capillary segments spreading on all sides. The floating leaves are reniform, from 3- to 5-parted, the lobes wedge-shaped, toothed at the top, the petals obovate, larger than the calyx, the flowers white. It is a native throughout Europe, Western Asia, North Africa, and also in America and England, in pools and stagnant waters. It is the *Βαρύκλον τέτρατον* of Dioscorides, 2, 206. Sometimes it produces very large flowers, and makes a handsome show in ponds and ditches. The curious variety in the floating and immersed leaves adds greatly to its beauty. Dr. Pulteney contradicts the assertion of its deleterious qualities, and says that it is not merely harmless but nutritive to cattle, and tells us that on the borders of the Avon the cottagers support their cows and horses almost wholly on this plant. Hogs are also fed upon this plant, and appear to thrive on it, so that it seems we cannot class this species with others of the same genus as having poisonous qualities.

R. flammula, Flame-Crowfoot, is a smooth plant with a rooting decumbent stem, branched, leafy, and hollow, sometimes hairy near the top. The leaves are on flat channelled half-sheathing stalks, alternate, usually ovate, lanceolate, but varying much in breadth often serrated. The flowers are terminal, opposite the leaves, and α'

a bright yellow colour. The leaves are vesicant. Dr. Withering recommends the distilled water as an instantaneous emetic in cases of poison. Lightfoot says the bruised leaves are used to raise blisters in the Isle of Skye and the Highlands of Scotland. It is a native of Europe, Asia, North America, and Great Britain.

R. glacialis has stalked radical leaves, palmated and trifid, the lobes rather blunt and thick; the stem generally 1-flowered; the calyx very hairy, the carpels compressed and sharp-edged; the petals white. It is a native of the higher Alps of Europe, among rocks, near the limits of perpetual snow, and of Lapland and Iceland. The mountaineers of Dauphiny call this Carlive or Caraline, and employ an infusion of it in hot water as a powerful sudorific in colds and rheumatism.

R. acris, Buttercup, has a fibrous root, the stem about two feet high, erect, round, hollow, leafy, clothed with close-pressed hairs, branched above and many flowered. The radical leaves are on long upright footstalks, in 3 or 5 deep lobes, the stem-leaves are nearly sessile, with fewer and narrower segments, the uppermost much smaller, in 3 linear entire lobes, or sometimes simple and linear. The flowers are of a bright yellow, on round even stalks covered with close hairs and not furrowed. The calyx is hairy, spreading, and deciduous; the carpels smooth, lenticular, with a slightly curved point. This species is extremely acrid and dangerous. Mr. Curtis says that even pulling up the plant and carrying it to some little distance has produced inflammation in the hand. Cattle in general will not eat it, but sometimes when they have been turned hungry into a field they have fed upon it, and in consequence their mouths have become sore and blistered. According to Linnaeus sheep and goats eat it, but cows, horses, and swine refuse it. When made into hay however, its noxious qualities are lost. It is commonly called Buttercup, under a notion that the yellow colour of butter is owing to these plants. A double variety of this species is cultivated in gardens under the name of Bachelor's Button.

R. sceleratus, Celery-Leaved Crowfoot, has a fibrous root, the radical leaves with 3 stalked trifid and cut leaflets, furrowed peduncles and reflexed calyx, the heads of the fruit oblong, the carpels minute and wrinkled. The flowers very small and pale yellow, numerous, on solitary stalks, either terminal, axillary, or opposite the leaves. The bruised leaves raise blisters on the skin, which are not soon healed, and are said to be used by impostors to cause ulcers on their bodies, and thus excite compassion. It is one of the most virulent of our poisonous indigenous plants. The distilled water of this species is highly acriminous, and when cold deposits crystals which are scarcely soluble, and are of an inflammable nature. The deleterious qualities are however dispelled in decoction, and accordingly the shepherds of Wallachia boil and eat it.

R. Thira has an extremely acrid and poisonous root, and is native of the Alps of Europe. It is said to yield the juice formerly used by the Swiss hunters to poison their darts; wounds so produced speedily become fatal.

R. scaria, Pilewort, has a root with fasciculated tubers, cordate stalked leaves, angular, or crenate, or leafy; single flowered stem, usually three sepals, and smooth blunt carpels. The flowers are golden yellow, and it is a native throughout the whole of Europe in meadows, hushy places, and about hedge-banks; it is plentiful in Britain. The young leaves of this plant, according to Linnaeus, are used as greens in Sweden. A notion that the root is efficacious in the cure of piles gives it its common English name. We usually find the flower closed from five to nine in the evening, and in wet weather. It is the *Χελιδόνιον* of Theophrastus, 'Hist. Plant.' 7. 14, and the *Χελιδόνιον μικρόν* of Dioscorides, 2. 212, and of Pliny, 'Hist. Nat.' 258.

R. arvensis, Corn-Crowfoot, has a fibrous root, the radical leaves 3-cleft, dentate, the stem-leaves once or twice ternate, with linear lanceolate segments, the calyx erecto-patent, the carpels margined, beaked, and spinous; the flowers are pale yellow. It is native throughout Europe, and is also found in North America. It is very acrid and dangerous to cattle, though they are said to eat it greedily.

M. Brugnon, who has given a particular account of its qualities, relates that three ounces of the juice killed a dog in four minutes. Several sheep were killed by eating this herb at Turin, which first led to an investigation of the matter.

R. bulbosus, like others of the genus, is extremely acrid, and raises blisters and produces extensive inflammation of the skin. Gilbert states that it vesicates with less pain than cantharides and without affecting the urinary passages.

R. Asiaticus, Common Garden Ranunculus, has ternate or triternate leaves, the segments toothed or deeply trifid, the stem erect, simple, or branched at the base, the calyx spreading, afterwards reflexed, the spikes of the carpels cylindrical. It is a native of the Levant, and is referred to by Dioscorides, 2. 206. Three varieties of this favourite plant in our gardens have been described, which some have regarded as species:—1. *R. A. vulgaris*, with the stem branched at the bottom, the leaves ternate, the segments trifid, cut, acute. The flowers of this variety are generally formed double, and have all colours except blue. It is called the Persian Ranunculus. 2. *R. A. sanguineus*, with a simple stem, ternate leaves, and obtuse toothed segments. The flowers are orange or yellow. This is called the Turkey Ranunculus. 3. *R. A. tenuilobus*, with a somewhat branched stem, and multifid leaves with

linear acuto lobes. It is a native of the island of Cyprus, and has white or yellow or purple flowers.

The *R. lanuginosus* of Linnaeus is the *Βαρπάχιον ἔρερον χλωδίστερον* of Dioscorides, loc. cit. The *R. muricatus*, Linn., is the *Βαρπάχιον ῥιπτόν* of Dioscorides, loc. cit.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*; Fraas, *Synopsis Florae Classicae Plantarum*; Burnett, *Outlines of Botany*.)

RAPA. [BRASSICA.]

RAPA'CES. [RAPTORES.]

RAPE. This plant, which is of the Cabbage Tribe, is cultivated like cole, or colza, for the sake of its seeds, from which oil is extracted by grinding and pressure. It is also extensively cultivated in England for the succulent food which its thick and fleshy stem and leaves supply to sheep when other fodder is scarce. [RAPE, in ARTS AND SC. DIV.; BRASSICA.]

RAPHANUS, a genus of Plants belonging to the natural order *Cruciferae*. It is mostly remarkable for containing the common radish, *Raphanus sativus*. This plant, a native of China, has been cultivated in this country for upwards of 250 years, and has given rise to numerous varieties, which are divided into long-rooted or spindle-shaped, and round or turnip-rooted. They are also denominated spring, summer, autumn, or winter radishes, according to the season in which the respective sorts are found best adapted for use. [RADISH, in ARTS AND SC. DIV.]

R. Raphanistrum, Jointed-Charlock, is a British species. It has moniliform pods, striated, shorter than the very long beak, the leaves simply lyrate. The petals are veined white and lilac. It is a native of corn-fields.

R. maritimus, Sea-Radish. It has moniliform striated pods, longer than the beak; the radical leaves are interruptedly pinnate. The petals are yellow. It is a rare inhabitant of the sea-coasts of Britain.

RAPHIOSAURUS, a genus of Fossil Reptiles from the lower parts of the Cretaceous System. (Owen.)

RAPHUS, Brisson's name for the Dodo. [DODO.]

RAPTATORES, Illiger's name for his third order of Birds, comprehending the Birds of Prey.

His *Raptatores* consist of the following families and genera:—

NOCTURNI.—*Strix*.

ACCIPITRINI.—*Falco*, *Gypogeras*, *Gypætus*.

VULTURINI.—*Vultur*, *Cathartes*.

This order is placed by Illiger between the *Ambulatores* and *Rasores*.

The *Accipitres*, Linnaeus's first order, include the genera *Vultur*, *Falco*, *Strix*, and *Lanius*.

RAPTORES, the name assigned by Mr. Vigors to the Birds of Prey. [RAPTATOIRES.]

The *Raptatores* of Mr. Vigors form his first order, and the following families are arranged by him under it:—VULTURIDÆ, FALCONIDÆ, STRIGIDÆ, *Gypogerasidæ* (1).

The *Raptatores* of Mr. Swainson comprise the families of *Vulturidæ*, *Falconidæ*, and *Strigidæ*.

Mr. G. R. Gray also makes the *Raptatores* consist of the families *Vulturidæ*, *Falconidæ*, and *Strigidæ*.

RARA. [MUSOPHAGIDÆ.]

RASORES. The *Rasores* of Illiger contained the following families and genera:—

GALLINACEI.—*Numida*, *Meleagris*, *Penelope*, *Crax*, *Opisthocomus*, *Pavo*, *Phasianus*, *Gallus*, *Menura*, *Tetrao*, and *Perdix*.

EVOLUCATIL.—*Ortyx* (Turnix), *Syrhaptes*.

COLUMBINI.—*Columba*.

CRYPTURI.—*Crypturus* (*Tinamus*, *Lathau*).

ISEPTI.—*Didus*.

The order, which is the fourth in Illiger's method, is placed between the *Raptatores* and *Cursores*.

The order *Gallinæ* of Linnaeus was placed between the *Grallæ* and the *Passeres*, *Struthio* being the last genus of the former, and *Columba* the first of the latter order.

The genera of *Gallinæ* are *Didus*, *Pavo*, *Meleagris*, *Crax*, *Phasianus*, *Numida*, and *Tetrao*.

The *Rasores* of Mr. Vigors consist of the families *Columbidæ*, *Phasianidæ*, *Tetraonidæ*, *Struthionidæ*, and *Cracidæ*.

The *Rasores* of Mr. Swainson comprehend the families *Paronidæ*, *Tetraonidæ*, *Struthionidæ*, *Columbidæ*, and *Megapodidæ*.

The *Rasores* of Mr. G. R. Gray embrace the families *Cracidæ*, *Phasianidæ*, *Tetraonidæ*, *Chionidæ*, and *Tinamidæ*.

RASPBERRY. [RUBUS; RASPBERRY, in ARTS AND SC. DIV.]

RAT. [MURIDÆ.]

RATANY, RHATANY, or RATANHIA. [KRAMERIA.]

RATARIA. [ACALEPHÆ.]

RATEL. [URSIDÆ.]

RATTLE, RED. [PEDICULARIS.]

RATTLE, YELLOW. [RUINANTHUS.]

RATTLESNAKE. [CROTALIDÆ.]

RATTLESNAKE-FERN. [BOTRYCHIUM.]

RATTLESNAKE-WEED. [ERRINGIUM.]

RAUCHWACKE (in Geology), one of the calcareous members of the Zechstein Formation of Germany, the equivalent of the Magnesian Limestone Formation in England. It is either compact, cellular, or dolomitic. Associated with gypsum and with beds called stinkstein,

asche, zechstein, and kupferschiefer, it makes a series of five terms which may be classed and arranged in comparison with English types and names. This is done by Von Meyer, after Sedgwick, thus:—

German.	English.
Asche (friable marl), and Stinkstein (thin-bedded fetid limestone).	Thin-bedded limestone of Knottingley.
Rauchwacke (limestone).	Coloured marls and gypsum.
Zechstein (limestone).	Yellow magnesian limestone.
Kupferschiefer (copper-slate).	Compact limestone.
	Marl-slate.

We may perhaps prefer to view the asche, stinkstein, and rauchwacke, as altogether only one feeble upper group comparable with the upper laminated and cellular limestones of Knottingley, and the zechstein as equivalent to our yellow magnesian limestone, in which case the Kupferschiefer is on the parallel of our marl-slate. These formations contain the remains of the genus of fishes named *Palæoniscus*.

RAVEN, the common name of the *Corvus Corax*. We subjoin a cut of the head and foot of this species omitted in the article CORVIDE, where an account of this bird is given.

Head and Foot of Raven.

RAYED or RADIATE ANIMALS, RADIATA, a class of Invertebrate Animals. It embraces the orders *Echinodermata* [ECHINODERMATA], *Acalephæ* [ACALEPHÆ], *Entozoa* [ENTOZOA], *Polypifera* [POLYPIFERA], *Porifera* [SPONGIÆ], and *Infusoria* [INFUSORIA]. It has the following characters:—The nervous system when present is without ganglia, and is composed of single filaments, which are disposed in a circular form around the buccal orifice. The organs of the body are arranged in a radiate manner around the digestive cavity. The organs of digestion consist of a single sac or short alimentary canal. The animals are mostly aquatic, breathing by gills, and usually free. Professor Owen in 1835 proposed a binary arrangement of these animals, according as the nervous system was filamentous or altogether absent. He observed that in those *Radiata* of Cuvier in which the nervous system could be most unequivocally traced in a filamentary form, likewise presented an alimentary canal suspended in a distinct abdominal cavity, and with a very few exceptions, provided with a distinct outlet. The nerves were accompanied with a corresponding development of the muscular system. The following is Professor Owen's plan:—

Sub-Kingdom RADIATA.

Nematoneura.

Acrita.

Class Radiaria, Lamarck.

Echinoderma, Cuv.

Acalephæ, Cuv.

Class Polypi, Cuv.

Ciliobrachiata, Farre; *Anthozoa*, Ehr.; *Nudibrachiata*, Farre.

Class Entozoa, Rudolph.

Cesteminta, Owen.

Sterceminta, Owen.

Class Infusoria, Cuv.

Rotifera, Ehr.

Polygastria, Ehr.

Some of the animals thus placed amongst the *Radiata* are removed by other naturalists. Thus the *Ciliobrachiata* of Farre are now frequently referred to the *Mollusca* [MOLLUSCA], and the *Rotifera* to the *Articulata*.

(Owen, *Lectures on Comparative Anatomy*.)

RAZOR-BILL. [AUK.]

RAZOR-FISH. [PYLORIDIA.]

REALGAR. [ARSENIC.]

REAUMURIACEÆ, *Reaumuriads*, a natural order of Plants belonging to the Exogenous class. It has a 5-parted calyx, surrounded externally by imbricated bracts; 5 petals, hypogynous, unequal-sided, sometimes having a pair of membranous plates planted upon their middle; definite or indefinite, hypogynous, monadelphous, or polyadelphous stamens, with or without a hypogynous disc; the anthers ovate, turned inwards, and bursting longitudinally; 2-4-5 carpels, partially separate from each other, surrounding a central placenta which passes into the base of each; 2 or 4 ascending anatropal ovules, with filiform or subulate styles; a capsular fruit with 2 to 5 valves and as many cells, unless the number is diminished by abortion; shaggy definite erect seeds, with a straight embryo surrounded by a small quantity of mealy albumen, and the radicle next the hilum. The species of this order are small shrubs, with fleshy scale-like leaves, which are alternate and have no stipules, and are overspread by resinous sunk glands.

This little order consists of three genera, *Reaumuria*, *Hololachna*, and *Eichwaldia*, which were formerly referred to *Tamaricaceæ*; they have however but little affinity with that order. Their true affinities seem to be with *Hypericaceæ*, near to which Lindley has placed them. The species are generally natives of the coast of the Mediterranean, and of salt plains in the milder parts of Northern Asia.

The genus *Reaumuria* was named by Haselquist in honour of René Antoine Ferchault de Reaumur. It has a 5-parted involucre calyx; 5 petals, permanent, furnished at the base on each side with a ciliated appendage; numerous pentadelphous stamens; 5-6 stigmas; a 5-valved 5-celled capsule, with valves easily separating from the septa, and shaggy seeds.

R. vermiculata has subulate semi-terete imbricated leaves, crowded on the branches. It is a native of Sicily, Bombay, and Egypt. This plant resembles *Salsola frutescens*. It is used at Alexandria as a remedy for the itch, being bruised and applied externally, and a decoction taken internally.

R. hypericoides has lanceolate flat rather remote leaves. It is a native of Syria and Persia. These plants are elegant little shrubs of easy culture, which thrive well in a mixture of sandy loam and peat; and young cuttings will grow freely in sand under a hand-glass.

Hololachna (from *ἅλος*, 'entire,' and *λῆχνη*, 'wool,' or 'thick hair') has a 4-5-parted calyx; 4-5-petals; 8-10 hypogynous monadelphous stamens inserted into an hypogynous gland; 2-4 short subulate styles; the capsule 2-4-angled, 2-4-valved, 2-4-celled; the seeds few, large, surface shaggy. The only species is *H. Songarica*, found by Ehrenberg in the Soongarian desert of Siberia. In cultivation this plant requires to be watered with salt-water. All the plants of this order abound in saline matter in their tissues.

(Lindley, *Vegetable Kingdom*; Don, *Dichlamydeous Plants*; Lindley *Flora Medica*.)

RECEPTACLE, in Botany, is that part of the flower on which any of the other organs rest. It represents the internodes of the stem and branches in their changed condition. It assumes a variety of forms, and enters very variously into the forms of flowers and fruits. [FLOWER; CALATHIDIUM; FRUIT.]

RECEPTACULITES, a genus of Fossils proposed by Defraunce synonymous with *Ischadites* of Murchison.

RECURVIROSTRA. [AVOSET.]

RED-BREAST. [ERYTHACA.]

RED-DEER. [CERVIDE.]

RED-EYE. [LEUCISCUS.]

RED LEAD. [LEAD.]

RED MARL. An argillaceous red portion of the series of rocks between the Coal and Lias is thus termed in geology. Almost identical marls, similarly associated with red-sandstones, lie also in the upper part of the coal, and below the coal and mountain limestone. Nor would it be always easy to distinguish in specimens, or even in sections on a large scale, the upper red marls immediately below the lias of the Trent or the Avon from the red marls above the uo-magnesian limestone of Knottingley, those above the magnesian limestone of Pontefract, those below the same limestone near Wetherby, those in the upper part of the coal formation of Manchester, or below the whole of the coal and mountain limestone in Monmouthshire.

RED-SANDSTONE FORMATION. In geology the term Red-Sandstone is used in a variety of senses, partly with reference to the mere colour of certain rocks, and partly as expressing rocks of certain geological periods. Thus we have in the latter sense New Red-Sandstone, Lower Red-Sandstone, and Old Red-Sandstone; and on the continent, Alter Rother Sandstein, Neuer Rother Sandstein, le Vieux Gres Rouge, le Nouveau Gres Rouge, &c. The Red-Sandstone also means, in some geological works, either the upper part or the whole system of the rocks, calcareous, argillaceous, and arenaceous, which occurs in the series of strata between the coal formation and the lias. If we

regard the analogy of the geological nomenclature most generally used, this latter sense will appear too inconvenient to be adopted; as substitutes we have the *Pæcilitio* System, from the various colours of the component masses; and the *Saliferous* System, from its frequently containing salt.

Sandstones or Gritstones, generally speaking, consist of abraded and worn pieces of quartz, felspar, mica, and other minerals, such as commonly occur in granite, gneiss, or mica-schist, and other rocks associated with these. The size of these pieces is sometimes such as cause the mass to deserve the title of conglomerate (as part of the millstone-grit of Derbyshire), and sometimes the grains are so fine and confluent, that the mass is not unlike some sorts of quartz rock (as the ganister of the Yorkshire coal-field). In regard to induration, there is every degree from uncoherent sand, through friable and argillaceous sandstones, to compact grits and indurated quartzose rocks. In colours they admit of every shade from whiteness, through gray tints by carbonaceous admixture, through yellow and brown hues by admixture of carbonate and oxide of iron, and through reds, blues, and purples of different kinds by diffusion of oxides of iron, manganese, &c.

In this most complex series of detrital deposits, red-sandstones present some remarkable characters when regarded as to the nature and diffusion of red colour, the association of this with other tints, the relation of their hues to organic life, and to other geological phenomena.

Red sandstones occur in the basin of the Allier in France, in tertiary strata; in the plastic clay group of the Isle of Wight; generally in the strata below the lias and above the coal; in the upper parts of the coal formation of Derbyshire and Lancashire; in the millstone-grit series of Lancashire; in the mountain limestone of the north of England; generally in the strata called old red-sandstone, above the strata of the Silurian districts; in the midst of the green and purple slates of north and south Devon; in the midst of older rocks in the Lammernuir, Cavan, and Longmynd ridges; but the most perfect and abundant types are in those parts of the series which lie above and below the carboniferous rocks, and constitute the New and Old Red-Sandstone groups.

The essential peculiarity of these reddened rocks is apparently a general diffusion in their mass, and especially round their constituent grains of quartz, of red peroxide of iron (with also often some oxide of manganese). If by means of muriatic acid the iron be removed from the red-sandstone of Manchester, what remains is a mass of mostly white and even translucent quartz grains, which had been invaded by the red oxide of iron. Singularly enough, amidst a great series of such red-sandstones and red-clays, nothing is more common and even characteristic than to find oval, round, or irregular patches of light-green colours, apparently due to the protoxide of the same metal. Nor is it at all rare to find perfectly white bands alternating with red or green stripes; and this applies almost equally to the sandstones, clays, gypsum-bands, and salt layers.

A very remarkable and general fact observed in studying these red rocks is the paucity of the remains of animals of every grade.

The explanation of this fact, which seems most probable, is that water in which by any cause abundance of peroxide of iron has been diffused, is rendered thereby unsuitable for the due performance of the vital functions of aquatic creatures, especially such as take the water into their bodies for respiration, or are nourished by the flowing of currents to the mouth.

The last point on which it seems here necessary to remark is the frequent concurrence of red-sandstones and clays, fibrous and lamellar gypsum, fibrous and lamellar rock salt. Most of the rock-salt, of Europe at least, is associated with red earthy deposits; but there are great exceptions, as at Salzburg and Wieliczka. This frequent concurrence will be found of great importance in reasoning on the physical agencies whereby the peculiarities of red-sandstones were occasioned.

As building materials, few of the red-sandstones are to be recommended, and even the white layers which accompany them are seldom of much value. The cathedrals of Carlisle and Chester, and the noble old churches of Coventry, offer a striking warning to the architect; though on the other hand, part of the ancient wall of Penrith Castle, still standing and in good preservation, shows that even among these justly suspected strata, some portions, either by their freedom from salt, or some other cause, are to be excepted from censure.

The term Red-Sandstone is more especially applied to two formations, the Old Red Sandstone, or Devonian (OLD RED-SANDSTONE), and the New Red-Sandstone Rocks. The latter are also sometimes called *Saliferous*, on account of the salt they contain, and they are also called *Triassic*.

"It is in Cheshire and the southern part of Lancashire, and the northern part of Shropshire, which together form an extensive and rich plain, watered by the Drie, the Mersey, and the Weaver, that the uppermost beds of the New Red-Sandstone are chiefly developed; and by a minute examination of these beds, and those of Warwickshire, the *saliferous* marls have been identified with the uppermost strata of the foreign Triassic System. Throughout this range the beds are nearly horizontal, the dip rarely exceeding ten or twelve degrees, and being

constantly towards the east, or a few degrees north or south of that point. They are however affected by some important faults. The whole district abounds with salt-springs, which are more especially plentiful in Cheshire; and in that county also there occur extensive masses of rock-salt in a solid state, their total thickness amounting to not less than sixty feet. These alternate with beds of gypsum; with numerous bands of indurated clay of a blue, red, or brown colour; and with sandstones, frequently marly, and of a red colour.

"The red-marl district, with brine springs, is continued southward into Worcestershire, and northward into the valley of the Ideu, and the same part of the formation extends also eastward, occupying for the most part the plains through which the Humber and its tributaries make their way to the German Ocean. In Somersetshire and Devonshire similar sandstones recur, and lie unconformably, overlapping the inclined edges of the older rocks, or abutting against them, but uniformly composed of the same materials, remarkable throughout for the ochraceous colour pervading them. Between Sidmouth and Seaton, in Devonshire, the red marls contain gypsum in abundance; and near Teignmouth the cliffs, which are of considerable height, consist of alternations of argillaceous beds of sandstone and of conglomerate.

"The beds which are lowest in position of the upper new red-sandstone are chiefly found in the middle of England, and consist of thick masses of whitish soft sandstone. In some places (as in Staffordshire) these are surmounted by conglomerates, composed of rounded pebbles of quartz rock, and other fragments, chiefly of Silurian rocks and old red-sandstone. The total thickness of this part of the formation is considerable, but has not been accurately calculated. It is only to be distinguished from the overlying *saliferous* marls by small differences of mineral character." (Ansted.)

Viewed on the great scale, the New Red-Sandstone system of rocks is one of the most varied and interesting we are acquainted with. There are peculiarities in its limestones, sandstones, and clays, as well as in its gypseous and salt deposits; the occurrence and nature of its organic contents, and the relation which it bears altogether to earlier and later classes of rocks, are worthy of careful study.

Sulphate of lime is found perhaps as frequently and under almost as many curious circumstances in the stratified rocks, as carbonate of lime, in menly aggregations, acicular prisms, broadly foliated crystals (selenite), fibrous masses and beds, and marmoroid or alabasterine rocks. It lies in strata of almost every age, and is not absent from diluvial, alluvial, and recent deposits. The mode of its occurrence is in a considerable degree characteristic of each particular mineral type. While long prismatic crystals appear in cavities of shells and in recent excavations (as in the gallery of Felling Colliery, Newcastle), the solitary broad flaky crystals of selenites abound in blue-clays of the tertiary and secondary series (which receive their colour from protoxide of iron), and the fibrous gypsum marks, spots, and irregular lines in the red-clays (coloured by peroxide) of the *Saliferous* system, the fibres being (in agreement with a general law of structures) arranged so as to lie at right angles to the broader surfaces which bound the mass. The marmoroid texture is most commonly found in real however irregular beds, as at Montmartre, and in some points near Fairburn in Yorkshire, on the line of the York and North-Midland railway. At these places fibrous, marmoroid, and flaky sulphate of lime may be obtained in association.

From what is known to take place at the present day, and from appearances in the distribution of the gypsum and selenite in masses of clay and cavities of shells, &c., it appears that in a great proportion of cases these crystallised masses owe their origin to the processes of segregation since the deposition of the earthy masses in which they appear. In no other way is it at all conceivable or even possible that the irregular masses of gypsum which appear in red-marl at Axmouth, Aust Passage, and the Trent's mouth could be formed. The marls in which they here lie were deposited as fine mud, and if we suppose merely a slow extrication of the liquid, so that its contained salts might remain, the arrangement of these salts in such irregular masses during crystallisation presents no particular difficulty.

Salt shows itself in the Cheshire mines as either granular, broadly laminated, or fibrous; in great beds or minutely mixed with marls, nearly as gypsum is, and probably in regard to its origin, similar suppositions will apply, the solid beds (of limited extent however and irregular area) being due to a great evaporation of liquid over the previously-deposited marls. That such water, in the case of rock-salt generally, was derived from the sea, is almost certain, from the occurrence of iodine and bromine in the brine-springs connected with them. (Daubeny's Memoir in 'Phil. Trans.'). But it does not follow that the area in which the salt was found was, at the time of its formation, or for some time previously or subsequently, connected with the sea. Lagoons may have been the theatre of the evaporation supposed, and earthy sediments, such as occur in Cheshire and Poland, may have been drifted in by fresh-waters or the sea, according to circumstances, and it is not difficult to imagine a repetition of the processes, such as might produce the two great beds of rock-salt in Cheshire. It is not known that organic remains of any kind accompany the salt of Cheshire, but this is almost true of the whole range of the red-marls, in which these deposits lie.

We find, then, associated together, abundance of red-oxide of iron

salt, and gypsum, but few or no organic remains. The prevalence of red-oxide of iron in any of the strata is accompanied by a paucity or total absence of organic remains. In the new red-sandstone these red strata extend through several hundred feet of thickness, and it is found in general terms, that the types of organic life above and below are widely different. Similarly the thick series of old red-sandstone contains few organic fossils, and separates two distinct groups of these productions. Some great physical changes then must be supposed to have occurred previous to and during the saliferous period, and to have influenced both chemical and vital phenomena.

M. Adolphe Brongniart ('Prodrome d'une Histoire des Végétaux Fossiles,' 1829), viewing the series of fossil plants, gives four great periods of ancient vegetation:—The first extending from the earliest strata to the new red-sandstone strata; the second including these strata; the third including the oolites and chalk; the fourth the tertiary strata. Of these the flora of the second period (chiefly terrestrial) is very limited, and may be looked upon as a transition group of plants connecting the earlier and later periods. Similarly the series of marine *Invertebrata* which lie in the new red-sandstone have characters intermediate between the early (palæozoic) and later races of pre-adamitic life.

Although the fossils of this rock are but few, they are highly interesting. It is amongst these rocks that we find the first traces of an air-breathing animal. This creature, which was at first called *Chirothemum*, is now known under the name of *Labyrinthodon*. It belongs to the amphibious tribe of Reptiles. [AMPHIBIA.] Footmarks of an extinct reptile have also been found in the red-sandstone of America, and described by Dr. Lea. [SAUROPS.]

The equivalents of the British beds of new red-sandstone on the continent of Europe are—the Kauper Marls, or Marres irisées, the Muschelkalk, and the Bunter Sandstein, or Grès Bigarre, of Germany and France.

RED SNOW. [SNOW, RED.]

REDPOLE. [LINOTA.]

REDSTART. [SYLVIAE.]

RED-WING. [MERULIDE.]

REED. [PHRAGMITES.]

REED, SEA. [PSAMMA.]

REED-BUNTING. [EMBERIZIDE.]

REED-BUR. [SPARGANIUM.]

REED-MACE. [TYPHA.]

REED-WARBLER. [SALICARIA.]

REED-WREN. [SALICARIA.]

REGENIA. [MONITORIDE.]

REGULUS. [COCCATRICE.]

REGULUS, a genus of Birds belonging to the family *Sylviade*.

The genus is thus defined by Mr. Yarrell:—Beak slender, straight, the edges dilated at the base, compressed towards the point; nostrils basal, lateral, oval, partly covered by small feathers directed forwards. Wings of moderate length; the first quill-feather very short; the second shorter than the third; the fourth or fifth the longest in the wing. Legs rather slender; feet with three toes before, one behind; the outer too joined at its base to the middle toe; claws curved and sharp. There are three British species of this genus.

R. cristatus, the Golden-Crested Regulus, Golden-Crested Warbler, or Kinglet.

R. ignicapillus, the Fire-Crested Regulus, Fire-Crested Wren.

R. modestus, the Dalmatian Regulus. This is a very rare species.

There are three other species natives of North America.

(Yarrell, *British Birds*.)

REH BOC. [CERVIDE.]

REIN-DEER. [CERVIDE.]

REIN-DEER MOSS. [CLADONIA.]

REMAINS, ORGANIC. [ORGANIC REMAINS.]

REMBUS. [LICINUS.]

REMIPES. [HIPPIDES.]

REMOPLEURIDES, a singular fossil genus of *Trilobites* found in the Silurian Strata of Tyrone by Portlock, who describes it in his 'Geological Report' on Tyrone.

REMORA. [ECHENEIS.]

REPRODUCTION IN PLANTS AND ANIMALS. The term Reproduction has been employed to denote those processes in organic beings by which the individual being is produced, developed, and maintained. It has thus been employed to express processes which are functionally distinct, and have very different ends in the economy of creation. The constant reproduction of the same tissues in the same part, is the means by which the form of the individual being is maintained during its life, and is the result of the ordinary processes of nutrition. This function is carried on throughout the whole animal and vegetable kingdom, until the death of a part or the whole of the being occurs. The power however of reproducing the same tissues, varies in different beings, and we find that although it is possessed even to the restoration of a lost limb amongst the lower animals, no such power is possessed by the highest.

The term Reproduction has also been applied to the origination of the germ from which individual plants and animals grow. The process employed in the initiation of life, seems to be essentially distinct from those engaged in carrying it on: hence the propriety of distinguishing

in terms between that production of cells by which the life of the individual is maintained, and the arrangements by which its existence as an individual is ensured. It has been proposed to restrict the term Generation to the latter process.

Although formerly great difficulties existed in distinguishing between these two processes from the want of sufficient observations, recent researches seem to have supplied all that is necessary. In the ordinary reproduction of the tissues of plants and animals each cell has the power of producing other cells, or a large number of the same kind of cells are developed simultaneously, but in generation it is necessary that two cells should take part. At one time it was supposed that this process did not take place in the generation of the lower animals and plants, but recent investigations have shown that the union of two cells is necessary to so large a number of the forms of lower plants and animals, that it is a fair inference that this is a universal necessity in the generation of organic beings. The two cells thus engaged have been called the germ-cell and the sperm-cell. The germ-cell is that in which the process of growth of the new being commences, whilst the sperm-cell is that which communicates the growing tendency to the other. These cells are of different sizes and forms in the animal and vegetable kingdoms, and are placed in very various positions in relation to other organs, and the means by which they are brought together are very various, but in all cases they perform the same fundamental function.

The discovery of the necessity of the union of these two cells, for the production of a new being, has gone far to settle the question of "equivocal" or "spontaneous generation." Ever since the extended use of the microscope in the investigation of the structure of the organic beings, it has become more and more apparent that there was no basis for the supposition that organic beings came into existence independent of a preceding organism. The only cases in which it is now pretended that such an origin of organic life could take place, are those in which the minutest forms of animal and vegetable life occur in infusions exposed to the atmosphere. But this occurrence admits of easy explanation, when it is remembered how exceedingly minute many of these organisms are, and that they are frequently produced from ova much smaller than themselves. Such organisms are easily taken up into the atmosphere, and can be thus conveyed from one spot to another. That such is the fact is proved by the experiment of passing atmospheric air through red hot tubes or strong sulphuric acid, when it is found that water exposed to such air never affords any indications of the existence of organic beings, whilst the same water exposed to ordinary atmospheric air will, in a few hours, teem with living beings.

Although the subject of the generation of animals and plants has been regarded as a subject of much mystery, the facts it presents are now as well understood as any other branch of physiological inquiry. The greatest mystery is the mystery of all nature, and that is the reason of the assumption of a particular form by what appears to be the same combination of elements. No difference can be discerned in the cells of the flowers of the oak and the apple, but the one always produce oak-trees, whilst the others always produce apple-trees. It is the same with the cells of animals, without the slightest appreciable external difference; the one set of cells will develop the form of one species of animal, and another set, another species. This fact has led some inquirers to the assumption of the existence of a 'vital principle,' of a distinct and independent essence giving to each species its definite form and character. There is no objection to such an hypothesis, provided it is not made use of to explain phenomena which are clearly under the influence of chemical and physical forces. As so much misunderstanding prevails with regard to the word 'vital principle,' it is better perhaps to discard it, and to speak of the limitation of form to which each species is subject, as under the control of a 'formative force.' This formative force being the ultimate fact in the history of each individual plant and animal, and regulating the chemical and physical processes, the result of which is usually called life, it has been proposed to call this a germ-force, or a germinal capacity; but as it is very clear that it is the same force that is in action to produce the whole life or growth of the plant or animal, there is no necessity for distinguishing its first effects, as observed in the act of generation.

In studying then the phenomena of generation, there are three conditions which have to be regarded.

Firstly, the Formative Force, which is peculiar in every species, and identical in all the generative cells produced in that species.

Secondly, the Physical Conditions in which the generative cells are placed. These are more especially heat and light, and the condition of the cell-membrane through which absorption takes place.

Thirdly, the Elements which are supplied for the nourishment of the new being, and which by their Chemical Properties are capable of exercising an influence on the form and development of the plant or animal.

Each of these circumstances is found exercising varying degrees of influence in plants and animals. Thus, amongst the lower forms of both the animal and vegetable kingdom, the formative force appears to exercise less influence than among the higher. This is seen in the very varied forms which the same species of plant and animal assume under different circumstances. In fact, till very recently, many of the

forms of *Fungi*, *Algae*, and Infusorial Animalcules, which had received different generic names, are now found to belong to the same species. These variations are found to be chiefly produced by the influence of the third set of circumstances. The highest animals and plants are however liable to great modifications of the activity of the formative force by the operation of both physical and chemical circumstances. Many insects are not hatched till a certain amount of external temperature takes place. Plants will not produce their leaves without the influence of light. Tadpoles are not developed into frogs and toads when deprived of light and heat. The ordinary bee is converted into a queen-bee by the speciality of its food. The *Brassica oleracea* of the sea-shore is converted into red and white cabbages, cauliflowers, and broccolis by garden culture. All cultivated plants exhibit more or less modification of their growth under the influence of physical and chemical circumstances. The dog, the pig, the horse, the sheep, and man himself present varieties which are manifestly dependent on external circumstances, and not on any change in the character of the formative or species-making force.

That there is no change in the character of this force is seen in the tendency which all the forms of a particular species have to recur to a definite type, or to cease to exist. This is seen especially in the case of cultivated plants and domesticated animals, which are subject to the greatest varieties of form, but which nevertheless retain through all, the evidence of a specific formative force. Thus, closely allied as are the species of apple and pear (the *Pyrus malus* and *Pyrus vulgaris* of botanists), and subject as they are to so great variations that above a thousand forms of apple have been produced in Great Britain alone, there is not the slightest tendency in any of these cases towards confusing the specific character of the apple-tree and the pear-tree. So with our domesticated animals. The horse and ass will even breed together, but the hybrid is not prolific, and there is no tendency on the part of the one species to degrade or develop into the other. All the facts that are known with regard to the nature of the formative force lead to the conclusion that it is specific and not general, and that it is regulated by the same laws throughout all time.

In what is called the alternation of generations (GENERATIONS, ALTERNATION OF), it might be supposed that an exception occurred to the ordinary process of generation. It will be seen however that in all the cases in which this phenomenon occurs, that it results from modifications of the ordinary processes of reproduction, and the unusual disposition of the sperm-cells and germ-cells.

Having made these general remarks, we shall now proceed to speak more particularly of the process of generation as it occurs in plants and animals, restricting this term to the phenomena which take place as the result of the union of two cells. That reproduction in plants which occurs as the result of the growth of the same tissues from single cells, when it results in the production of a bud, is termed Gemmation or Sprouting. This kind of reproduction also takes place in the animal kingdom, and amongst many of the lower animals the power of reproducing new individuals* by a process of budding is seen. To this process of forming new beings as it were, from single cells, Professor Braun of Berlin has applied the term 'Verjungung,' which has been translated by Mr. Henfrey 'rejuvenescence.'

Amongst plants the lowest position must be assigned to the families *Diatomaceae* and *Desmidiaceae*, and it is amongst these that the most clear evidence has been obtained of the union of cells in order to the production of the zoospores from which the new beings are developed. [DESMIDIACEÆ; DIATOMACEÆ.] The union of two cells is also seen in a large number of *Conferaceae*, especially in the groups to which the *Zygnemata* belong. [ZYGNEMA.]

Although amongst the *Algae* the production of spores can be traced in so large a number of cases to the union of two cells, their multiplication more ordinarily takes place by means of zoospores or zoosporoid bodies, which are perfectly homologous with the buds or sprouts of the higher forms of plants.

In the *Fungi* we meet with a variety of reproductive organs. As these have been investigated very recently, we give the following extract from Dr. Sanderson's account of the vegetable ovum in the 'Cyclopædia of Anatomy and Physiology':—

The simplest form of reproductive organs in the *Fungi* are those in which the spores occur on a basis or basidium. This form of organ is best seen in *Geaster*. The next form of reproductive organs in the *Fungi* is in the form of a vesicle or bag, which is called a theca, or ascus. "Of these, the first which we shall mention belong to a group of subterranean plants, of which the Truffle is the best known example. The receptacle of the Truffle consists of a fleshy mass, throughout which numerous sinuous cavities are interspersed. Each cavity is partly lined, partly filled with the thecae and the cells upon which they are supported. This receptacle, like that of all other *Fungi* with which we are acquainted, originates from a pre-existing mycelium. In its unripe condition it displays on section a number of sinuous empty

cavities, which either communicate with each other, or open at one or more points of the external surface. As the Truffle advances towards maturity the cavities are obliterated by the formation of a whitish tissue, so that on section, we observe the whole to consist of two substances—the one translucent, of firm consistence, and of a dark-brown colour; the other white and opaque. The former, which corresponds to the partitions which, in the young state of the Truffle, separated the cavities, is continuous with the external tissue which composes the envelope or peridium, and constitutes the vena interna of Vittadini. The laminae which it forms consist of filaments running, for the most part, parallel to each other. The white substance which occupies the original cavities of the tuber is formed of closed tubes, which are given off in great numbers from the surfaces of the laminae. These tubes, which are the terminations of the filaments of which the laminae are composed, are of two kinds. Some are of equal diameter throughout, and divided at intervals by septa; others much shorter are dilated at their extremities, and contain spores (thecae). Each theca is an obovate vesicle, and contains two, three, or more spores, never more than eight. Each spore is invested with a beautifully reticulate or sometimes warty epispore, within which may be distinguished a smooth inner membrane, immediately inclosing the oleaginous contents.

"The ascophorous *Fungi* are represented in their simplest form by the *Uredineae*, a family which has been studied by numerous observers on account of the destructive properties of the plants belonging to it. The mass which is formed by the growth of the reproductive organs of *Uredo* under the epidermis of the leaves of the plants upon which it grows parasitically, may be aptly compared to a pustule, a grumous-looking substance, occupying, as it were, the place of the pus. On more minute examination of the cavity, we find that it is bounded by a kind of irregular wall, or lining of pyriform cells, the smaller ends of which rest upon a reticular cushion of mycelium. These are probably the enlarged extremities of the mycelium filaments, with which many of them can be distinctly traced to be connected. Towards the base of the cavity other cells are developed, resembling those first mentioned in their general form, as well as in their relation to the mycelium. In these however the membrane is produced inferiorly, so as to form a tabular pedicle; while in the club-shaped upper extremity it is lined by a considerable deposit of granular protoplasm, so that here the central cavity is very much smaller than that of the external membrane. It is in this cavity that the spore is formed, at first not exceeding it in size, but afterwards increasing at the expense of the protoplasm, so as almost to fill the theca. In other genera, as in *Phragmidium*, there are pedicled cells of a similar form, and originating in a similar manner, which however, instead of one spore, develop a number in their interior; these spores are arranged in linear series, and are formed in the same manner. The protoplasm however never disappears completely, but remains as a more or less consistent membrane, glueing the ripe spore to the spore-case which encloses it. Some of the *Uredineae* possess a cyst which reminds us of the perithecium of the *Sphæriaceae*, to which they are evidently closely related. The cyst is formed (*Ecidium*) of a single layer of roundish cells.

"From the *Uredineae* we pass by a natural transition to the *Discomycetes* and *Pyrenomycetes*. These plants have been investigated with much success by Messrs. Tulasne, who have shown that they possess the closest relationship not only to the Lichens, but to the most simple thread *Fungi*. The very remarkable facts which these observers have discovered, render the study of these plants more satisfactory and instructive, than that of any other family of the class. The *Pyrenomycetes* are represented by *Sphæria*, the receptacle of which consists, as is well known, of a spherical cyst, which is open above. Its wall is frequently prolonged upwards into a tubular beak, which projects beyond the surface of the bark or wood in which the whole plant is imbedded. The membrane of the cyst (perithecium) is usually composed of polygonal tabular cells; it is lined by an inner layer, formed of the commencement of the paraphyses and thecae, and of the filaments with which they are connected. The thecae are obovate cells, the membrane of which is of extreme delicacy. When fully formed, they contain from three to eight oval spores, the epispores of which are in the early condition delicate and pellucid, but by degrees become brown and opaque. The contents of the spores, as is observed throughout the higher *Fungi*, consist of a fluid loaded with oily granules. The thecae are arranged with their long axes perpendicular to the inner surface of the perithecium from which they spring, and are intermixed with a greater or less number of slender cylindrical paraphyses. The whole perithecium is usually enveloped in the filamentous stroma or mycelium, from which it takes its origin. The *Discomycetes* are represented by the *Peizae*; between these and the *Sphæriae* there are differences of external form, which, though they strike the superficial observer as important, are in reality trivial. While the receptacle of the *Sphæria* is a cyst with an apical aperture, that of the *Peiza* is a cup-shaped disc, the concave surface of which looks upwards. This surface is lined with an ascophorous membrane, which resembles in every respect that of a *Sphæria*.

"Along with the *Peizae* and *Sphæriae*, and those allied genera which resemble them in producing their spores inclosed in thecae, there are other forms also included in the *Pyrenomycetes* and *Discomycetes*, which, while they resemble those last named in the general outline

* The right use of the term 'individual' in Natural History is a difficulty. If the term is restricted only to the direct produce of the germ-cell and sperm-cell, then all trees propagated by slips belong to the same individual. In order to confine the term individual to such cases, it has been proposed among animals to give the term zooid or zoönites to the independent structures which result from sprouting, gemmation, or fission.

and structure of their receptacles, differ from them completely in the mode of origin of the spores. The simultaneous occurrence of some of these forms, along with their ascophorous analogues, or, in other instances, the successive development of both kinds of receptacles in the same position, had been frequently observed, and had given rise in the minds of some mycologists to the suspicion of the existence of a relation more close than was generally admitted. This suspicion did not, however, take a sufficiently distinct form to lead to observation, until the MM. Tulasne, in a series of researches scarcely completed, showed that the genera in question, hitherto considered as distinct, were in fact identical, and that receptacles containing thecae and paraphyses, are produced on the same stroma, or, in other words, on the same individual plant, as those which contain acrogenous spores.

"The earliest researches of MM. Tulasne were directed to the Pyrenomycetes. In some species of *Spheria*, they found not only that the same stroma produces receptacles with acrogenous spores, which are followed by others bearing thecae, but that, under certain circumstances, it may give rise to spore-bearing organs of a much simpler character; namely, branching filamentous pedicles, bearing at their terminations single spores, and rising directly from the mycelium filaments, with which they are continuous. In this condition the plant cannot be distinguished from a thread fungus, and has been hitherto described as such.

"The later observations of MM. Tulasne, which are much more in detail, refer almost entirely to Discomycetes. In a species of *Rhytisma*, a genus of Discomycetes, which inhabits the epidermis of the leaves of plants, the stroma at first presents the appearance of a black spot of various extent on the surface of the leaf. In the substance of this stroma the first receptacles are formed; they are cushion-shaped capsules, furnished with apical apertures, like those of *Spheria*, and are entirely occupied by a pulpy nucleus, which consists of slender branched filaments, often so long as to project considerably beyond the aperture. These filaments bear at their extremities innumerable minute linear sporules, which are enveloped in an abundant mucilage, and are expelled from the ripe capsules in the form of a long cirrus. After the capsules, which are developed during the early summer months, have discharged their contents, they are succeeded by the lirelliform discs of the perfect *Rhytisma*. These do not arrive at maturity until the following spring, and bear upon their upper surface thecae and paraphyses, like those of a *Peziza*. In other genera MM. Tulasne found that the ascophorous receptacles are preceded by capsules, which produce, instead of the linear sporules above mentioned, cylindrical spores of a much larger size, each of which is supported at the extremity of a pedicle of its own.

"Thus in the plants under consideration we find that, without counting the sporules which are produced by filaments rising directly from the stroma, there are no less than three varieties of spore-like structures, which can be easily distinguished from each other. All of these may be produced upon the same individual, and one is recorded in which a capsule of a *Peziza* was found, which bore, among the normal thecae, paraphyses with innumerable slender linear sporules at their extremities. As has been already hinted, the capsules which contain acrogenous spores, have been hitherto considered as belonging to genera distinct from those represented by the ascophorous receptacles with which they were found associated. The genus *Cytispora* is characterised by a structure which corresponds completely with that of the capsules described above in *Rhytisma*; and other genera, as, for example, *Sporocadus*, have a similar relation to the capsules, containing the larger variety of pedunculated cylindrical spores."

We know less of the reproductive organs of the Lichens; they however closely resemble those of the *Fungi*. The following is a summary of the reproductive organs found in these two orders:—1, Sporules which are formed by the constriction and separation of the extremity of a simple cylindrical filament. 2, Spermatia, with their supporting pedicels. 3, Stylospores, with their styles. 4, Thecae, or asci. 5, Basidia, with their basidia-spores. Although the evidence is as yet imperfect, there is still good reason for supposing that the asci and spermatia are truly sperm-cells and germ-cells, whilst the other organs represent the germe or buds.

An account of the reproductive organs of the higher *Cryptogamia* will be found under the articles FILICES and MUSCI. That the organs there described may be regarded as containing the two elementary cells, which we have called germ-cells and sperm-cells, is now matter of little speculation. Mr. Henfrey in a report made to the British Association in 1851, says, in regard to the question of sexes,—“We have several kinds of evidence:—

"1. The inferences to be deduced from the universality of the existence of two kinds of organs in connection with the reproductive process. We have seen that these exist in all the families at some period or other of the life of the representative of the species. In the Mosses and the *Hepaticae* they occur in the fully developed plant. In the Ferns and *Equisetaceae* they occur upon cellular structures of frondose character developed from all the spores, which frondose bodies or pro-embryos have an existence of some permanence, especially in the *Equisetaceae*. In the *Lycopodiaceae*, the *Isoëtaceae*, and *Rhizocarpeae*, the pistillidia occur upon very transitory cellular structures produced from one kind of spore, the larger, while the

smaller spores at once develop in their interior cellules containing moving spiral filaments such as occur in the antheridia of the other families.

"2. The inferences to be deduced from the observations on the development of those plants in which the two kinds of organs, occurring in distinct places, can be separated. Strong evidence has been brought forward that the dioecious Mosses, as they are called, do not produce sporangia when the pistillidia are kept apart from the antheridia by natural accident. The majority of observers state that the large spores of the *Rhizocarpeae* do not germinate if the small spores are all removed from contact with them; a few counter-statements however do exist. Again, the majority of authors, and all the recent ones, state that only the large spores of the *Lycopodiaceae* and *Isoëtaceae* produce new plants; while some older writers believed that they had seen the small spores do so.

"3. The direct observation of a process of fertilisation, of which we have only testimony from two authors, Suminski and Mercklin, in reference to the Ferns alone; since the assertions of Schleiden in regard to the *Rhizocarpeae* have been demonstrated by Nägeli, Hofmeister, and Mettenius to have been based on very imperfect observation."

To the question as to the homologues of the organs in the higher *Cryptogamia*, Professor Henfrey gives the following answer:—

"In the Mosses and *Hepaticae* the pistillidia occur upon the plant when the vegetative structure is perfect, and the immediate product of the great cell is a sporangium. If a process of fertilisation take place here, we may regard the antheridia and pistillidia as analogues of the anthers and pistils of flowering plants, the sporangia of their fruits; or with Hofmeister we may regard the phenomenon as an instance of an 'alternation of generations,' where the pistillidium would be looked upon as an ovule, producing (in the sporangium) a new individual of totally different character from that developed from the spore (the leafy Moss plant in the usual acceptation of the term).

"In the Ferns and *Equisetaceae*, we find the spores producing a frondose structure of definite form, upon which are developed antheridia and pistillidia, or 'ovules.' Here then we seem to have one generation complete, and the new development from the pistillidium or 'ovule' appears in a totally new form, producing stem and leaves which have a distinct individual form and existence, and produce the spores after a long period upon temporary parts of the structure, on the leaves; and by no means cease to exist when those are matured. Here we seem to have a real 'alternation of generations;' and Hofmeister compares the whole permanent plant of the Fern, or *Equisetum*, to the sporangium of the Mosses and *Hepaticae*. In all the other families, the *Lycopodiaceae*, *Isoëtaceae*, the *Rhizocarpeae*, the pro-embryo is a very transitory production, and is developed from a different spore from the epical filaments. This pro-embryo is clearly analogous to that of the Ferns and *Equisetaceae*; and if the existence of sexes be a fact, we have here a dioecious condition as contrasted with a monœcious condition in the two last-named families. Hofmeister here again assumes that the pro-embryo developed from the large spore is an intermediate generation between the two perfect forms of the plant.

"It is rather difficult to decide upon the real analogies of these structures with those of the flowering plants. The resemblance of structure is so close between the pistillidia of the Mosses and *Hepaticae*, and the 'ovules' of the other Vascular *Cryptogams*, that they must be regarded as analogues, and then the former could not well be conceived to be analogous to the pistils of flowering plants, but rather to ovules; if this be the case, the sporangium must be considered the analogue of the perfect plant in the Fern, &c., and the leafy stem as the analogue of the pro-embryo of the Ferns, &c. The pistillidium of the Mosses can indeed hardly be regarded as analogous to the fruit of a flowering plant, as in that case the spores would be ovules produced long after fertilisation; and on the other hand, if we consider the pistillidia of the Mosses as an ovule, which it might be, analogous to that of the *Coniferae*—in which a large number of embryonal vesicles or rudiments of embryos are produced after fertilisation on the branched extremities of the suspensors—then we seem to lose the analogy between the product of the pistillidium of the Mosses and that of the ovule of the Fern, unless we would regard the entire plant of a perfect Fern as analogous to the ovule of a *Conifer*."

We close this part of our subject with a tabular view (given in the next page), of the analogies in the development of different classes of plants, drawn up by Dr. Sanderson.

The process of generation is much more clearly apprehended in the flowering plants. Here we have two sets of organs whose functions are clearly and definitely the preparation of germ-cells and sperm-cells. The organ in which the germ-cells are prepared is called the Pistil [PISTIL], whilst the Stamen [STAMEN], in that part of its structure called the Anther, elaborates the sperm-cells. In the pistil the germ-cells are called Ovules, or Seed-Buds; whilst in the anther the sperm-cells are called Pollen, or Pollen-Grains. In the growth and development of both these sets of organs great differences are observed but their function is always the same.

The history of the development of the ovule of *Orchis Morio* may be taken as an example of the germ-cells of the flowering plants. In this plant the ovule springs from a placental surface as a single projecting cell, which by subdivision forms at last a central cell called the nucleus, and this becomes surrounded by a layer of cells. This nucleus, or central cell, becomes the embryo-sac, or germ-cell. The pollen-cells from the anthers having fallen on the stigma, now pass down the passage of the style, and at last, through a little opening in the ovule called the micropyle, come in contact with the outside of the apex of the embryo-sac. Within the embryo-sac are to be observed at this time three small cells called embryonal vesicles. "Soon after the pollen-cell has reached the embryo-sac, one of the embryonal vesicles begins to enlarge, and becomes divided by a cross septum into two cells; and while the upper one grows out in a filamentous form through the micropyle by a continued process of cell-division, the lower cell enlarges and divides repeatedly, so as to form a cellular globule." (Hensley.) This is the embryo. The prolonged part subsequently dies away.

The development of the pollen-cell is more uniform in the different families of plants. The part of the stamen called the anther at first appears in the young flower-bud as a little cellular papilla. In process of time this papilla divides into two portions. These are the rudiments of the future loculi, or valves. In each half, a single axile vertical column of cells soon becomes distinguished by their greater size and granular contents. In each of these cells the nucleus disappears, and is replaced by two others; this being followed by a division of the cell-contents, which form the primordial utricle, into a new cell round each nucleus. This process is repeated, and a mass of cells is thus formed which become the parents of the true sperm-

cells or pollen-grains. The walls of these parent cells now become thickened, their nuclei disappear, but are replaced by four permanent nuclei, which become each invested with a primordial sac. In this manner each of the parent cells is divided into four compartments. A cellulose integument is afterwards formed over each compartment, which now become the pollen-grains. Like the nucleus or embryo-sac of the ovule, these pollen-grains have no further power of independent development or growth, but by contact with each other the embryo of the seed is produced. When the anther is fully developed, the external case which contains the pollen bursts, and pollen-grains are distributed upon the surface of the stigma. No sooner does the pollen-grain arrive upon the stigma than it loses its spherical shape, and becomes elongated, forming the so-called pollen-tube. It is this tube which, passing down the style, becomes applied to the embryo-sac, and is the cause of the development and growth of the embryo. A question has however arisen as to whether the pollen-tube acts dynamically upon the embryo-sac, or becomes part and parcel of the new embryo.

Schleiden maintains that if the pollen-tubes be followed into the ovule, it will be found that usually one, and rarely more, penetrates the intercellular passages of the nucleus and reaches the embryo-sac, which being forced forward, is pressed and indented, and by its folding-in, forms the embryo in the first stage of its development. A bag is thus formed consisting of a double membrane, the indented embryo-sac, and the membrane of the pollen-tube itself. Schleiden infers the identity of the embryo and the pollen-tube from the three following circumstances:—1, The constantly equal diameter of the pollen-tube when it is just within it. 2, The invariable chemical similarity of their contents shown by the reaction produced by the application of

water, oil of sweet almonds, iodine, sulphuric acid, and alkalies. The general contents of the grain of pollen are starch, and this either proceeds unchanged downwards through the pollen-tube, or else passes along after being changed by a chemical vital process into a transparent and colourless fluid, which becomes gradually more and more opaque; and is coagulable by the application of alcohol; out of this, by an organising process, the cells are produced which fill the end of the pollen-tube, extending in *Orchis Morio* far beyond the ovule, and thus forming the parenchyma of the embryo. 3. The identity of the embryo and the pollen-tube is further supported by the fact, that in such plants as bear several embryos, there is always precisely the same number of pollen-tubes present as we find embryos developed.

These views of Schleiden, with his conclusion that the pollen-tube should be regarded rather as the representative of the female than of the male in the animal kingdom, have been adopted by Wydlar of Berne and others.

On the other hand, observations were made by Messrs. Mirbel and Spach, on another class of plants, in which they did not meet with the structure described by Schleiden, and consequently they object to the general application of his conclusions. They examined the development of the ovule of the *Zea Mays* (Common Maize). In this plant there is no true embryo-sac, but they found the commencement of the embryo, which they call the primary utricle, and which Schleiden described as the result of an involution of the sac, existing in the cavity of the nucleus. In this plant also, only one, and not two membranes, as described by Schleiden, existed in the embryo. They also found in other plants the primary utricle existing in the interior of the embryo-sac, and at a period anterior to the act of impregnation. They therefore conclude that the pollen-tube does not become the embryo, and that no involution of the embryo-sac takes place. The ir conclusions are probably as much too general as those of Schleiden.

Mr. Griffiths, in a paper published in the 'Linnæan Transactions,' gives the result of a long series of investigations on the development of the ovulum in the genera *Santalum*, *Osyris*, *Loranthus*, and *Viscum*. From his observations on these plants, which differ from those investigated by Schleiden, and Mirbel and Spach, he has arrived at conclusions somewhat different from those of any of these observers, and he carefully refrains from drawing an inference from the facts which he has observed that would apply to the whole vegetable kingdom. "The first process," he says, "in the development of the seed subsequently to the penetration or application of the boyau (the pollen-tube) to the embryo-sac would, in *Santalum*, *Osyris*, *Loranthus*, and *Viscum*, appear to consist of the formation of cellular tissue. This may be applied, I believe, to most if not to all instances. This cellular tissue appears to have two different origins; one, and this is the earliest in development, being perhaps referable to the embryo-sac, while the other appears directly referable to the anterior ends of the pollen-tubes." Thus far he agrees with Schleiden, that the pollen-tube penetrates into the embryonal sac, and that the embryo is derived from its intruded extremity, his observations on *Santalum* and *Loranthus* confirming this fact, whilst *Osyris* is an exception confirmative of the rule. "But none of my observations," says Mr. Griffiths, "have tended to confirm Schleiden's idea of the infection of the embryo-sac before the pollen-tube; and it appears to me sufficiently obvious, that if such were the case the cylindrical bag (the primary utricle of Mirbel), constituting the embryo in its first stage of development, would consist of three membranes or layers, namely, the first, or outer, of the ordinary and uninflected membrane of the sac; the second, of its inflected portion; the third, that of the pollen-tube itself." He also expresses his conviction that the primordial or primary utricle of Messrs. Mirbel and Spach is the sac of the embryo, which no doubt often and perhaps generally exists before fecundation.

Dr. Giraud, has published a paper in the same volume of the 'Linnæan Transactions.' He made a series of observations upon the ovulum of the *Tropæolum majus*. He concludes from his observations on the *Tropæolum majus*, "that in this plant the primary utricle and the future embryo never have any structural connection with the extremity of the pollen-tube at their first origin, or at any subsequent period of their development, as is sufficiently obvious from the fact that the pollen-tube is never brought into contact with the embryo-sac. As the primary utricle makes its appearance before impregnation has occurred, it cannot be possible that the organ has ever formed the extremity of the pollen-tube, as is believed by Schleiden and Wydlar. Moreover, as the primary utricle takes its origin wholly within the embryo-sac, and at the earliest period of its formation is not in contact with that membrane, it cannot have been formed by the pollen-tube pressing before it a fold of the embryo-sac in its passage into the cavity of that structure, as Schleiden has maintained."

In the 'Annals of Natural History,' 1852, Professor Hensley has published a paper on the Reproduction of the higher *Cryptogamia* and *Phanerogamia*, in which he states that he has not been able to observe the penetration of the pollen-tube into the embryo-sac.

We now pass to the consideration of the function of Reproduction amongst Animals. General Reproduction occurs in many of the lower animals in the same manner as plants. There is a common reproduction of destroyed tissues which frequently extends to the production

of an entire limb. This is seen amongst the *Radiata*, especially the *Echinodermata*, also amongst the *Articulata*. The highest families of animals in which this kind of reproduction occurs regularly are the Reptiles, in which instances are recorded of legs and tails being renewed. Occasional instances occur in which the limbs of higher animals are reproduced. The case of a Thrush, in which such renewal had taken place in a leg, was brought before the British Association meeting at Hull. A case is also related in which an abnormal finger in a human being having been removed, it was again reproduced almost entire.

Reproduction by division into two, or by gemmation, the Fissiparous and Gemmiparous methods of Reproduction, occur to a very considerable extent among the lower animals. These modes of reproduction do not essentially differ, and both occur in the same families of animals. [HYDRA; ACALEPHE; POLYZOA.] The individuals which are thus produced by fission or by gemmation are called Zooids. This process occurs in unicellular as well as multicellular plants and animals, and the single cells produced by the division of the *Desmidiæ*, the *Diatomaceæ*, and the *Vorticellæ*, are as much entitled to the term Zooide as the more complicated forms of the *Acalephæ*.

The true generative act is performed in animals in the same manner as plants. In order to the production of the new individual it is necessary that there should be a union of germ-cells on the one hand with sperm-cells on the other. We shall not here attempt to describe the various forms of organs in the animal kingdom in which these sperm-cells and germ-cells occur. They are described in considerable detail in this work under the head of the families, and sometimes of the genera and species of the various animals described. We shall however describe generally the nature of these cells. The germ-cells and sperm-cells in animals are usually produced from tissues and organs that are structurally different, but as in plants these organs may be placed on different individuals, or on the same. When the two sets of cells are found on the same individual, or zooid, they are said to be Hermaphrodite; but if these cells are found on different individuals they are said to be Monosexual. The term hermaphrodite is also applied to plants; but when their sperm-cells and germ-cells are placed on different flowers, as happens sometimes in the *Phanerogamia*, they are called Monocious and Dioecious.

The sperm-cells in the animal kingdom assume a more definite form than those of the vegetable kingdom. In the higher *Cryptogamia*, where they assume the form of self-moving filaments, they most closely resemble those of the animal kingdom. These filaments are formed in the interior of cells, from which they escape by bursting. They usually present an elongated filamentous appearance, with a slight dilatation at one extremity. At one time they were regarded as a kind of animalcule, and called 'epermatic animalcules,' and were supposed to have an interior organisation. This is not the case, and they have no more claim to be regarded as animalcules than moveable blood-discs, or ciliated epithelium-scales. The movements performed by these bodies are in many instances due to the presence of cilia, which are found upon their surface. The movements of such filaments would vary according to the disposition of the cilia. In other cases the movement seems due to molecular activity. The object is very obviously to bring the spermatozoon, as these epermatic filaments have been called, into contact with the germ-cell. These movements soon cease after the filaments have been removed from the matrix in which they have been formed. Some agents rapidly destroy these movements, whilst others renew them after they have apparently ceased. This subject has been recently investigated by Kölliker, and the results which he has arrived at in regard to the movements observed in the epermatic filaments of *Mammalia*, are embraced in the following propositions:—

1. In the epermatic fluid, taken from the epididymis and vas deferens, motile spermatic filaments exist in very great abundance.
2. In water and aqueous solutions of all innocuous indifferent substances and salts, the motion of the filaments ceases, and they form loops.
3. These filaments, thus furnished with loops, are not dead, as has hitherto been generally believed; for, on the contrary, they revive completely upon the subsequent addition of concentrated solutions of innocuous indifferent substances (sugar, albumen, urea), and of salts.
4. In all animal fluids, when considerably concentrated, or highly saline, which are not too acid nor too alkaline, nor too viscid, the motions of the spermatic filaments are unimpaired; this is the case, for instance, in blood, lymph, alkaline or neutral urine, alkaline milk, thin mucus, thick bile, the vitreous humour—but not in saliva, acid or strongly ammoniacal urine, acid milk or mucus, the gastric juice, thin bile, and thick mucus. When the proper degree of concentration of the latter fluids is successfully attained, and their reaction is rendered neutral, they are innocuous.
5. In all solutions of indifferent organic substances moderately concentrated, the filaments move with perfect facility—thus in all kinds of syrup, in albumen, urea, glycerin, salicin, amygdalin. More concentrated solutions of these substances cause the motion to cease, but it is restored upon their subsequent dilution with water. Too dilute solutions act in the same way as water (vide 2 and 3).
6. Certain solutions, as they are termed, of indifferent organic

substances act like water, however much they may be concentrated, such as solutions of gum arabic, vegetable mucus (gum tragacanth, mucilage of quince-seeds), and of dextrin. Concentrated solutions of other substances, in this case also, restore the motions.

7. Many organic substances cause the motions of the filaments to cease, owing to their chemical action upon them, such as alcohol, creasote, tannin, and ether; others owing to their mechanical effects, as most oils. Narcotics, in certain degrees of concentration, are not injurious.

8. Metallic salts are injurious, even in extremely dilute solutions; such, for instance, as a solution containing 1-10,000th of corrosive sublimate.

9. Most of the alkaline and earthy salts are innocuous in certain degrees of concentration, which in some is greater and in some less; so little hurtful, in fact, are they, that the filaments may be kept alive in them for from one to four hours. Among these may be enumerated solutions of common salt; chloride of potassium; sal ammoniac; nitrate of soda; nitrate of potash, containing 1 part to 100; moreover, solutions containing from 5 to 10 parts in 100 of phosphate of soda; sulphate of soda; sulphate of magnesia; chloride of barium. As regards some of these salts, the fact had been previously noticed by older writers, and more recently by Quatrefages, Newport, and Ankermaun. Solutions unduly diluted have the same effect as water, and cause the formation of loops, but the filaments are revived upon the addition of a concentrated solution of the same salts and of indifferent substances (sugar, urea, &c.). Stronger saline solutions than are required, also interfere with the motions; but, in this case likewise, the filaments are capable of revival upon the addition of water. These salts can scarcely be regarded properly as revivifiers, as was asserted not long since by Moleschott and Ricchetti, for filaments which have become quiescent in indifferent substances, as sugar, for instance, are not revived again by them; and their action is widely different from that of the real excitants—the caustic alkalies. It cannot be denied that their influence is very favourable, and that (but perhaps owing only to their rapid diffusion in the water) they produce motion in a seminal mass more rapidly than other less diffusible substances, such as sugar and albumen; on which account the above-named authors ascribe revivifying properties to them—a fact which, before them, had been made known, as regards common salt, by Quatrefages, and by Newport, for carbonate of soda and potash; while latter salts, moreover, in certain experiments, caused the motion to cease in 10' or 15', almost like the caustic alkalies.

10. Acids, even in very small quantity, are injurious; such as hydrochloric acid, in the proportion of 1-7,500th.

11. Caustic alkalies (soda, potash and ammonia, not lime and barytes), in all degrees of concentration, from 1-31th to 6-10th are special excitants of the spermatic filaments. Whether the latter have become quiescent spontaneously, as in old sperm-fluid, or have ceased to move in indifferent solutions, the above substances recal the most active movements which are not distinguishable from the vital. But these motions cease after two or three minutes, and from this quiescence the filaments cannot be roused by any means. When mixed with indifferent substances in small proportions (from 1-1000th to 1-500th), as, for instance, in syrup, the caustic alkalies afford a means by which the motions of the spermatic filaments may be maintained for a long time.

12. The sperm-fluid dried in indifferent substances, and in saline solutions, may, in certain cases, have its motion restored by dilution with the same fluid, or with water.

The cells which give origin to the spermatic filaments are found upon the surface of the organs which secrete them. At first they are not to be distinguished from ordinary epithelial cells, but they increase in size, and at last present a corpuscle (seminal corpuscle) in their interior. These corpuscles are filled with granular matter, which is gradually converted into the spermatic filament, which is at first coiled up, and lies in contact with the inner surface of the wall of the corpuscle. The spermatic filaments usually present themselves in clusters, which arise from their tendency when set free from their cells to arrange themselves in this manner.

The size of the spermatic filaments varies. In human beings they are from 1-500th to 1-600th of an inch in length. The head is about 1-5000th to 1-8000th of an inch long, and is about half as wide.

In the females of most animals it is not difficult to find a large cell, which is called an ovum or egg. If this ovum be examined in the *Mammalia*, it will be found to present a vesicle, which is called the germinal vesicle, and this vesicle presents a spot, called the germinal spot. There seems to be little doubt that this vesicle is truly the germ-cell. In the *Mammalia* the ova are found in an organ called the ovary.

"If the structure and formation of the human ovary be examined at any period between early infancy and advanced age, but especially during that period of life in which the power of conception exists, it will be found to contain, on an average, from fifteen to twenty small vesicles or membranous sacs of various sizes; these have been already alluded to as the follicles or vesicles of De Graaf, the anatomist who first accurately described them. At their first formation, the Graafian vesicles are small, and deeply-seated in the substance of the ovary;

but as they increase in size, they make their way towards the surface; and when mature they form little prominences on the exterior of the ovary, covered only by the peritoneum. Each follicle is formed with an external membranous envelope composed of fine fibro-cellular tissue, and connected with the surrounding stroma of the ovary by networks of blood-vessels. This envelope or tunica is lined with a layer of nucleated cells, forming a kind of epithelium or internal tunic, and named *membrana granulosa*. The cavity of the follicle is filled with an aluminous fluid, in which microscopic granules float; and it contains also the ovum or ovule. The ovum is a minute spherical body situated, in immature follicles, near their centre; but in those nearer maturity, in contact with the *membrana granulosa*, at that part of the follicle which forms a prominence on the surface of the ovary. The cells of the *membrana granulosa* are at that point more numerous than elsewhere, and are heaped around the ovum, forming a kind of granular zone, the *discus proligerus*.

"In order to examine an ovum, one of the Graafian vesicles, it matters not whether it be of small size or arrived at maturity, should be pricked, and the contained fluid received upon a piece of glass. The ovum then, being found in the midst of the fluid by means of a simple lens, may be further examined with higher microscopic powers. Owing to its globular form, however, its structure cannot be seen until it is subjected to gentle pressure.

"The human ovum is extremely small, measuring, according to Bischoff, from 1-240th to 1-120th of an inch. Its external investment is a transparent membrane, about 1-2500th of an inch in thickness, which, under the microscope, appears as a bright ring, bounded externally and internally by a dark outline: it is called the *zona pellucida* or vitelline membrane, and corresponds with the chorion of the impregnated ovum. It adheres externally to the heap of cells constituting the *discus proligerus*.

"Within this transparent investment, or *zona pellucida*, and usually in close contact with it, lies the yolk, or vitellus, which is composed of granules and globules of various sizes, imbedded in a more or less fluid substance. The smaller granules, which are the more numerous, resemble in their appearance, as well as their constant motion, pigment granules. The larger granules, or globules, which have the aspect of fat globules, are in greatest number at the periphery of the yolk. The number of the granules is, according to Bischoff, greatest in the ova of carnivorous animals. In the human ovum their quantity is comparatively small.

"The substance that combines the globules and granules of the yolk is in many animals quite fluid. The yolk then completely fills the cavity of the *zona pellucida*, and escapes in a liquid form when that membrane is ruptured: but in ova of the human subject, and some animals, the yolk is much more consistent, and sometimes escapes as a solid globular mass when the *zona pellucida* is torn. It is, according to Bischoff, solely owing to this firm consistence of the yolk that in many cases preserves its form when a watery fluid passes by imbibition through the *zona pellucida*, and that an interval is then apparent between the yolk and that membrane. From the appearances resulting from the action of water on the ovum, and from other circumstances, it has been thought that the mass composing the yolk is surrounded by another membrane within the *zona pellucida*, but the evidence for such a view is not satisfactory.

"In the substance of the yolk is imbedded the germinal vesicle, or vesicula germinativa. This vesicle is of greatest relative size in the smallest ova, and is in them surrounded closely by the yolk, nearly in the centre of which it lies. During the development of the ovum the germinal vesicle increases in size much less rapidly than the yolk, and comes to be placed nearer to its surface. In a mature ovum of the rabbit it is about one-sixtieth of a line in diameter (Bischoff): its size in the human ovum has not yet been ascertained, owing to the difficulty of isolating it. It consists of a fine transparent structureless membrane, containing a clear watery fluid, in which are sometimes a few granules.

"At that part of the periphery of the germinal vesicle which is nearest to the periphery of the yolk is situated the germinal spot, a finely-granulated substance, of a yellowish colour, strongly refracting the rays of light, and measuring, in the *Mammalia* generally, from 1-3600th to 1-2400th of an inch (Wagner)." (Kirkes and Paget, 'Handbook of Physiology.')

The act of fecundation is effected in the same manner in animals as in plants, that is, by the contact of the sperm-cells with the germ-cells. Much discussion has taken place as to how this occurs, but the following account may be regarded as embracing the facts most generally accepted:—As the germinal vesicle becomes fitted for fecundation, it loses its pellucid character, arising from the development of a large number of cells in its interior. It is at this period that the spermatic filaments, coming in contact with it, produce that tendency to growth which results in the formation of the new being. The nature of this contact has been a question. Mr. Newport however, in a series of very carefully-conducted experiments upon the *Amphibia*, comes to the conclusion that the spermatic filament penetrates the vitelline membrane, and comes directly in contact with the germinal vesicle. There is no special foramen for the admission of the spermatic filaments, but they pierce through this membrane, and may be seen floating about in the yolk. Mr. Newport found that a single sperma-

tozoon did not produce fecundation, but that the penetration of several were required for this purpose.

In the human female the ova are brought from the ovaries along the Fallopian tube into an organ called the uterus. It grows rapidly after reaching the uterus; it at first consists of two sacs, one inclosing the other, and the inner containing a liquid. When it is about half a line in diameter a new element becomes visible in it; a round, opaque, granular disc is seen, with a dark spot in its centre, upon the surface of the internal globule or sac. This spot, which is seen either on or through the inner membrane of the ovum, corresponds with the cicatrícula of the egg, and is the first rudiment of the fœtus.

In birds the cicatrícula, or germ-spot, lies upon the surface of the yolk: soon after the commencement of incubation it expands and separates into two layers; the outer is called by Pander the serous layer, and subsequently forms the osseous, nervous, muscular, and tegumentary systems of the body; the inner, which is in contact with the yolk, is called the mucous, which (together with a third developed between the two others, and named the vascular layer) appears to give rise, by the changes which it undergoes, to the intestinal, respiratory, vascular, and glandular systems. The mucous layer of the germinal membrane gradually expands over the yolk, till it nearly incloses it in a sac, which towards the body of the chick contracts into an oblong canal, which extends the whole length of the embryo, and becomes the future alimentary tube. The sac containing the yolk, and communicating with the intestines, is called the intestinal vesicle, or yolk-bag, and towards the close of incubation is drawn into the belly of the chick, and its contents are used as nourishment. The lower end of the alimentary canal (the cloaca of birds) shoots out into a sac which is termed the allantois, or allantoïd membrane. After a time arteries and veins are seen ramifying upon this sac, which protrudes more and more out of the body of the chick, till at length it forms a double bag, laid immediately under the membrane of the shell. On this sac the blood-vessels are so distributed that their contents are influenced by the atmosphere through the porous egg-shell and its membrane, and thus a true respiratory organ is established.

The original structure of the ovum, and the early development of the embryo, in *Mammalia*, appear to be much the same as in the egg of a bird; though there are some characteristic differences. When a human ovum of any magnitude is examined, the embryo is seen suspended in a loose bag filled with fluid, called the amnios, which is a shut sac: this sac is the outermost product of the serous layer of the germinal membrane; for its formation a membrane is reflected from the sides and extremities of the embryo (the reflection, according to Velpeau, not commencing before the twelfth day), so as to inclose a space behind it. As the walls of the trunk close in front, the circle at which the amnios is attached to the body of the embryo gradually contracts, till at length it is limited to the edge of the umbilical opening; it then invests the umbilical cord, and spreads out from its placental extremity into an ample sac filled with fluid, in which the fœtus floats. The mucous layer of the germinal membrane in *Mammalia* is supposed from analogy to form a sac, as in birds, containing a yolk, or substance subservient to the nourishment of the fœtus in its early stage. Whether this view of its formation and use be correct or not only rests on analogy; but in the early part of gestation a small sac or bladder, which from its being filled with a whitish fluid has been called the vesicula alba, may be found on the placenta, at or near the extremity of the umbilical cord, and exterior to the amnios; from this sac a fine tube may be traced along the cord to the navel, and in some animals it has been seen communicating with the intestinal canal. This tube becomes obliterated so early (Velpœau says in the sixth week of gestation) that its communication with the intestines was long undetected, though the sac was known to the older anatomists. The intestinal vesicle finally differs in *Mammalia* and birds in this circumstance, that in the former it is not drawn into the body of the fœtus, but remains without between the membranes, and gradually wasting becomes obliterated by the third month. The duct of the umbilical vesicle is accompanied along the cord by an artery and vein, which are called the omphalo-mesenteric vessels; the artery communicates with the superior mesenteric, and the vein with the vena portæ. The allantois exists in all mammals as well as in birds, though its use in the former, which are furnished with a placenta, is not obvious. In some animals, as in man, it becomes obliterated at a very early period, as soon as the sixth week, but in others, as the *Carnivora*, &c., it attains a large size, and continues during the whole period of fœtal existence. In *Mammalia* it communicates with the fundus of the bladder, and the remains of the duct by which it is connected is denominated the urachus. The channel of communication between the allantois and the bladder, or cloaca (in birds), at first is short, so that the sac lies directly against the body of the embryo, but it afterwards becomes elongated, like the corresponding duct of the umbilical vesicle.

In man, after impregnation has taken place, a spongy membrane is formed on the inner surface of the uterus by an exudation of lymph. This membrane, called decidua, lines the whole of the uterus before the descent of the ovum; but when this passes down through the Fallopian tube it gradually pushes the deciduous membrane before it, inverting one portion of it which surrounds the ovum, and is called the decidua reflexa; this grows with the ovum till it fills the cavity

of the uterus, and comes in contact with the other portion called the decidua vera, lining the walls of the uterus.

The point at which the decidua is reflected upon the ovum is where the placenta is fixed to the uterus. The ovum has two proper membranes, the amnios, which we have described, internally, and an outer membrane, which is called the chorion; this latter membrane in man, during the first two months of pregnancy, has a shaggy external surface, being covered with vascular villi, which become united with the membrana decidua, which is also thick and vascular. This thickening and vascularity of both these membranes gradually diminishes, and becomes concentrated on one part, usually towards the fundus of the uterus; this thickened part is called the placenta. In ruminating animals the thickening and vascularity of the chorion is confined to a number of circular and spongy elevations varying in number from thirty to one hundred, which are called cotyledons. These vascular processes dip in between corresponding processes attached to the uterus of the mother, which are called maternal cotyledons, the surface of which is supplied with numerous vessels derived from the uterine arteries and veins. The result of this arrangement is that a large vascular surface of the maternal system is applied to an equally extensive one of the fœtus, and though there is no direct communication between the arteries and veins, we must suppose that nourishment is imbibed from the vessels of the mother by those of the fœtus through the fine intervening membranes by which they are separated. In man the relation between the maternal and fœtal systems is not so clearly understood as in the preceding instance. In the human subject the placenta is a spongy vascular mass like a cake, from six to eight inches in diameter, about an inch thick in the middle, and two or three lines at the circumference. It adheres by one surface to the uterus, and by the other is connected with the fœtus by means of the umbilical cord. The uterine surface is lobulated, and is connected with the uterus by blood-vessels. The fœtal surface is covered by the chorion and amnios, and presents the ramifications of the umbilical vessels, which consist of two arteries and a vein. The radicles of these vessels communicate with each other, but no communication has ever been shown to exist between them and the utero-placental vessels; for if we inject from the umbilical arteries we find that the placenta is rendered turgid, and that vessels are found filled in every part of it, but between their ramifications there will remain an uninjected substance, and the uterine surface will not be injected, for the fœtal vessels do not pass all the way to that surface. In like manner, if we inject from the uterine vessels, the placenta will be rendered turgid, but nothing passes into the fœtal vessels. From this circumstance it is concluded that the placenta consists uniformly of two portions: the one is furnished by the deciduous coat of the uterus, the other by the vessels of the chorion, and these two portions may, during the first three months, be separated from each other by maceration. The structure of the fœtal portion, so far as can be made out, appears to be similar to that of the pulmonary vessels, the artery terminating in the vein. But the maternal portion is somewhat different; there is not a direct communication, but the arteries, as Mr. Hunter thought, seem to terminate in irregular cells, and the veins appear to commence with open mouths from these cells, for by throwing wax in the uterine arteries we fill the cells, and frequently inject the uterine veins also.

It has always been considered doubtful whether the placental cells of Hunter were real or artificial, being, in the latter case, produced by extravasation of the injection; and recent researches have confirmed this doubt, but without throwing any satisfactory light on this very obscure subject. With regard to the use of the placenta we may infer that it is very similar in man to what it is in ruminating and other animals; it most probably serves to produce a change in the blood of the fœtus analogous to that which the blood of the adult undergoes in the lungs; and, from considering that the fœtus itself cannot create materials for its own growth and support, we may further infer that the placenta is the source of nutrition also.

The navel-string, or umbilical cord, which connects the child to the mother, is composed of the umbilical vein and two umbilical arteries twisted together, and surrounded by a gelatinous substance and the reflections of the chorion and amnios; it also contains the urachus, and the remains of the duct of the vesicula alba and omphalo-mesenteric vessels. It is visible in the human embryo in the sixth week as a short and straight cord; at birth the length of it is, on an average, about two feet. The outer tunic of the cord, the amnios, is continuous with the epidermis, or cuticle of the fœtus at the umbilicus; and in the same way the chorion, which is also reflected on the navel-string, is continued into the dermis, or true skin of the fœtus.

The following is Valentin's account of the development of the principal organs of the human embryo.

"The primitive streak or groove is the first indication of the future embryo. It consists of a very small longitudinal groove in the middle of the upper surface of the serous lamina. It soon after enlarges, while its two margins are raised to form the laminae dorsales. They grow over towards each other, meet in a longitudinal suture, and thus inclose a cavity, the primitive tubo. Anteriorly this tube dilates into several vesicles, which lie behind each other, and in which is deposited the cerebral substance. The spinal cord is laid down in its remaining cylindrical portion. The several parts of the brain of

the human embryo gradually pass through numerous transitional forms, which correspond with their permanent conditions in various of the lower animals.

"A dense cord, the chorda dorsalis, is early deposited beneath almost the whole length of this primitive tube. At the same time, square spots are observed on either side, symmetrically arranged in pairs. Each two corresponding squares subsequently grow towards each other, to construct the body of a vertebra. In doing this, they include between them a corresponding segment of the chorda dorsalis, and gradually altogether displace it. In *Mammalia* and birds, the remaining portions of this structure subsequently disappear.

"The vertebral arches commence as dense curved pairs of streaks; each of which unites on the one hand with the body of the vertebrae, and on the other with its opposite fellow. The various processes of the vertebrae are only added subsequently.

"The first rudiment of the skull is formed by a membranous capsule, which gradually merges into a special cartilaginous covering, called the primordial skull. Some portions of the latter are ossified immediately afterwards, while others disappear after new pieces of bone have been opposed to them.

"The blastema adjoining the inferior surface of the skull produces a series of pairs of processes, which finally give rise to the chief structures of the face and neck. Those which lie between the future mouth and the chest are called the branchial or visceral processes; and the fissures which remain between them, the branchial fissures. Their form and relations to the vascular trunks which supply them somewhat resemble the type met with in the gills or branchial respiratory organs of the fish.

"The margins of the central portion of the serous lamina are gradually involutioned, so as to form the walls of the thoracic and abdominal cavities. But as they only subsequently meet in the inferior median line of the embryo (which we are supposing to be horizontal), there remains at first a long fissure, through which are protruded the heart, a large portion of the intestinal canal, and the allantois. This aperture afterwards closes in the region of the thorax, and the posterior part of the abdomen; and finally disappears, leaving no relic save the navel. The ribs commence as dense striz, which first become cartilaginous, and are then ossified. The several pieces of the sternum are developed by a similar process.

"The extremities are at first altogether absent. They subsequently sprout in the form of small stumps. Each of these is first divided into an internal segment which pertains to the trunk, and corresponds to the thigh or upper arm, and a free terminal plate which is developed into the hand or foot. The fore arm and leg are only formed subsequently. The fingers and toes are at first united by a kind of web, so as to resemble fins. This membrane begins to disappear from without inwards.

"The eye at first forms a hollow vesicle, which is connected with the brain by a tubular handle, the future optic nerve. The retina is produced from a deposit which resembles that of the cerebral substance in the vesicles of the brain. The crystalline lens, the vitreous humour, and the iris, are only developed subsequently. A special vascular tunic, the capsulo-papillary sac, surrounds the lens of the early embryo. Its anterior segment then forms the papillary membrane, a vascular coat which is stretched immediately in front of the papillary aperture. By the gradual loss of its blood-vessels, this is converted into a simple transparent membrane, which disappears a few days after birth.

"The labyrinth of the ear also begins as a hollow vesicle, having a handle which is continuous with the brain. The vestibule, the cochlea, and the semicircular canals are then developed, at what is comparatively a very early date. The formation of the auditory ossicles is ultimately connected with the development of the most anterior visceral arches. At this period the long process of the malleus extends on the first maxillary process, or the future lower jaw, as far as to the median line; in the *Mammalia*, however, it afterwards gradually disappears, so as to leave scarcely a trace. The tympanic cavity is chiefly developed from the gap situated at the first visceral arch. The external ear is produced last of all.

"The organs of smell are also first indicated by vesicles which are connected with the brain. The nose is developed afterwards, during the evolution of the face. The palate, which is subsequently laid down, ends by separating the cavities of the nose and mouth. The tongue grows out of the first maxillary arch. The external integument is only separated into corium and epidermis towards the end of the second month, or the beginning of the third. It afterwards acquires its nails, together with its various glands and hairs. In the advanced embryo, almost all the surface of the body is covered by a very fine down. The copious desquamation and fatty secretion of the skin result in a caseous substance which covers many portions of the foetal body, and is capable of protecting it like an ointment from the injurious action of the liquor amnii.

"Those primary changes by which many of the embryonal organs commence, are effected without the aid of the vascular system. The heart subsequently begins as a tube, which, anteriorly, is continuous with centrifugal vessels or arteries; posteriorly, with centripetal tubes or veins. It afterwards undergoes a peculiar involution, divides into segments, produces the auricular appendages, and finally, presents two

auricles and a single ventricle. The latter gradually acquires a septum, which is at first an incomplete, and finally a perfect one. These embryonal vessels gradually undergo numerous changes, which are due, not only to the formation or metamorphosis of those organs of the body that are rich in vessels, but also to a variety of causes which belong to the vascular system itself.

"The contrast of a systemic and a separate circulation obtains at a very early date. A great part of the surface of the yolk is at first covered by a vascular distribution, the *aurea vasculosa*, in which the blood of the embryo is changed by a process, the details of which are at present unknown. This vitelline circulation begins soon after the heart of the embryo has commenced to beat. In the *Mammalia* it subsequently disappears, to make way for the placental circulation. The blood then runs through the umbilical arteries into the foetal placenta, where it undergoes a diffusion with the blood of the maternal placenta, returning to the foetus through the umbilical vein. The renovation thus produced corresponds, not only to the respiration of the more developed being, but also to the most pressing requirements of its nutrition.

"The connection between the state of development of the heart and that of the great vessels, produces a peculiar movement of the blood, which has been designated the foetal circulation, or the circulation of Sabatier. It is most distinct shortly after the middle of pregnancy. The blood of the right ventricle then passes chiefly into the lower half of the body and the placenta; while that which returns from this organ goes chiefly to the left heart, in order to flow thence to the head and neck, from which it finally returns to gain the right auricle and ventricle. So that there is a partial contrast between the circulations of the upper and lower halves of the body. After birth it is replaced by the systemic and pulmonic circulations.

"The placental circulation ceases soon after birth, being replaced by the pulmonic on the respiration of air. But in the normal course of development the preparations necessary for this change are made some months before the end of pregnancy. Hence, under favourable circumstances, a child which comes into the world seven or eight months after conception may nevertheless continue to live.

"The foramen ovale is due to the fact, that the inferior vena cava originally opens into the left auricle, and not into the right, being only gradually pushed over into the latter. This explains why the greater part of the blood that returns from the umbilical vein and the lower parts of the body passes into the left auricle during the foetal circulation. The groove which conducts it in this course is the relic of a special adaptation, which dwindles and disappears in proportion as the left auricle is claimed by the advancing development of the pulmonary veins. Immediately after birth, the foramen ovale is at first closed mechanically by the action of the auricle; but it finally becomes organically occluded. The superior and inferior vena cava then belong exclusively to the right auricle.

"The pulmonary artery and aorta of the new-born infant are connected with each other by means of the ductus arteriosus, or duct of Botalli. This structure—which is a necessary result of the development of the embryonal vessels—prevents the two divisions of the foetal circulation being completely separated from each other, and also hinders the perfect separation of the scarlet and dark-red blood in the new-born infant whose lungs have begun to work. But in the first few weeks after birth, the ductus arteriosus is closed by a process which somewhat resembles that seen in a deligated artery. It is thus converted into a ligamentous band, in which form it remains during the remainder of life.

"After a certain period of embryonal life, the umbilical vein which returns the renovated blood from the foetal placenta, sends branches to the liver. Besides this, it unites with the portal vein, which also ramifies in this gland. And it has also a certain communication with the inferior vena cava, by means of a vessel—the nervous duct of Arantius—which passes between the two. Hence, part of the purified blood which is returning from the foetal placenta can avoid the liver, and flow immediately into the auricle."

"The umbilical cord of the infant is usually tied and cut through in some part of its course. The brute mammals gnaw it asunder as soon as their young have breathed. After some time that portion which remains attached to the belly dries up, and falls spontaneously from the navel. Those portions of the umbilical arteries which first run along the bladder, and then ascend on the abdominal walls to the umbilicus, become converted into ligamentous tissue. The duct of Arantius and a large part of the umbilical vein also experience the same fate.

"The development of the intestinal canal commences by the centre of the mucous lamina being raised and folded inwards. In this way it produces an intestinal groove, which is open towards the yolk. This groove is soon afterwards shut off anteriorly and posteriorly, so that there only remains a median gap, the intestinal navel. The circumference of the mucous lamina furnishes a covering for the umbilical vesicle. The portion which intervenes between this and the intestinal navel is drawn out into a cylindrical duct, the pedicle or stalk of the umbilical vesicle." (Valentin, 'Text-Book of Physiology.')

The foetus has many peculiarities which distinguish it from the child after birth, most of which are peculiar to its mode of life, and are lost immediately after being separated from the mother, or are

gradually removed during gestation. The most characteristic difference is that it lives in a medium of water, and not of air, and consequently does not breathe by lungs, but has the blood which is deteriorated by circulating through the system purified in some manner in passing through the placenta. The umbilical vein carries the blood from the placenta to the foetus: it enters the liver by the longitudinal fissure, and in the transverse fissure communicates with the vena portæ, sending the greater part of the blood to be circulated in the liver. This organ is of great size, and seems to perform some important office in the foetal economy. It is conjectured by Dr. R. Lee to secrete albuminous matter, which nourishes the foetus. The rest of the blood is transmitted directly to the vena cava inferior by the ductus venosus, which seems to be a continuation of the umbilical vein in man, though in most animals it is merely a branch arising from the sinus of the vena portæ. The blood conveyed by the vena cava inferior to the right auricle of the heart, does not all pass, as in the adult, into the right ventricle, but a great portion goes immediately into the left auricle through an opening in the septum of the auricles called the foramen ovale, which closes up immediately after birth. The blood that still goes into the right ventricle through the auriculo-ventricular orifice is propelled into the pulmonary artery, but, as there is no use for it at present in the lungs, it nearly all passes through a vessel named the ductus arteriosus into the aorta. This duct also becomes obliterated after birth, its functions having ceased when once the child has breathed.

By the aorta the blood is sent from the left side of the heart and ductus arteriosus to the different parts of the body, from which it is returned by the veins, but a great part of it passes out of the body of the foetus by the umbilical arteries, which are continued from the internal ilia, and pass out at the navel to go to the placenta. The blood of the foetus differs in its physical and chemical qualities from that of the adult. There is before birth no distinction between arterial and venous blood; it is of a dark colour in both systems of vessels. The purified blood is brought from the placenta by the umbilical vein, and is mixed before arriving at the heart with that which has been circulating through the foetus: the mixed blood is then transmitted by the aorta to various parts of the body; some of it only going again to the placenta by the umbilical arteries to be again purified.

The position of the child in the uterus is that which takes up the least room; it lies with the head downwards, the chin being bent on the breast; the knees are doubled up close to the belly, and the arms are folded in the space between the head and legs. This is the most general position, and the child thus forms an oval figure, of which the head forms one end and the breech the other. The long axis of this ellipse measures in the ninth month fully ten inches, and the short one five or six inches. The quantity of fluid which surrounds the child at the full time is, on an average, about two pints.

The ordinary period of utero-gestation in man is forty weeks, though labour often takes place before this period, or is delayed a little beyond it. The embryo having now arrived at a sufficient degree of maturity to exist separately, the fibres of the uterus contract, accompanied by contraction of the abdominal muscles and diaphragm. In consequence of this pressure the membranes gradually dilate the mouth of the womb; they then burst and evacuate the liquor amnii, when the pressure acts upon the child itself, which is gradually forced into the world, and commences a new existence. In man, and other *Mammalia*, the young being for a considerable time depends upon its mother for the whole of its nourishment, and very generally requires a supply of warmth and a degree of protection till it is able to provide for itself.

REPTILIA, a class of Animals belonging to the sub-kingdom *Vertebrata*, and embracing the creatures usually known as Crocodiles, Lizards, Turtles, Tortoises, Frogs, Toads, and Serpents. In the articles AMPHIBIA, CROCODYLIDÆ, CHELONIA, OPHIDIA, and SAURIA, will be found an account of the principal forms and organisation of these creatures. We here propose to give a slight sketch of their history, and the attempts made at their general classification.

The ancient monuments of the Egyptians prove that the great groups of the tortoises, the lizards, the serpents, and the frogs, as well as their habits, were well known to that people; and the Sacred Scriptures abound in passages (the Old Testament especially) showing that a similar knowledge obtained when they were written. Indeed from the earliest times these forms must have attracted the attention of man; and a natural desire on his part to ascertain which of them were dangerous, and which were innocuous, must have led him to particular inquiry in order to solve the doubt.

In Herodotus and Athenæus there are not wanting passages indicative of precise notions respecting many species of reptiles.

That this class of animals had employed no small portion of the acute observation of Aristotle, and that he was well acquainted with their form, structure, and habit, appears from the great work which has justly immortalised him as a zoologist. We need only refer to the following passages in his 'History of Animals' to be well satisfied of the fact (lib. i., c. 1.; lib. ii., c. 10, 17; lib. v., c. 3, 4; lib. viii., c. 2, 17). We find noticed the oviparous quadrupeds, namely, the land and marine *Testudinata*, the crocodiles, the lizards, &c.; the serpents, with an observation that they may be placed at the side of the lizards,

as resembling them closely, if we suppose the lizards to be lengthened and deprived of their feet. The frogs are also often mentioned. Aristotle was quite aware of the generation of most of this class; he knew that the viper was ovoviviparous, and states that it brings forth its young alive, having produced an egg internally (*ὁ μὲν ἔχουσιν ἔσω ὥσπερ ὄντα, ἐν αὐτῷ πρῶτον ὠοτόκους*); and he indicates what animals should be designated as *Amphibia*.

Pliny writes much and elegantly concerning this class; but the best of his observations are borrowed from Aristotle, and his far from well-digested compilation is mixed up with so great a portion of error and so large a measure of credulity, as justly to merit the censure passed by Cuvier on this voluminous and pleasant author, but too often fabulous natural historian.

Darkness settles on the period from the fourth to the ninth century as far as the history of the sciences is concerned; but at that epoch the best Greek works were translated by the Arabs, who thus handed on the most curious known facts, especially those which had any reference to the art of medicine. Again there is a great void till the early part of the sixteenth century, when France produced Belou and Rondeletius, Italy Salviani, and Switzerland that prodigy of erudition, as he is designated by Boerhaave, Conrad Gesner. Two of Gesner's books are devoted to the natural history of reptiles—lib. ii., 'De Quadrupedibus Oviparis'; and lib. v., 'De Serpentiis Naturalibus'.

Towards the end of the same century Aldrovandus appeared. The results of fifty years' research in collecting objects of natural history, the drawings which he caused to be made of them, and his diligent studies relative to every point bearing on their history, appeared after his death, which happened in 1605, in fourteen volumes folio. The two books upon serpents and lizards do not appear to have been published till 1640, when they were given to the world by Professor Ambrosini of Bologna: twenty-two chapters are occupied by the serpents, and six only are dedicated to basilisks, dragons, and other lizards, the greater part of which however are fabulous.

Jonston's 'Historia Naturalis,' edited by Henry Ruysch, son of the celebrated anatomist, under the title of 'Theatrum Universale Omnium Animalium,' is principally a selection of the remarks of those who preceded him, and he has but few observations which can be called his own; still fewer indeed than Aldrovandus, who does not abound in originality.

But it is to our countryman John Ray that we owe the first arrangement which can be truly called systematic: in his 'Synopsis Methodica Animalium Quadrupedum et Serpenti Generis,' which first appeared in 1693, we have a classification based on the mode of respiration, the volume of the eggs, their colour, &c. This basis is not indeed strengthened by any description of the habits or organisation of the reptiles on which he treats, and cannot but be considered as insufficient; still it is valuable, and has the merit of leading the way to more accurate methods.

The *Amphibia* form, in the last edition of the 'Systema Naturæ,' published by Linnæus himself, the third class of the animal kingdom. This class consists of three orders:—

1. *Reptiles*, which are described as 'pedati, spirantes ore.'
2. *Serpentes*, which are characterised as 'apodes, spirantes ore.'
3. *Nantes*, which are characterised as 'pinnati: epiantes etiam branchiis lateralibus.'

The last order, which consists of cartilaginous and other fishes, forms no part of our present inquiry, which is confined to animals included in the two first.

The Reptiles are thus designated:—'Os respirans pulmonibus. Pedes quatuor:—and they consist of the genera *Testudo* (Land, Marine, and Fresh-Water Tortoises); *Rana* (Frogs and Toads); *Draco* [DRACONINA]; and *Lacerta*, which includes the Crocodiles and the rest of the Saurians.

The *Serpentes* have the following general character:—'Os respirans tantum pulmonibus. Pedes nulli, pinnæ natatorie nullæ. Aures nullæ; and they comprise the following genera:—*Crotalus* (the Rattle-Snakes); *Boa* (Boas and Pythons); *Coluber*, including all serpents which have abdominal scuta and subcaudal scales, whether poisonous or not; *Anguis*, including the Slow-Worms, *Bipes* and other serpents, the poisonous *Cerastes*, &c.; *Amphibena*; and *Cecilia*.

The work on Oviparous Quadrupeds, published by Klein in 1751—'Quadrupedum Dispositio Brevisque Historia Naturalis'—requires hardly any notice, and another which made its appearance in 1755—'Tentamen Herpetologiæ'—deserves as little. The latter, notwithstanding its extensive title, treats only of serpents; and the value of the criticisms of this opponent—he cannot be called rival—of Linnæus may be appreciated by his arranging in the same category the Earth-Worms, Tape-Worms, and Leeches.

But it is to the 'Specimen Medicum' presented by Laurenti at Vienna, in order to obtain the degree of Doctor, that we must look for the first well-digested history of reptiles. This remarkable work, which omits the Tortoises, but, in other respects may be said to have formed an era in the science of Herpetology, is divided into two parts: the first relates entirely to the natural history and characters of the genera; the second is devoted to specific descriptions, and the record of experiments made to detect the existence of poison in some species, and the effect of remedies in certain cases. But though this most able treatise is always quoted as that of Laurenti, it has been

attributed to Winterl, a distinguished chemist of Vienna, whose name appears oddly in the last page of the work as having been the assistant of Laurenti—or rather his 'collaborateur'—in his therapeutic experiments.

Though Scopoli devoted but a few pages to the Reptiles, his observations must not be passed by. The pupil of Linnaeus, he showed himself worthy of his master: but at the same time he appears in his arrangement to have been fettered by the principles adopted by the great Swede, though he varied the application of them.

The Count Lacépède (1788-90) divided the Reptiles into three great groups:—

1. Oviparous Quadrupeds, subdivided into (1) those which possess a tail, and (2) those which are tailless.
2. Biped Reptiles.
3. Serpents.

In 1799 the method of M. Alexandre Brongniart was read to the French Academy of Sciences, and it seems to have been first published in the 'Bulletin des Sciences,' in 1800; it was afterwards printed among the other Memoirs of the National Institute. His classification may be regarded as a considerable step in advance of those who had preceded him, and had principally confined themselves to external characters, well defined doubtless, but of little moment when compared with those based on organisation and habits. Whilst they carefully attended to the presence or absence of tail or feet, they neglected those essential points which spring from generation and development. Brongniart pointed out the approximation of the Tortoises to the Lizards, and even to the Serpents, and was the first to show that the Toads, Frogs, and Salamanders, ought to constitute a separate order.

M. Brongniart recognised the following orders:—

1. Chelonians (Tortoises).
2. Saurians (Lizards).
3. Ophidians (Serpents).
4. Batrachians.

The method of Lacépède seems to have found more favour in the eyes of M. Latreille than that of M. Alex. Brongniart, which last must have been known to the former when he published his 'Natural History of Reptiles,' in 1801. He places in his first division the Oviparous Quadrupeds, whose body is provided with feet, dividing them into two sections, according as they have unguiculated or clawless toes, and a scaleless skin. His second division is formed by the Serpents; and in his third, designated by the name of Pneumobranchians, he places the genera *Proteus* and *Siren*, as well as another, which he names *Ichthyosaurus*, which last is only a Tadpole.

In 1825, when the science had very much advanced, M. Latreille, in his 'Families of the Animal Kingdom,' published another arrangement, which Messrs. Duméril and Bibron have digested into the following table:—

HEMACRYMES PULMONÉES.			
CLASSES.	SECTIONS.	ORDERS.	FAMILIES.
Reptiles.	Cuirassé	Chelonians	Cryptopods (<i>Testudo</i> , &c.).
		Emydoursians	Gymnopods (<i>Sauropsis</i> , <i>Trionyx</i> , &c.).
	Saurians		Crocodylians (<i>Crocodylus</i> , &c.).
		Lacertiform	Lacertians (<i>Monitor</i> , &c.).
			Iguanians (<i>Iguana</i> , &c.).
			Geckotians (<i>Gecko</i> , &c.).
	Anguliform		Chameleoniens (<i>Chamaeleo</i> , &c.).
			Tetrapods (<i>Scincus</i> , <i>Seps</i> , <i>Chalcides</i>).
	Scaly		Dipods (<i>Bipes</i> , <i>Bimanus</i>).
			Apods (<i>Anguis</i> , <i>Ophisaurus</i> , &c.).
Amphibia.	Saurians		Amphibaniens (<i>Amphisbæna</i> , &c.).
			Cylindrical (<i>Triton</i>).
			Coluberians (<i>Acrochordus</i> , <i>Boa</i> , <i>Python</i> , &c.).
			Anguilliform (<i>Dongarus</i> , <i>Hydrophis</i> , <i>Pelamis</i> , &c.).
	Ophidians		Vipers (<i>Crotalus</i> , <i>Berus</i> , <i>Naja</i> , &c.).
			Gymnophidians (<i>Cecilia</i>).
	Batrachophida		Anurous (<i>Pipa</i> , <i>Bufo</i> , <i>Rana</i> , &c.).
			Urodeles (<i>Salamandra</i> , <i>Triton</i> , <i>Axolotl</i>).
	Perennibranchians		Ichthyoids (<i>Proteus</i> , <i>Siren</i>).

In 1802 and 1803 appeared the 'Traité Général' of Daudin. In this distinguished work the method of M. Alexandre Brongniart is followed, in so far as the division of the Reptiles into four orders. In the three sections of Chelonians 57 species are named and described. In the order Saurians, Daudin first places *Crocodylus*, with its three sub-genera [*Crocodylinae*], and then the genera *Draco*, *Tupinambis* (in which he describes several new species), *Lacerta* (subdivided into the Ameivas, the Collared, Ribanded, Spotted, Gray, Dracénoid, and Striated Lizards)—31 species in all, and including the genera *Trachydromus*, *Draco*, *Basiliscus*, and *Agama* (which last is subdivided into five sections), *Seps*, and *Chalcides*. The third order, Ophidians, contains numerous and natural genera, some of them rather overloaded, *Coluber* for instance, under which 172 species are arranged; and others with only one or two. The fourth order, Batrachians, appears to have employed his particular attention. [*Amphibia*.] He includes *Salamandra* and *Triton* in one genus, and assigns a single species to the genera *Proteus* and *Siren*. Such is a mere sketch of the great work of Daudin, founded, as he himself declares, upon his personal examination and study of 517 species.

In the short notice published by George Cuvier, in his 'Tableau Elémentaire de l'Histoire Naturelle' (1798), he divided the Reptiles, like Lacépède, into Oviparous Quadrupeds, Serpents, and Biped Reptiles.

Oppel (who had been a diligent attendant at M. Duméril's course of lectures in 1807 and 1808, and in whose works much of the lessons of the latter are to be traced, as Oppel himself acknowledges), after publishing in the 19th volume of the 'Annales du Muséum,' a Memoir on the Ophidians, and another on the Batrachians, produced, in 1811 at Munich, his treatise 'Die Ordnungen, Familien, und Gattungen der Reptilien, als Prodom einer Naturgeschichte derselben' (thin 4to.).

The following synoptical table exhibits Oppel's method:—

REPTILIA . . .	Testudinata	{ Chelonii. Emydæ.
	Saurii	{ Crocodylini. Geckoides. Iguanoides. Lacertini. Scincoides. Chalcidii.
	Squammata	{ Anguiformes. Hydri. Crotalini. Viperini. Constrictores. Pseudovipera. Colubrin.
	Ophidii	
	Nuda	{ Apoda. Caudata. Ecaudata.

In 1790 Merrem published a paper in German, with the title of 'Materials for a Natural History of Amphibia,' and in 1820 and 1821 two other papers followed. These papers treat of serpents and several genera of Saurians, and are illustrated with coloured plates. But his system appears to have been published (in 1800) at the suggestion of Bechstein, who had translated Lacépède's 'History of Reptiles' into German; and in 1820 a second edition of this system, which is shown in the following table, made its appearance:—

CLASSES.	ORDERS.	TRIBES.	SUBDIVISIONS.
PHOLIDOTA	Testudinata	with feet	{ Pinniform. Digitated.
	Loricata (Crocodyles)		
	Gradientia		{ Acalabota. Sauræ. Chalcidict.
	Repentia (Anguis, Ophisaurus, Acontias).		
	Squammata		
	Serpentia		{ Gulonæ { Innocui. Typhlini. Pernati.
	Incedentia (Chirotes).		
	Trendentia (Chamaeleon).		
	Apoda (Cæcilia).		
	Salientia (Rana, &c.).		
BATRACHIA		with eyelids	{ Mutabilia (Salamandra, &c.).
		without eyelids	{ Amphipneusta (Hypocothon, or Proteus).

M. De Blainville, in 1816, published in the 'Nouveau Bulletin des Sciences de la Société Philomatique,' the prodromus of his systematic distribution of the animal kingdom, which he produced, in 1822, in his 'Principes d'Anatomie Comparée.' Under the type *Osteozoa*, and the sub-type *Ovipara* or *Amastozoa*, he places the Reptiles, which he divides into two classes, namely—1, Reptiles or Ornithoid Squamifera; 2, Amphibians or Nudipellifera, Naked Ichthyodians.

The First Class is separated into three orders:—

I. Chelonians, consisting of the genera *Testudo*, *Emys*, *Chelys*, *Trionyx*, *Chelonia*, and *Dermochelys* (Sphargis).

II. Emydosaurians, or Crocodiles, divided into three sub-genera.

III. Saurorhians, or Bipennians, which are separated into two sub-orders:—

A. Saurians, consisting of the families of Geckoidians, Agamoidians (the Normal, as *Agama* and *Basiliscus*, and the Anormal, as *Chamaeleo* and *Draco*), the Iguanoidians, *Tupinambis*, and the Lacertoidians (divided into Tetrapods, Dipods, and Apods).

B. Ophidians, which are divided into—

1. The Dipods (Chirotes).

2. Apods:—*a* (with numerous teeth), *Pelamys*, *Hydrophis*, the Vipers, and the Lethifers; *B* (without venomous teeth), the Amphisbænas, the Climbers or Boas, and the Colubers.

The Second Class, Ichthyoid or Nudipelliferous Amphibians, is composed of four orders:—

1. The Batrachians, divided into two sub-orders—*a* (Aquiparous), *Rana*, &c.; *B* (Dorsigerous), *Pipa*.

2. The Pseudosaurians or Salamanders.

3. The Subichthyans, or True Amphibians (*Proteus*, *Siren*).

4. The Pseudophidians (*Cæcilia*).

Dr. John Edward Gray published in 1825 his 'Synopsis of the Genera of Reptiles and Amphibia,' in the 'Annals of Philosophy.' He considers the Reptiles, or scaly-skinned group, and the Amphibia, or naked-skinned group, as distinct classes.

The class *Reptilia* are thus divided:—

§ I. Body covered with imbedded hard plates; legs distinct, fit for walking. *Loricata*, Gray, not Merrem.

Order I. *Emydosauri*, De Blainville.

Families.—1, *Crocodylidae*; 2, *Ichthyosauridae*; 3, *Plesiosauridae*.

Dr. Gray thinks that *Megalosaurus* of Buckland is perhaps allied to this order.

Order II. *Sauri*, De Blainville.

Section 1. Tongue not extensible. *Ascalabota*, Merrem.

Families.—1, *Stellionidae*; 2, *Geckotidae*.

Section 2. Tongue extensible. *Sauræ*, Merrem.

Families.—3, *Tupinambidae*; 4, *Lacertinidae*; 5, *Chamaeleonidae*.

Order III. *Saurorhidi*, Gray.

Section 1. Body covered with imbricate scales; anus transverse, not terminal; tongue extensible.

Families: 1, *Scincidae*, Gray; 2, *Anguidae*.

Section 2. Body covered with intricate (imbricate?) scales; anus terminal.

Family: 3, *Typhlopidae*, Gray.

Section 3. Body covered with rings of square scales.

Families: 4, *Amphisbæniidae*, Gray; 5, *Chalcididae*.

Order IV. *Ophidii*, Brongn. (*Serpentes*, Linn.)

Section 1. Upper jaws with fangs only. *Venati*. (*Venenati* must be meant.)

Families: 1, *Crotalidae*; 2, *Viperidae*.

Section 2. Upper jaw with teeth, and with or without fangs; oviparous.

Families: 3, *Hydridæ*; 4, *Colubridæ*; 5, *Boidæ*.

Order V. *Chelonii*. (*Testudinata*, Oppel.)

Section 1. Feet and head retractile into the carapace; carapace solid, covered with horny scales. *Cryptopodi*.

Families: 1, *Testudinidae*; 2, *Emydidae*, Bell.

Section 2. Feet and head not or only partly retractile into the carapace; carapace mostly soft. *Gymnopodi*.

Families: 3, *Trionycidae*; 4, *Sphargidae*; 5, *Chelonidae*.

The following table of the affinity of Reptiles is given by Dr. Gray:—

Normal Groups.

Annexant Groups.

Order I.—*Sauri*.

1. *Stellionidae*.

2. *Geckotidae*.

3. *Lacertinidae*.

4. *Chamaeleonidae*.

5. *Tupinambidae*.

Order II.—*Emydosauri*.

1. *Crocodylidae*.

2. ———.

3. *Plesiosauridae*.

4. *Ichthyosauridae*.

5. ———.

Order III.—*Chelonii*.

1. *Testudinidae*.

2. *Emydidae*.

3. *Trionycidae*.

4. *Sphargidae*.

5. *Caretidae* (*Chelonidae*?)

Order IV.—*Ophidii*.

1. *Crotalidae*.

2. *Viperidae*.

3. *Hydridæ*.

4. *Colubridæ*.

5. *Boidæ*.

Order V.—*Saurorhidi*.

1. *Scincidae*.

2. *Anguidae*.

3. *Typhlopidae*.

4. *Amphisbæniidae*.

5. *Chalcidæ*.

The 'Neue Classification der Reptilien' of Fitzinger was published at Vienna in 1826. This work, the result of much anatomical and physiological study, has always held a prominent place in the history of Herpetology, and its leading principles will be seen in the following table:—

CLASS.	ORDERS.	TRIBES.	FAMILIES.
REPTILIA.	I. <i>Testudinata</i>	I. <i>Testudinata</i>	1. Carettoidea.
			2. Testudinoides.
	II. <i>Loricata</i>	II. <i>Loricata</i>	3. Emydoides.
			4. Chelydoidea.
	III. <i>Squamata</i>	III. <i>Squamata</i>	5. Trionychoides.
			6. Ichthyosauroides.
REPTILIA.	IV. <i>Nuda</i>	IV. <i>Nuda</i>	7. Crocodyloidea.
			8. Ascalabotoidea.
	V. <i>Mutabilia</i>	V. <i>Mutabilia</i>	9. Chamaeleonides.
			10. Pseudosauroides.
	VI. <i>Immutabilia</i>	VI. <i>Immutabilia</i>	11. Agamoides.
			12. Cordylidae.
REPTILIA.	VII. <i>Monopnoea</i>	VII. <i>Monopnoea</i>	13. Tachydromoides.
			14. Ophisauroidea.
	VIII. <i>Dipnoea</i>	VIII. <i>Dipnoea</i>	15. Chalcidoidea.
			16. Scincoides.
	IX. <i>Amphibioidea</i>	IX. <i>Amphibioidea</i>	17. Amphisbænoidea.
			18. Typhlopoidea.
REPTILIA.	X. <i>Scincoides</i>	X. <i>Scincoides</i>	19. Gymnophthalmoides.
			20. Ilysioides.
	XI. <i>Pythoidea</i>	XI. <i>Pythoidea</i>	21. Pythonoides.
			22. Colubroides.
	XII. <i>Bungaroides</i>	XII. <i>Bungaroides</i>	23. Bungaroides.
			24. Viperoides.
REPTILIA.	XIII. <i>Cæcilioidea</i>	XIII. <i>Cæcilioidea</i>	25. Crotaloides.
			26. Saurians and Ophidians.
	XIV. <i>Ranoides</i>	XIV. <i>Ranoides</i>	27. Cæcilioidea.
			28. Ranoides.
	XV. <i>Bufonoides</i>	XV. <i>Bufonoides</i>	29. Bufonoides.
			30. Bombinatoroides.
REPTILIA.	XVI. <i>Pipoides</i>	XVI. <i>Pipoides</i>	31. Pipoides.
			32. Salamandroides.
	XVII. <i>Cryptobranchioidea</i>	XVII. <i>Cryptobranchioidea</i>	33. Cryptobranchioidea.
			34. Phanerobranchioidea.
	XVIII. <i>Anguilla</i>	XVIII. <i>Anguilla</i>	35. Anguilla.
			36. True Serpents.
REPTILIA.	XIX. <i>Naked Serpents</i>	XIX. <i>Naked Serpents</i>	37. Naked Serpents.
			38. Batrachians.
	XX. <i>Batrachians</i>	XX. <i>Batrachians</i>	39. Batrachians.
			40. Batrachians.
	XXI. <i>Amphibia</i>	XXI. <i>Amphibia</i>	41. Amphibia.
			42. Amphibia.

The following is a synoptical table from the second edition of Cuvier's 'Règne Animal.'

		ORDERS.		FAMILIES.				
Heart with an Auricle.	Double	Limbs: Jaws	Horny, without teeth	Chelonians	Chelonians.			
			Toothed	Sanrians	Feet	Five before, four behind	Crocodylians.	
		Ordinary, toes to the number of				Five to four feet: Tongue	Bifurcated, extensible	Lacertians.
							Not extensible: Body	Ordinary
		Single	No Limbs	Ophidians	Skin	Flattened		Geckotians.
	Vermiform, very extensible					Chamaeleonians.		
	Very short, or to the number of four at least					Scincoidians.		
	Scaly: Eye					With three eyelids	Anguis.	
						Without a third eyelid	True Serpents.	
				Naked	Naked Serpents.			
				Batrachians.				

Messrs. Carus and Ficinns have, in their zoological arrangement, adopted very nearly the classification of Merrem and the principles of Oken for the Reptiles.

In the method proposed by Dr. Harlan, in the 'Journal of the Academy of Natural Sciences of Philadelphia,' he adopts the four orders of Batrachians, Ophidians, Saurians, and Chelonians.

In 1828 Ritgen's classification of Reptiles appeared in the 'Nova Acta Nat. Cur.,' to which we refer those of our readers who may wish to consult it. This classification is not much attended to.

Wagler published his 'Naturalisches System der Amphibien,' founded upon the organisation of the animals, at Munich in 1830.

In this system the *Amphibia* consist of eight orders:—1, the Tortoises; 2, the Crocodiles; 3, the Lizards; 4, the Serpents; 5, the Urrets; 6, the *Cecilia*; 7, the Frogs; and 8, the Ichthyodes.

In 1832 Professor Müller of Bonn published his 'Beiträge für Anatomie und Naturgeschichte der Amphibien.' ('Zeitschrift für Physiologie von Tiedemann und Treviranus,' Heidelberg.) Much interesting detail relating to the history of reptiles is here entered into, but the Professor treats more especially of the Batrachians and Serpents. He divides the *Amphibia* into two great orders, consisting of the scaly and the naked.

Scaly *Amphibia*.

Occipital condyle simple	Occipital condyle double.
True ribs	None or rudimental.
Auricle of the heart double	Single.
Internal ear with round and oval fenestrae	Oval only.
With a distinct cochlea	None.
Penis of the males simple or double	None.
No metamorphosis	Most frequently a distinct metamorphosis.
No branchiae	Distinct branchiae, or with persistent or not permanent holes.
Skin scaly, scutcheoned, or cuirassed	Naked.

Naked *Amphibia*.

Professor Müller divides the Serpents in accordance with their anatomical structure.

The Microstomes, or those which have a not dilatible mouth, correspond very nearly to the Homoderms of M. Duméril. They are separated into four families:—1, the Amphibeneids; 2, the Typhlepias; 3, the Uropeltaceans; 4, the Tortriculans.

The second sub-order (Macrostomes) corresponds with the Heteroderms of M. Duméril. These are divided into seven families:—1, the Oligodonts; 2, the Holodonts (*Python*, &c.); 3, the Isodonts (*Boa*, *Pseudoboa*, &c.); 4, the Heterodonts (*Dendrophis*, *Coronella*, &c.); 5, Amphiboles (*Dryophis*, *Dipsas*, &c.); 6, the Antiochalinans (*Bongarus*, *Naja*, &c.); and 7, the Serpents with three sorts of teeth, and in which all the mandibular teeth are perforated and venomous (*Elaps*, *Scytale*, *Crotalus*, &c.).

In 1833 the first part of Schinz's 'Naturgeschichte und Abbildungen der Reptilien' was published at Leipzig; in 1834 it was concluded. It brings down the information to the time of its publication, is well digested and well illustrated with coloured figures of the true reptiles and amphibians, mostly from good originals, but some from nature, and will be found very useful, especially as a book of reference.

Mr. Swainson ('Natural History of Fishes, Amphibians, and Reptiles,' in Lardner's 'Cyclopædia') places the *Amphibia* and the *Reptilia* in different classes.

He gives the following as "a natural arrangement of the class of *Amphibia*, according to Professor Bell:—

Order 1. *Amphipneura* (*Amphipneusta*!) (*Proteus*, *Siredon*, *Menobranchus*, *Siren*, *Pseudobranchius*). Order 2. *Anoura* (Frogs and Toads). Order 3. *Urodela* (*Salamandrina*, *Salamandra*, *Tritonella*, *Molge*). Order 4. *Abranchia* (*Menopoma*, *Amphiuma*). Order 5. *Apoda* (*Cecilia*).

The same author gives the following as a 'Synopsis and Natural Arrangement of the Class of Reptilia:—

Order 1. *Emydosaures*—Crocodiles (*Crocodilus*, *Champsä*, *Stenosaurus*). Order 2. *Chelonides*—Tortoises (Families: *Chelidridæ*, *Crocodile* *Tortoises*; *Testudinidæ*, *Land* *Tortoises*; *Emydræ*, *River* *Tortoises*; *Trionycidæ*, *Soft* *Tortoises*; and *Chelonidæ*, *Sea* *Turtles*). Order 3. *Elanosaures* (*Eraniosaures*!)—Fish Lizards (*Plesiosaures*, *Ichthyosaures*, *Sauropscephalus*, *Pterodactylus*). Order 4. *Ophides*—the Serpents (Families: *Hydrophidæ*, *Water* *Serpents*; *Crotalidæ*, *Poisonous* *Serpents*; *Coluberidæ*, *Snakes* *not* *poisonous*; *Anguidæ*, *Slow-Worms*; and *Amphibienidæ*, *Blind-Worms*). Order 5. *Saures*—the Lizards (Families: *Chamaeleonidæ*; *Iguanidæ*, *Thick-Tongued* *Lizards*; *Laceridæ*, *Slender-Tongued* *Lizards*; *Agamidæ*; and *Scincoidæ*).

In the same year Professor Bell published his interesting 'History of British Reptiles.' He considers the *Reptilia* and *Amphibia* as distinct classes, and justifies his opinion by a reference to their characters, which appear to him to be sufficiently marked and important to warrant their separation.

Dr. J. E. Gray has more recently developed his classification in

the very valuable British Museum Catalogues. Those devoted to the *Reptilia* are not yet completed.

With the exception of the Paris collection, that of the British Museum is more rich in *Reptilia* than any other public or private museum.

RESEDA'CEÆ, a natural order of Plants belonging to the class of Exogens. It has a many-parted calyx; the petals unequal, of broad fleshy plates having lacerated appendages at the back; an hypogynous one-sided glandular disc; definite stamens inserted into the disc, the filaments erect, the anthers 2-celled, opening longitudinally; a 3-lobed 1-celled many-seeded sessile ovary, scarcely closed, usually with 3-6-parietal placentæ, sometimes surrounding a free central ovule-bearing body; 3 glandular sessile stigmas; campulitropal or amphitropal ovules; the fruit dry and membranous or succulent, opening at the apex, or apocarpous, with empty carpels surrounding a central placenta, or even hooded and 1-seeded; the seeds seveal, reniform, with a taper arcuate embryo without albumen, and a radicle next the hilum. The species of this order are soft herbaceous plants, or in a few instances small shrubs with alternate entire or pinnately-divided leaves, and minute gland-like stipules. The flowers in racemes or spikes. They are natives of Europe, the adjoining parts of Asia, the basin of the Mediterranean, and the adjacent islands. A few species occur in the north of India, the Cape of Good Hope, and California.

This order embraces the genera *Reseda*, *Ochradenus*, *Oligomeris*, *Holoptalum*, *Atrocarpus*, and *Caylusea*.

R. odorata is the Common Mignonette. It has lanceolate bluntish entire or trifid leaves; a 6-parted calyx equal in length to the petals, which are finely cleft into many club-shaped divisions, the two lowest simple, the capsules 3-toothed. It is a native of the North of Africa and Egypt, but its delicious fragrance has caused it to be cultivated all over the world. It is naturally an herb, but when trained in the greenhouse it becomes shrubby. The arborescent form of this plant is called Tree-Mignonette. [MIGNIONETTE, in ARTS AND SC. DIV.]

R. luteola, Weld, Wood, or Woad, is a British species. It is known by its elongate-lanceolate undivided leaves. [WOOLD, in ARTS AND SC. DIV.]

R. lutea has 3-cleft or pinnatifid leaves.

R. suffruticulosa is a rare British plant with the leaves all pinnatifid. It grows near the sea.

RESINS. [SECRECTIONS OF PLANTS.]

RESPIRATION is that function in the animal kingdom by means of which the various tissues of the body are exposed to the chemical influence of the gases of the atmosphere, and the products thus formed expelled from the body. The advance of chemical knowledge has demonstrated that this function is one essentially of oxidation, and hence it has been proposed to consider all cases of oxidation in organic bodies as instances of respiration. Such an extension of the use of the term has led to its application to plants as well as animals. It should however be remembered that the older physiologists applied the term Respiration to that function of plants by which they take up carbonic acid and give out oxygen, and which was regarded as an equivalent process to the taking up of oxygen and disengaging carbonic acid in animals. It was subsequently found that plants, during certain processes, gave off carbonic acid and absorbed oxygen gas; and it was hence inferred that plants performed a function essentially the same as that effected in animals by the oxidation of carbon in respiration.

The cases in which plants have been observed to consume oxygen and throw off carbonic acid are as follows:—1. During the growth of the order *Fungi*. 2. During the growth of the leafless parasites. 3. During night by most plants. 4. During the active growth of the *Conifera*. 5. During the flowering of most plants. 6. During the germination of plants.

This process has been observed to be attended with the same results in certain of these cases, as in the respiration of the higher animals, that is, with the disengagement of heat. [HEAT, VEGETABLE.] When the process of oxidation takes place rapidly, disengagement of heat is the necessary result. That these phenomena take place cannot be doubted, but the propriety of classing them with those of the respiration of animals must be questioned, and on these grounds:—

1. The oxidation that takes place in the vegetable kingdom is not a constant phenomenon, but only occurs occasionally in the life of the plant. It is during the latter stages of the growth of *Fungi* that it is observed, when it may be supposed that these plants are entering upon a stage of decay. The oxidation in the *Conifera* arises from their secreting resinous matters, which unite readily with oxygen. Again, in the flowering of plants it is only an occasional and exceptional phenomenon in the life of plants. The carbonic acid given out by plants at night can be quite as readily accounted for on the supposition that a certain quantity of the carbonic acid taken up in the day has been undecomposed, and is given out at night, as on the theory of its being the result of oxidation. So likewise in germination, the carbonic acid given off is not the result of a process of life in the young embryo, but of a process of decomposition going on in the starch of the albumen by which it is surrounded. [GERMINATION.]

2. If the term Respiration is to be applied to the evolution of carbonic acid, and absorption of oxygen gas from the fluids of organic beings wherever found, then it must be used to comprehend the processes of fermentation, putrefaction, and cremecausis, which take

place either out of the structure of organic beings, or in their interior. The carbonic acid given off from food in the stomach or intestines ought not most assuredly to be regarded as the result of respiration, yet this would be the case if we accepted a mere chemical definition of respiration.

Respiration then appears to be a purely animal process, by which the fluids of the animal are brought into contact with the oxygen of the air, the final result of which is the discharge of carbonic acid gas. This process is continuous in the animal kingdom; and in the great majority of cases in the higher animals, if it be suspended for a few minutes the animal dies. When an animal dies from being deprived of oxygen gas, it is said to be suffocated.

In the higher animals special organs are provided for the performance of that portion of this function which consists in the taking up of oxygen gas directly from the atmosphere, and allowing the carbonic acid to escape. Hence these arrangements have been called Organs of Respiration. It should however be understood that the chemical changes involved in the disappearance of the oxygen, and the appearance of the carbonic acid, are carried on in the tissues themselves. The lungs, gills, or sacs, are organs where the blood receives the oxygen gas, and gets rid of its carbonic acid; whilst the capillaries of the systemic circulation are the organs by which the blood gets rid of its oxygen, and the tissues their carbonic acid. The process of respiration then is the same in the highest as in the lowest animals, with this exception, that in the lowest animals there are no organs of circulation, and no organs of ventilation, as the lungs and gills may be called, for conveying the oxygen and carbonic acid to and from the tissues.

The absorption of oxygen by the animal cell seems to effect three great objects:—1. The preparation of the materials taken up as food for the purposes of nutrition. 2. The removal of certain constituents which have been employed in nutrition, and destroyed during the performance of the function of the part. 3. The production of heat, arrangements for the accumulation of which are made in the higher animals, which are from this circumstance called warm-blooded. [HEAT, ANIMAL.]

That the performance of one or other of these functions is essential to the life of animals is seen from the fact that, should the supply of oxygen to the tissues of animals be limited or suspended, they exhibit deficient vitality or die. It is not only one function of the animal body that is affected by this deprivation, but all; so that we find the amount of oxidation performed by this process becomes the exponent of the amount of vital activity displayed by any particular animal, or class of animals. When the functional activity of an animal is great it consumes more oxygen, and gives off more carbonic acid, than when it is small. Thus, in animals which hibernate, the amount of oxygen consumed, and carbonic acid given out, is much less during their period of repose than during their period of activity. Sluggish and slow-moving animals consume less oxygen than those which are active. Thus the *Mollusca* consume less oxygen than the various tribes of active insects. It is also found that animals whose movements are slow will support the absence of oxygen gas for a very much longer time than those whose movements are quick.

Under the head of the various articles devoted to the classes and families of animals some account is given of the general character and structure of what are called the Respiratory Organs. In the lowest forms of animals, the *Infusoria*, the whole surface of the animal is exposed to the fluid in which they live, and which contains the oxygen necessary to produce the respiratory changes. When a number of cells are congregated together, as in the sponges, and cavities or tubes are formed, special provision is made by means of cilia, or molecular movements, for carrying the fluid into these cavities, or tubes, as seen in many of the polygastric animalcules and the sponges. Passing higher in the forms of radiate animals, as in the *Polypifera*, we find the arrangements for introducing water into the interior of the animal becoming more complicated, till in the *Holothuriadae* we find a special system of vessels for supplying this fluid, which have been called an 'aquiferous,' or 'water vascular system,' and which becomes more fully developed in the *Entozoa*, the lowest tribe of the *Articulata*.

These arrangements amongst the lower animals are preparatory to the two predominant forms of respiratory apparatus which are found in the higher animals. The provision for supplying the system with oxygen is in them made by means of a fluid called blood, and which is carried by a circulating apparatus to all parts of the body. [BLOOD; HEART.] This circulating apparatus brings the blood in contact with the air by one of two arrangements. Either the aerating organ is a projection from the surface of the body, when it is called a Gill; or it is a depression in the surface, when it is called a Sac or Lung. The first of these arrangements is found in all animals which breathe through the agency of water, whilst the second is found in those which breathe air. [LUNGS.] In the Aquatic *Mollusca*, the *Cirripedia*, the *Annelida*, the *Crustacea*, the aquatic larvae of insects, the fishes, the tadpole condition of the *Amphibia*, and the perennibranchiate forms of that family, we meet with a vast variety of forms of gills adapting these animals to lead an aquatic existence. On the other hand, we find in the Terrestrial *Mollusca* and the Insects the simplest forms

of air-breathing apparatus; whilst in the Reptiles, the Birds, and *Mammalia*, we have varied forms of lungs.

Man breathes by means of lungs. The structure and arrangement of those organs, and the nature of the movements performed by the muscles which contribute to the performance of their peculiar function, are described under the article LUNGS. The lungs of man are so constructed that they are alternately expanded and contracted. During each expansion, a certain quantity of air is taken into the lungs, and this act is called Inspiration. This expansion is followed by a corresponding collapse, during which the lungs occupy a smaller space, and a certain quantity of air is expelled—this is called Expiration. The quantity of air changed in the human lungs at each respiratory effort varies. It is however easily measured by blowing into a vessel filled with water or other fluid, when the amount of fluid displaced will be the measure of the quantity of air thrown out from the lungs. Instruments of this kind, with an index attached, under the name of Spirometers, are now frequently employed as a means of diagnosis in diseases of the chest. The difficulty however of securing freedom from disturbing causes renders their results less to be depended on than could be wished. The quantity of air thrown out from the lungs has been variously estimated, but probably from 20 to 25 cubic inches is near the truth. Scharling conducted a series of experiments on the quantity of carbonic acid thrown out of the lungs by persons of different sexes and various ages. The following table gives an idea of the average relations of the excretion of carbonic acid gas during one hour:—

Subject.	Age.	Weight.	Carbonic Acid expired in one hour.	Amount of Carbonic Acid expired in one hour for each 1000 grammes' weight.
	Years.	Kilogrammes.	Grammes.	Grammes.
Man . . .	35	65.50	33.530	0.5119
Youth . . .	16	57.75	34.280	0.5887
Soldier . . .	23	82.00	36.623	0.4466
Girl . . .	17	55.75	25.342	0.4546
Boy . . .	9½	22.00	20.338	0.9245
Girl . . .	10	23.00*	19.162	0.8331

The air that is habitually and almost uniformly changed in breathing is by Mr. Hutchinson called Breathing Air. "The quantity over and above this which a man can draw into the lungs in the deepest inspiration he names Complementary Air; its amount is various, as will be presently shown. After ordinary expiration, such as that which expels the breathing air, a certain quantity of air remains in the lungs, which may be expelled by a forcible and deeper expiration: this he terms Reserve Air. But even after the most violent expiratory effort the lungs are not completely emptied; a certain quantity always remains in them, over which there is no voluntary control, and which may be called Residual Air. Its amount depends in great measure on the absolute size of the chest, and has been variously estimated at from 40 to 260 cubic inches.

"The greatest respiratory capacity of the chest is indicated by the quantity of air which a person can expel from his lungs by a forcible expiration after the deepest inspiration that he can make. Mr. Hutchinson names this the Vital Capacity: it expresses the power which a person has of breathing in the emergencies of active exercise, violence, and disease; and in healthy men it varies according to stature, weight, and age.

"It is found by Mr. Hutchinson, from whom nearly all our information on this subject is derived, that at a temperature of 60° Fahr., 225 cubic inches is the average vital capacity of a healthy person 5 feet 7 inches in height. For every inch of height above this standard the capacity is increased on an average by 8 cubic inches; and for every inch below it is diminished to the same amount. This relation of capacity to height is quite independent of the absolute capacity of the cavity of the chest; for the cubic contents of the chest do not always or even generally increase with the stature of the body, and a person of small absolute capacity of chest may have a large capacity of respiration, and vice versa. The capacity of respiration is determined only by the mobility of the walls of the chest; but why this mobility should increase in a definite ratio with the height of the body is yet unexplained, and must be difficult of solution, seeing that the height of the body is chiefly determined by that of the legs, and not by that of the trunk or the depth of the chest. But the vast number of observations made by Mr. Hutchinson leave no doubt of the fact as stated above.

"The influence of weight on the capacity of respiration is less manifest and considerable than that of height; and it is difficult to arrive at any definite conclusions on this point, because the natural average weight of a healthy man in relation to stature has not yet been determined. As a general statement however, it may be said

* The kilogramme=2.205 lbs. very nearly. The gramme=15.434 grains.

that the capacity of respiration is not affected by weights under 161 lbs., or 11½ stones; but that above this point it is diminished at the rate of one cubic inch for every additional pound up to 196 lbs., or 14 stones; so that, for example, when a man of 5 feet 6 inches, and weighing less than 11½ stones, should be able to expire 217 cubic inches, one of the same height, weighing 12½ stones, might expire only 203 cubic inches.

"By age the capacity appears to be increased from about the 15th to the 35th year, at the rate of five cubic inches per year; from 35 to 65 it diminishes at the rate of about a cubic inch and a half per year, so that the capacity of respiration of a man 60 years old would be about 30 cubic inches less than that of a man 40 years old of the same height and weight.

"Mr. Hutchinson's observations were made almost exclusively on men, and his conclusions are perhaps true of them alone; for women, according to Bourguery, have only half the capacity of breathing that men of the same age have.

"The number of respirations in a healthy adult person usually ranges from 14 to 18 per minute. According to Mr. Hutchinson, the force with which the inspiratory muscles are capable of acting is greatest in individuals of the height of from 5 feet 7 inches to 5 feet 8 inches, and will elevate a column of three inches of mercury. Above this height the force decreases as the stature increases, so that the average of men of 6 feet can elevate only about 2½ inches of mercury. The force manifested in the strongest expiratory act is, on the average, one-third greater than that exercised in inspiration; but this difference is in great measure due to the power exerted by the elastic reaction of the walls of the chest, and it is also much influenced by the disproportionate strength which the expiratory muscles attain through being called into use for other purposes than that of simple expiration. The force of the inspiratory act is therefore better adapted than that of the expiratory for testing the muscular strength of the body.

"Much of the force exerted in inspiration is employed in overcoming the resistance offered by the elasticity of the walls of the chest and of the lungs. Mr. Hutchinson estimated the amount of this elastic resistance by observing the elevation of a column of mercury raised by the return of air forced, after death, into the lungs, in quantity equal to the known capacity of respiration during life; and he calculated that in a man capable of breathing 200 cubic inches of air, the muscular power expended upon the elasticity of the walls of the chest, in making the deepest inspiration, would be equal to the raising of at least 301 lbs. avoirdupois. In tranquil respiration, supposing the amount of breathing air to be 20 cubic inches, the resistance of the walls of the chest would be equal to lifting more than 200 lbs. The elastic force exerted in ordinary expiration must therefore be much greater than enough to lift this weight; because in it the elastic force of the lungs is also in action—a force which is not included in these estimates, because the lungs were in both cases burst by the air forced into them." (Kirkc and Paget, 'Handbook of Physiology'.)

The changes of the air in the lungs effected by the respiratory movements are assisted by the air itself. It is a well-known fact that carbonic acid, although heavier than atmospheric air, is speedily diffused through it, according to the known laws of the diffusion of gases. There is no doubt that this law is in active operation during the respiratory changes, and that it assists the oxygen in passing into the lungs, and the carbonic acid in passing out. If it were not for this interchange the reserve and residual air would probably be injuriously charged with carbonic acid. It is also probable that the difference of temperature within and without the lungs assist in the interchange of the air.

The air which is taken into the lungs during respiration is the air of the atmosphere, which in round numbers consists of 21 of oxygen, and 79 of nitrogen in every 100 parts. A small proportion of carbonic acid exists in it, about 4 parts in 10,000. It also contains a varying quantity of watery vapour. The changes which occur in this air during respiration are—1. It contains a larger quantity of carbonic acid gas. 2. Its oxygen is diminished. 3. Its watery vapour is increased.

An easy proof of the existence of carbonic acid in the air expired from the lungs, is afforded by blowing through a tube into lime water, when the carbonic acid will unite with the lime, and carbonate of lime will be precipitated. The quantity of this gas which is calculated by Valentin and Brunner, as thrown out from the lungs in 24 hours, is 1345·3 cubic inches, or about 636 grains an hour. This would make about 173 grains of carbon in an hour, or 8 ounces in the 24 hours. Andral and Gavarret calculated the quantity at 9 ounces, and Mr. Coatsworth at 5 ounces. Liebig gives 18 ounces as the quantity of carbon thrown off from both the skin and lungs.

The quantity of carbon however which is thrown out from the lungs varies under different circumstances. As is seen in the table above, sex and age make a considerable difference in the quantity of carbon expired.

Diet exercises a considerable influence on the quantity of carbon thrown out from the lungs. The following table exhibits the quantity of oxygen required by certain articles of diet to convert them into carbonic acid and water. It should always be recollected in relation

to this subject, that although carbon is spoken of so frequently, that not only is carbon oxidated, but also hydrogen. Wherever hydrogen is present in the tissues, it sustains apparently the same relation to oxygen as carbon. Hence, in the calculation of the influence of diet on respiration it should never be left out:—

Substance.	Carbon.	Hydrogen.	Oxygen.	The quantity of Oxygen required for the formation of Carbonic Acid and Water in addition to the amount already present.
100 parts of Fat . . .	78·13	11·74	10·13	292·14
" Starch . . .	44·45	6·17	49·33	118·52
" Sugar . . .	40·00	6·66	53·34	106·67
" (C ₁₂ , H ₂₂ , O ₁₁) } Malic Acid	41·38	3·45	55·17	82·78
" (C ₄ , H ₈ , O ₄) } Albuminates	47·48	4·98	13·14	153·31
" Collagen . . .	42·52	4·47	13·50	135·56
" Muscular substance				
" Muscular Fibrin and Collagen (Schmidt).	46·10	4·72	13·66	147·04

From this table it may be gathered that vegetable diet consumes more oxygen in the production of carbonic acid and water than animal diet. This is also found to hold good in the case of carnivorous and herbivorous animals—the latter taking up a larger quantity of oxygen than the former, as seen in the following result of an experiment by Regnault and Reiset:—

Species of Animal.	Food.	Proportion of 100 parts of absorbed oxygen which are given off to the carbonic acid.	For 1000 grammes' weight of the animal in one hour.		
			Consumed Oxygen.	Exhaled Carbonic acid.	Exhaled Nitrogen.
Dog . .	Meat . .	Per Cent. 74·5	Grammes. 1·183	Grammes. 1·211	Grammes. 0·0078
Rabbit .	Carrots	91·9	0·883	1·116	0·0036

The same result is indicated by the following experiment on Birds:—

Animals.	Food.	Of 100 parts of absorbed oxygen there pass into the Carbonic Acid	For 1000 grammes' weight of the animal in one hour.		
			Consumed Oxygen.	Exhaled Carbonic Acid.	Exhaled Nitrogen.
Iteus . .	Oats.	Per Cent. 80·7	Grammes. 1·053	Grammes. 1·320	Grammes. 0·0079
Small Birds	Sparingly	75·3	11·473	11·879	0·1206

It has been found that the carbon and hydrogen of nitrogenous foods become oxidised, and are given out during respiration, but they do not supply sufficient for the wants of the system, and when animals are fed on nitrogenised foods, the fat is oxidised and converted into carbonic acid and water.

It appears to be now an established fact, that the imbibition of spirituous drinks of all kinds is attended by a diminished excretion of carbonic acid. This was indicated by Prout, and has since been confirmed by Vierordt and others. This shows the importance of such drinks in cases where the oxidating processes are proceeding too rapidly, and of their injurious tendency where these processes need to be stimulated. Dr. Prout observed that strong tea exercises the same influence on the system.

Sleep produces a very considerable diminution of the excretion of carbonic acid. Scharling found that the ratio of carbonic acid exhaled during sleep in one hour in the night, to that eliminated in one hour in the day after dinner, was as 31·39 to 40·74. A much greater difference is found between animals during their waking and hibernating states.

Bodily exercise increases the exhalation of carbonic acid, whilst rest diminishes it. Seguin, Prout, Vierordt, and Hoffman, have all proved this by experiment.

With regard to the quantity of oxygen consumed during respiration, it was at one time supposed to be exactly equal to the quantity found in the carbonic acid expired. This however is not the case, for accurate experiments show that, after all allowance made for oxygen present in the tissues, there is constantly a small quantity more taken into the lungs than is thrown out. The destination of this oxygen is undoubtedly to be found in the carbonic acid gas thrown out from the lungs, in the formation of the substances found in the bile and urine, and in the formation of phosphoric and sulphuric acids. The quantity of oxygen consumed is nevertheless measured by the carbonic acid thrown off from the lungs, so that, where there is an increase of excretion of carbonic acid, there is an increase of absorption of oxygen. It is an interesting fact that small animals consume a relatively much greater proportion of oxygen gas than larger ones. It is also a fact of practical importance, that the quantity of carbonic acid gas exhaled is not increased by increasing the quantity of oxygen in the atmosphere. As a proof of the necessity of the changes involved in the absorption of oxygen gas, it has been found that the eggs of birds, and undoubtedly this applies to the eggs of all animals, absorb oxygen and give out carbonic acid. The following table gives the result of some experiments of Valenciennes on this subject:—

In 1000 grammes' weight of Eggs.	From the 9th to the 12th day of Incubation.	From the 16th to the 19th day of Incubation.
The loss of weight amounted to .	Grammes. 26·26	Grammes. 41·72
The absorbed oxygen	5·74	10·70
The exhaled carbonic acid	4·33	11·92
The exhaled water	2·88	3·66
The ratio of absorbed O to the O in CO ₂	100 : 54·9	100 : 81·0

The nitrogen of the atmosphere appears to act as a diluent, and to temper the activity of the oxygen gas. Although when animals are placed in atmospheres of pure oxygen, or hydrogen, a certain quantity of nitrogen is thrown out from their lungs, it still requires proof that this has been taken up from the atmosphere. It is not improbable that a certain quantity of nitrogen may be thrown off by the decomposition of the nitrogenous tissues in the blood, or excretions.

With regard to the watery vapour which passes off from the lungs, it may be stated as a general rule that it is sufficient to saturate the expired air. Its absolute amount is therefore influenced by the following circumstances:—1, By the volume of air expired; 2, by the quantity of watery vapour contained in the air previous to its inspiration; 3, by the temperature of the expired air; 4, by the length of time which each volume of inspired air is allowed to remain in the lungs.

We have thus considered the principal physical and chemical phenomena presented during the respiration of animals. It should however be recollected that these phenomena are dependent for their existence on the influence of the nervous system. All the respiratory movements effected by the muscular tissues, as far as they are independent of the consciousness of the individual, are under the absolute governance of that part of the brain which is called the medulla oblongata. It is this portion of the nervous system which acts as the centre of all the impressions which convey the necessity of breathing, and which initiates all the motions which result in respiratory action. [NERVOUS SYSTEM; BRAIN.]

(Kirkes and Paget, *Handbook of Physiology*; Lehmann, *Physiological Chemistry*, translated for the Cavendish Society by Dr. Day; Valentin, *Text-Book of Physiology*, translated by Dr. Brinton.)

REST-HARROW. [OXONIS.]

RESTIACEÆ, *Cordleaves*, a natural order of Plants, principally inhabiting the southern hemisphere, and nearly related to *Cyperaceæ*. They abound at the Cape of Good Hope and in Australia, where they form a hard wiry rush-like herbage. They have not been found in America. They have in general a scaly creeping rhizoma, or root-stock; simple stems clothed with the sheaths of abortive leaves; and glumaceous flowers with a tolerably regular structure. The floral envelopes generally consist of 4 or 6 glumes in two rows. The stamens are 2 or 3; the ovary for the most part 2-3-celled, with a single ovule in each cell. The fruit is either a nut or a 3-celled seed-vessel; the seeds are pendulous, and the embryo is a small lenticular body lying within the hilum at the end of the seed most remote from the hilum. In almost all cases the sexes are separate. The hard texture of some species renders them suited for thatch for houses, but they are of no other use. There are 23 genera and 171 species of this natural order.

RETEPORA. [POLYZOA.]

RETIFERA, a family of *Mollusca*.

RETINA. [EYE.]

RETINALITE, a Mineral, having a resinous appearance, found with and allied to Serpentine. It is found at Granville in Upper Canada. (Dana.)

RETINASPALTUM. [RETINITE.]

Restia tetraphyllus. [RESTIACEÆ.]

1, the male; a, the stamens and abortive ovary; b, the same inclosed within the floral envelopes.

2, the female. c, the flower; d, the ovary with abortive stamens; e, a section of the ripe seed, showing the embryo.

RETINITE, a Mineral Resin. It occurs in roundish masses. Its colour is light yellowish brown, green, or red; lustre earthy or slightly resinous in the fracture. It is sub-transparent to opaque. Often flexible and elastic when first dug up, but loses these qualities on exposure. Its hardness is 1·2·5, and its specific gravity 1·135. It takes fire, and burns with a bright flame and fragrant odour. It is soluble in alcohol. It is found in the Bovey coal of Devonshire, and also in the brown coal of Wolchow in Moravia, and near Halle. (Dana, 'Mineralogy'.)

REUSSITE, a Mineral, called also Soda Sulphate of Magnesia. It occurs in flat six-sided prisms, acicular crystals, and mealy efflorescences. Its colour is snow-white. Fracture conchoidal. Taste saline and bitter. It is found in the vicinity of Seidlitz and of Seidschutz in Bohemia. According to Reuss, it contains Sulphate of Soda, Sulphate of Magnesia, Muriate of Magnesia, and Sulphate of Lime.

RHAMNACEÆ, a natural order of Exogenous Plants, remarkable for having a valvate calyx, hooded petals, opposite to which their

Rhamnus Alaternus.

1, a flower about to expand; 2, a flower cut open to show the position of the stamens and petals; 3, a transverse section of a fruit, and seeds.

stamens are inserted into the tube of the calyx, and a superior or half inferior fruit which is either dry or fleshy. The species are found nearly all over the world, except in the arctic zone. The chief number of species is said to be dispersed through the hottest parts of the United States, south of Europe, north of Africa, Cape of Good Hope, and Australia. They are all shrubs, with small greenish or inconspicuous flowers.

The species which are best known in this country are the *Rhamnus frangula*, Alder; *R. catharticus*, Buckthorn; *Paliurus Australis*, Christ's Thorn; and Buckthorn, the evergreen *Rhamnus Alaternus*. The useful species are of some importance:—*R. catharticus* and several others have purgative berries; *R. infectorius* yields the French berries of the shops employed for dyeing yellow; the fruit of the Jujube, *Zizyphus Jujube* and *Z. vulgaris*, is sub-acid and eatable, and the species are cultivated for it in the south of Europe and the temperate parts of Asia; *Z. Lotus* gave its name to the Lotophagi, or Lote-Eaters, of Africa; and *Rhamnus frangula* is extensively cultivated for the manufacture of charcoal. *Ceanothus Americanus* yields the New Jersey Tea. [CEANOTHUS; HOVINTIA; PALIURUS; RHAMNUS.]

RHAMNUS (the word is Greek, *ῥάμνος*), a widely diffused genus of Plants, the type of the natural family *Rhamnaceæ*. It is chiefly found in the temperate parts of Europe, in Siberia, and in the Himalayas at elevations of 6500 feet; also in the New World, and at the Cape of Good Hope.

The genus is characterised by having an urceolate 4-5-cleft calyx; petals wanting, or emarginate; anthers ovate, 2-celled; disc thin, overspreading the tube of the calyx; ovary superior, 3-4-celled; styles 3 or 4, distinct or united; fruit fleshy, with 3 or 4, or in consequence of abortion, 2 fibrous indehiscent stoues.

R. catharticus (called also *Spina cervina*, hence Buckthorn), an indigenous shrub, with opposite branches, spreading, straight, round, smooth, hard, and rigid, each terminating in a strong spine after the first year. Leaves deciduous, bright green, smooth, ribbed, the young ones downy. Flowers yellowish green, on the last year's branches numerous; the fertile ones with narrow petals, rudiments of stamens, and a deeply 4-cleft style; barren ones with an abortive ovary, and broader petals. It flowers in May, ripening its berries in September, at which time they are collected. The berries are about the size of a poppercorn, black externally, but within of a deep violet, the pulp inclosing three or four seeds. The taste is nauseous and repulsive at last, though at first sweetish and only bitter. They contain a peculiar extractive, a colouring principle, acetic acid, and gum. The fresh and dried berries, the expressed juice, or a syrup prepared from them, all possess purgative properties, exemplified in that form which has led to the designation 'hydragogue.' Its action is attended with much sickness, griping, and thirst. It should be restricted to the arts, in which it is serviceable, being the source of the pigment called Sap-Green or Bladder-Green. [BUCKTHORN, in ARTS AND SC. DIV.]

R. frangula, Alder Buckthorn, has alternate branches and elliptical acuminate leaves. It is a native of the British Islands.

R. infectorius is a dwarf shrub found in wild places in the south of Europe among rocks. The fruit is purgative, and contains also a colouring principle, for which it is sold under the name of French Berries. *R. saxatilis*, *R. amygdalinus*, and *R. oleoides* have similar properties.

RHÆTIZITE, a Mineral, a form of *Kyanite*. [KYANITE.]

RHAMPHASTIDÆ. [RAMPHASTIDÆ.]

RHATANY. [KRAMERIA.]

RHEA. [STRUThIONIDÆ.]

RHEE BOC. [CERVIDÆ.]

RHENTITE, a Mineral, a Hydrated Phosphate of Copper. It occurs crystallised and massive. Its primary form is an oblique rhombic prism. Cleavage indistinct, parallel to the horizontal diagonal. Colour blackish green, and green of various shades; streak light green. Its fracture is uneven. Hardness 5.0. Lustre vitreous. Translucent, opaque. Specific gravity 4.2 to 4.3. It is found at Rheinbreithach, near Bonn, on the Rhine.

Its analysis by Lunn gives—

Phosphoric Acid	21.687
Oxide of Copper	62.847
Water	15.454

—99.988

RHESUS MONKEY. [MACACUS.]

RHEUM, a genus of Plants belonging to the natural order *Polygonaceæ*, of which the name is taken from the *ῥέον* of Dioscorides, and which includes the different species of plants which yield the stalks and root so well known by the name of Rhubarb. It is doubted by some whether the root to which the name 'rhu' and 'rheon' was applied by the Greeks was the same as that to which we now apply the name of rhubarb, because the descriptions of the former given by Dioscorides and Pliny do not apply to the latter. It is admitted however that our rhubarb was known to the later Greek physicians, as Alexander of Tralles and Paulus of Aegina, and there is no doubt that the Arabs were well acquainted with it; and it is remarkable that they quote 'rheon' as the Greek synonyme of their 'rawund,' which is rhubarb, and which they describe as being of various kinds, as Indian, Turkish, Chinese, and from Khorassan. From this it is probable that one kind

may have become substituted for another as the communication with the east increased.

Long as the Rhubarb root has been known, it is remarkable that the species of *Rheum* yielding it is yet unknown; this is in consequence of the best rhubarb, Turkey rhubarb, being only obtained by the Russians at Kiachta from the Chinese. That called Chinese may be the produce of the same, or of a different species, from the northern boundaries of that country. Dr. Royle, after reviewing the different accounts of the commerce of rhubarb, states:—"This would bring the rhubarb country within 95° of E. long., in 35° of N. lat., that is, into the heart of Tibet. As no naturalist has visited this part, and neither seeds nor plants have been obtained thence, it is as yet unknown what species yields this rhubarb." Slevers had previously said that his travels had satisfied him that as yet nobody, that is, no scientific person, has seen the true rhubarb plant. The Himalayan and Persian rhubarbs have alone been ascertained.

The different species of rhubarb are important plants, not only on account of the roots being so extensively employed, and so valuable for their medicinal qualities, but also on account of the stalks of the leaves being now so much employed, from their agreeable acidity, in making tarts, &c. As the species are all indigenous in cold parts of the world, that is, from the southern parts of Russia, Siberia, Tibet, the north of China, and the Himalayas, so they may all be grown in the open air of this country, and several are cultivated on account of their stalks. Some also, both in England and France, are cultivated on account of their roots, often for the purpose of adulteration.

The genus *Rheum* is characterised by having an inferior petaloid sex-partite calyx, into the bottom of which the stamens, about nine in number, are inserted; anthers opening lengthwise; ovary superior, with a single erect ovule; styles three, reflexed; stigmas petate, entire; fruit (achenium) 3-cornered, winged, with the withered calyx at the base.

The species which are known and cultivated are the following:—

R. Emodi, Wallich, *R. australe* of Dou, is found in Kumaon. The root is a valuable medicine, though bearing hardly any resemblance to that of the shops. Stems much branched, six to ten feet high, very thick below, gradually diminishing, and spreading into large panicles, and there rough, with minute warts. Leaves very large, cordate, acute, dull-green, but little wavy, very rough, covered with little hairs. Petioles very rough, furrowed, and very much narrower at the upper than the lower end. Panicles terminal, very long. Flowers blood-red, very small.

R. Webbianum, Royle, 'Illust.' t. 99; *R. Emodi* of Meisner, found by Mr. Moorcroft at the height of 12,000 feet above the level of the sea, and by Dr. Royle on the Choor Mountain. Root-leaves large, long-stalked, rather downy above, veiny beneath, margin hairy. Axillary racemes clustered, terminal, panicked; pedicels in threes, twice as short as the ripe fruit.

R. spiciforme, Royle, 'Illust.' t. 78, found on the northern face of the Himalayas. Leaves thick, leathery, cordate, blunt, red and netted beneath, and covered with stellate down on each side. Pedicels numerous, clustered, as long as the ripe fruit. The roots are lighter coloured and more compact than those of *R. Emodi*.

R. Moorcroftianum (Royle), Small-Stalked Rhubarb. Leaves and stems covered with short pubescence; petioles deeply furrowed; the stipules as long as the petioles, and very membranous; scales at the base yet longer, extremely thin, and towards the summits much torn. This species was found by Messrs. Moorcroft and Hearsay near the Niti Pass in the Himalayas, at an elevation of 12,000 feet.

R. leucorhizum, Pall. (*R. nanum*, Sievers; *R. tataricum*, Linn.). A small plant for the genus; the root is white and branched, though said to be equally efficacious with the best sorts. Radicle leaves about three, short stalked, from four to six inches long, and from five to nine inches broad; smooth on both sides, toothletted at the edge. Flowering stem about two inches high when in flower, afterwards becoming ten to twelve inches high.

R. rhaponticum, Linn.; north of the Caspian. According to Guibour, cultivated largely near Lorient, in the department of Morbihan in France, at a place called from that circumstance Rheumpole. Leaves roundish, ovate, cordate, obtuse, but little wavy, very concave, even, very slightly downy on the under side. Panicles very compact and short, always rounded at the ends, and never lax. *R. rhaponticum*, *R. hybridum*, *R. compactum*, and hybrid varieties of them, are the common garden rhubarbs.

R. undulatum, Linn. (*R. rhubarbarum*, Linn.); China and Siberia. Leaves oval, obtuse, deep-green, with veins purple at the base, often shorter than the petiole, downy on each side when young, looking as if frosted. Petiole downy, blood-red, semi-cylindrical.

R. Caspicum, Fischer (*R. rhaponticum*, Ledbour); In the Altai Mountains. Leaves ovate, acuminate, obtuse, cordate, inflexed at the base, thick, very wavy, glossy on the upper but slightly downy on the under side. Petiole pale green, minutely downy.

R. compactum, Linn.; Tartary and China. Leaves heart-shaped, obtuse, very wavy, deep-green, thick, quite smooth on both sides, glossy on the upper. Siliques nearly closed with parenchyma. Petiole green.

R. crassivernium, Fischer. Leaves heart-shaped, acuminate, obtuse, wavy, bullate, deep-green, quite smooth, rather glossy above; ribs

slightly coloured red, the centre ones above half an inch deep at the base. Petiole dull red, rounded, rather angular.

R. palmatum, Linn., generally thought to be the source of the true official rhubarb; near the great wall of China. Leaves roundish, cordate, half palmate; the lobes pinnatifid, acuminate, deep dull-green, not wavy, but uneven and very much wrinkled on the upper side, hardly scabrous at the edge, downy on the under side. The flowering stems are taller than those of any other species.

R. Ribes seems to be so named from the Persian name Ribas, which is as frequently written Rewash, and which Elphinstone, Burnes, and other travellers notice as being highly esteemed by the Persians, and of which the stalks are prepared in a variety of ways, and considered a great delicacy.

(Royle, *Illustr. Himal. Bot.*; Lindley, *Flora Medica*; Pereira, *Elements of Materia Medica*.)

RHEXIA. [MELASTOMACEÆ.]

RHINACANTHUS (from *ῥίς*, a snout, and *ἀκάνθα*, a thorn), a genus of Plants belonging to the natural order *Acanthaceæ*. It has a regularly 5-parted calyx with small subulate bracts and bractlets; a hypocrateriform 2-lipped corolla, with a long slender tube, the upper lip narrow, the lower trifid, with equal segments; 2 stamens inserted in the throat of the corolla, the anthers 2-celled, awnless, with one cell placed above the other almost in a line; a clavate capsule much compressed at the base, with the commissure of the valves in contact and seedless; the upper part 4-seeded, or by abortion 2-seeded; the dissepiment complete, adnate; the seeds ovate, bi-convex, augmented with hooks which are concave and obtuse.

R. communis is a native of the continent of India, with opposite stalked broad-lanceolate obtuse leaves, above smooth, below a little downy, entire, from two to four inches long and from one to two inches broad, and a fleshy ring surrounding the base of the ovary. The roots of this plant are boiled in milk, and are reckoned by the natives of India an aphrodisiac. In conjunction with lime-juice and pepper they are used as an external application for ringworm.

(Lindley, *Flora Medica*.)

RHINANTHUS (from *ῥίς*, a snout, and *ἄνθος*, a flower), a genus of Plants belonging to the natural order *Scrophulariaceæ* of Jussieu, and the type of the order *Rhinanthaceæ* of De Candolle. It has a compressed membranous inflated 4-toothed calyx; the superior lip of the corolla galeate, compressed, bidentate at the apex, the lower one spreading, 3-lobed; the anthers bipartite, mutic, villous; the capsule 2-celled, obtuse, compressed; the seeds compressed, marginate, or girded by a membranous wing. The species are annual plants, inhabiting marshes and confined in their geographical distribution to Europe.

R. Crista Galli, Cockscomb, or Common Yellow Rattle, has oblong-lanceolate serrate leaves; the flowers in lax spikes, the calyx glabrous, the lobes of the upper lip of the corolla short, roundish, the bracts ovate incise-serrate, the seeds with a broad membranous border. This plant has the name of Yellow Rattle from the colour of its flowers, and the rattling noise made by the seeds in the capsule when ripe. On this account the fruits are called rattle-boxes in Ireland. In some parts of England this plant is known by the name of Penny-Grass, and in Yorkshire it is called Henpenny, from the seed-vessels resembling in shape and size a silver penny. The term Cockscomb has been applied to this plant from the fringed appearance of the bracts which surround the flowers. The seeds of a species of *Rhinanthus* were at one time used in infusion for destroying vermin in bedsteads and furniture.

R. major has linear-lanceolate serrate leaves; the flowers in crowded spikes, the calyx glabrous, the lobes of the upper lip of the corolla oblong, the bracts incise-serrate, with an attenuated point, the seeds with a very narrow membranous border. This is the plant of British botanists, but the *R. major* of Koch and Reichenbach has a broad membranous margin to the seed, and the central part of the upper lip of the corolla as prominent as the lateral lobes. This plant is found in meadows and corn-fields in the North of England, and also in Scotland.

Several other species of this genus have been described. Koch, in his 'Flora Germanica,' has five—*R. minor*, the *R. Crista Galli* above described, *R. major*, *R. alectorolophus*, *R. angustifolius*, and *R. alpinus*. (Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*.)

RHINELLA. [AMPHIBIA.]

RHINOBATIDÆ. [RAPIDÆ.]

RHINOCEROS (the Greek *ῥινόκερως*), the name of a genus of Pachydermatous Quadrupeds, placed by Linnaeus in his order *Bruta*; and by Illiger in his order *Multungula*, family *Nasicornia*. It has been a question whether one of the species, *Rhinoceros unicornis*, Linn. (*R. Indicus*, Cuv. and Desm.) is not the Reem (Reem), or ریم (Reim), of Scripture (Numb. xxiii. 22; xxiv. 8; Deut., xxxiii. 17; Job, xxxix. 9, 10; Psalms, xxii. 21; xxix. 6; xcii. 10; Isaiah, xxxiv. 7).

In the Septuagint the word is translated *Μονοκέρας*, or Unicorn, except in Isaiah, where it is rendered *Ἀπόλ* (or the mighty or powerful ones).

In the Tigurine and Vulgate versions the word is rendered (Numb., xxiii. 22; Job, xxxix. 9, 15) *Rhinoceros*, with a note to the former, that others read *Monoceros*; and in Scheuchzer's 'Physica Sacra' we have (Tab. 313) Numb., xxiii. 22, illustrated by a somewhat extra-

vagant and exaggerated figure of a one-horned Rhinoceros, with "Reem: Rhinoceros" below the plate.

In the Bible "Imprinted at London by Robert Barker, Printer to the King's most excellent Maestie" ('Breeches' Bible), the word used is 'Unicorne;' and 'Unicorn' is the expression in the version now in use in our churches.

Some are of opinion that the Reem, or Reim, of Scripture were savage animals of the Bovine genus, and others that the word signified the Oryx, observing that Reem is the Arabian name for a species of wild-goat or gazelle. These allege that the Reem was two-horned. (Deut. xxxiii. 17; Psalms, xxii. 21.) The better opinion seems to be that the animal or animals intended to be designated in most of the passages quoted, if not in all, was or were the *Rhinoceros unicornis*, or Great Asiatic one-horned Rhinoceros. M. Lesson expresses a decided opinion to this effect; and indeed the description in Job (chap. xxxix.) would almost forbid the conclusion that any animal was in the writer's mind except one of surpassing bulk and indomitable strength.

It has also been doubted whether accounts of the Indian *ὄνοι ἄγριοι* (Wild Asses) given by Ctesias ('Indic,' ed Bähr) were not highly coloured and exaggerated descriptions of animals of this genus, and whether the *ὄνος Ἰνδικός* (Indian Ass) of Aristotle was not a Rhinoceros.

The account of Ctesias is evidently tinged with fable; but there are parts of it which suit well with the habits of a Rhinoceros. He describes his Wild Asses as being as large as horses, and larger, with white bodies, red heads (*πορφύροι*), and blue eyes (*κυανέους*), having a horn on the forehead a cubit long, which for the extent of two palms (*παλαιστράς*) from the forehead is entirely white; above it is pointed and red (*φουνικοῦν ἐρυθρὸν πᾶν*), and black in the middle. Of this horn drinking-cups are formed, and those who use them are said not to be subject to spasm (*πασμῶν*) nor epilepsy (*ἐπερὰ νόσῳ*), nor to the effects of poison, provided, either before or after taking the poison, they drink out of them wine or water or any other liquid. Other asses, whether wild or domesticated, have no astragalus, neither have the other wild solipeds (*μόνυχας*); but these have an astragalus and a gall-bladder (?) (*χολή ἐπὶ τοῦ ἡπατος*). "Their astragalus," adds Ctesias, "which I have seen, is very beautifully formed (*κάλλιστον*), in figure and size like that of an ox, heavy as lead, and red throughout like cinnabar. This animal is very swift and very strong. Neither a horse nor any other pursuer can overtake it. It begins its progress slowly, increasing in speed as it goes on, and runs quicker and faster. They are not naturally ferocious, but when they first lead forth their little young ones to graze, and are surrounded by many horsemen, they are unwilling to fly and leave their young, but fight with horns and heels (*λακτίσμασι*) and teeth (*δῆγμασι*), killing many horses and men. They are also destroyed by arrows and javelins, for they are not to be taken alive. The flesh is not eatable by reason of its bitterness, but the animals are hunted for the sake of the horns and astragali."

It is not at all improbable that these parts, so much sought after on account of supposed virtues, underwent some process by which they were artificially coloured in the manner above described.

Aristotle, who (lib. viii. c. 28) speaks of Ctesias as not being worthy of credit, notices (lib. ii. c. 1) the *Ἰνδικὸς ὄνος* (Indian Ass). He observes that he has never seen a one-horned solidungulous animal; but there are a few which are monoceratous and solidungulous, such as the One-Horned Indian Ass (*Ἰνδικὸς ὄνος μονόκερος*), and that it is the only one of the solidungulous animals which has an astragalus.

Agatharchides describes the One-Horned Rhinoceros by name, and speaks of its ripping up the belly of the Elephant. ('Phot. Bibl.' ccl.) This is probably the earliest occurrence of the name Rhinoceros.

The Rhinoceros which figured in the celebrated pompa of Ptolemy Philadelphus was an Ethiopian, and seems to have marched last in the procession of wild animals, probably on account of its superior rarity, immediately after the camelopard, and before the wain carrying Bacchus fleeing to the altar of Rhea from the persecution of Juno. (Athenæus 'Deipn.' v. c. xxxii.)

Dion Cassius (lib. li.) speaks of the rhinoceros killed in the circus with a hippopotamus in the show given by Augustus to celebrate his victory over Cleopatra; and says that the hippopotamus and this animal were then first seen and killed at Rome. If the rhinoceros was one-horned, as it appears to have been from his description, he was certainly wrong as to the sight at least; for Pliny ('Hist. Nat.' viii. 19), alluding to the games of Pompey the Great, remarks, "Isdem ludis et rhinoceros unus in nare cornu, qualis sepe visus;" and probably equally wrong as to the killing, for upon great occasions few animals left the arena alive, and Pompey was not likely to have risked his popularity by baulking the Roman appetite for blood. It is not improbable that the rhinoceros slain upon the occasion of the victory of Augustus with the hippopotamus was African, and two-horned. If so, Dion would be right; for it does not appear that a two-horned rhinoceros had ever been either seen or slain previously.

The rhinoceros so clearly described by Strabo (lib. xvi. p. 774), as seen by him, was one-horned. The folds of the skin are distinctly alluded to. That noticed by Pausanias (lib. ix. c. 12) as 'the Bull of Ethiopia' was two-horned, and he describes the relative position of the horns.

Mr. Wood ('Zoography') gives an engraving of the coin of Domitian (small Roman brass, on the reverse of which is the distinct form of a two-horned rhinoceros—that coin which, with the epigram of Martial, has so puzzled antiquaries, and led some of them astray, when a very little knowledge of natural history would have kept them in the right road.

"The exhibition of the Two-Horned Rhinoceros to the Roman people, probably of the very same animal represented on the coin," says Mr. Wood, "is particularly described in one of the epigrams attributed to Martial ('De Spectaculis Libellus,' 'Ep.' xii.), who lived in the reigns of Titus and Domitian."

The following are the lines:—

"Sollicitant pavidum rhinocerosa magistri,
Sæpe dic magnum colligit ira furor.
Desperabant promissi prelia Marti:
Sed tamen is rediit cognitus ante furor,
Namque gravem gemino cornu sic exultat ursum,
Jactat ut impositus taurus in astra pilas."

"By this description it appears that a combat between a rhinoceros and a bear was intended, but that it was very difficult to irritate the more unwieldy animal, so as to make him display his usual ferocity; at length however he tossed the bear from his double horn, with as much facility as a bull tosses to the sky the bundles placed for the purpose of enraging him. Thus far the coin and the epigram perfectly agree as to the existence of the double horn; but unfortunately commentators and antiquaries would not be convinced that a rhinoceros could have more than one horn, and have at once displayed their sagacity and incredulity in their explanations on the subject. Hence we find a similar coin engraved in the second volume of Cooke's 'Medallio History of Rome,' where the animal is misrepresented, and particularly the horns, which appear like tusks, bending in different directions. After quoting the lines of Martial, Mr. Cooke observes, that it is the opinion of Bochart that the disputed line should be read thus—

"Namque gravi geminum cornu sic exultat ursum."

By which alteration we should have two bears instead of one;* but Mr. Cooke proposes to omit only one letter, the *s* in the word 'ursum,' by which means he turns the bear into a wild bull; and as it is perfectly natural that the wild bull, or urus, should have two horns, he translates the line thus—

"Struck with amazement, we beheld upborne
The buffal dreadful with his double horn."

If Cooke had seen the coin himself, or had consulted that book so useful to a medallist, the 'Catalogue of Dr. Mead's Coins,' he would not have deprived the epigram of its original and curious information."

Two at least of these two-horned rhinoceroses were shown at Rome in the reign of Domitian.

The emperors Antoninus, Heliogabalus, and Gordian, also exhibited rhinoceroses, and Captain W. H. Smyth, R.N., noticing a coin of the emperor Philip (large brass), speaks of a noble lion on the reverse as representing one of the *Leones Mansueti* mentioned by Capitolinus. "It seems," says Captain Smyth, speaking of the 'Sæculares Augustorum' (the legend on the reverse), "that there were provided no fewer than 32 elephants, 10 tigers, 10 elks, 60 lions, 30 leopards, 1 hippopotamus, 1 rhinoceros, 40 wild horses, 20 wild asses, and 10 cameloopards, with a vast quantity of deer, goats, antelopes, and other beasts; and, still further to increase the public hilarity, 2000 gladiators were matched in mortal affray." ('Descriptive Catalogue of a Cabinet of Roman Imperial large Brass Medals.')

Cosmas speaks expressly of the Ethiopian Rhinoceros as having two horns, and of its power of moving them.

The first rhinoceros seen by modern Europeans appears to have been a *Rhinoceros unicornis* (Linn.), sent from India to Emmanuel, king of Portugal, in 1513. Emmanuel sent it as a present to the Pope, but the animal in an excess of fury sunk the vessel on its passage. A sketch of the animal was sent from Lisbon to Nürnberg for Albert Dürer, who engraved the extravagant figure from which those of Gesner, Aldrovandi, Jonston, and Scheuchzer were taken. Among other monstrosities, the animal, which is represented as if it were clad in offensive and defensive armour, has a second small horn projecting from the top of the shoulders. A reduced copy of the same figure is given in the early edition of Pétiver. In 1656 we find in the 'Catalogue of the Museum Tridescantianum' (sec. ii., 'Four-Footed Beasts, with some Ilides, Hornes, Hoofs')—

"The Rhinoceros . . . { horn.
 { jaw-bone.
 { back-bone."

In 1655 one was brought alive to England; another was shown throughout a great part of Europe in 1739; and a fourth, a female, in 1741. The rhinoceros of 1739 was described and figured by Parsons ('Phil. Trans.' xlii.), and he also mentions that of 1741, which animal Cuvier believes to be the same that was shown at Paris in 1749, painted by Oudry, and afterwards engraved by Edwards

* And also a piece of bad Latin.

('Gleanings'), and that figured by Albinus. It was certainly that described by Daubenton, and the subject of the observations of Meckel. The Rhinoceros whose osteology is described by Cuvier was the fifth that had come to Europe. It arrived at Versailles in 1771, being then very young, and Buffon notices it in his supplement. This animal died in 1793, at the age of 25 or 26. In 1790 a rhinoceros was brought from the East Indies to this country as a present to Mr. Dundas, who gave the animal away. It was afterwards purchased by Piddcock for 700*l*, and was exhibited at Exeter Change and about the country. A seventh, very young, destined, it is said, for the menagerie of the emperor of Germany, arrived from the East Indies in 1800, and died in London soon after its arrival. This animal was dissected by Mr. Thomas, who published his observations in the 'Philosophical Transactions.' An eighth, which afterwards went to Germany, was seen at Paris some years afterwards. All these were one-horned. Of late years several of the same species (*R. Indicus*) have arrived in London. One of these, a fine healthy animal, is now living in the Zoological Gardens in the Regent's Park.

No two-horned rhinoceros seems to have been brought alive to Europe in modern times.

The bony framework of the animal of this genus approximates to that of the *Myrras*, the Tapirs, and the Horse among living genera. Though a general resemblance pervades the entire skeleton of the animals of this genus, there are certain differences, in the skull especially, which render it advisable to notice certain of the species separately with regard to their osseous structure. All the species have seven molar teeth on each side, both in the upper and under jaw, but the species differ as to the incisors. The following is the dental formula of *R. Indicus* (*R. unicornis*, Linn.):—

$$\text{Incisors, } \frac{4}{4}; \text{ Canines, } 0; \text{ Molars, } \frac{7-7}{7-7} = 36.$$

The pyramidal elevation of the cranium is the first point that strikes the observer on viewing the skull of the *R. Indicus*. The next remarkable parts are the ossa nasi, which are of a size and thickness without example among quadrupeds: these form an arch or vault, which overhangs what may be termed the incisive bones, and gives support to the horn, forming, with the parts of the maxillary bones which carry the incisives, the great nasal notch which distinguishes the skull of these animals. Hence three pair of bones—the nasal, the incisive, and the maxillary—contribute in the Rhinoceros to form the contour of the external apertures of the nostrils; whilst, with the exception of the Tapir, the two first only are employed for this purpose in the other quadrupeds. The form of the molar teeth varies but little from that which characterises those of other species. The upper incisors are very much compressed, and placed obliquely at a very considerable angle; the lower incisors are large, pyramidal, and pointed, and between them are two very little incisors, which are supposed never, or hardly ever, to cut the gum. There are also two little incisors on each side of the two upper great ones; but these are, on the contrary, on the outside of the large incisor teeth. The form of the lower incisor teeth reminds the observer of the instrument generally used by husbandmen for extracting docks (*Rumex*) from their pastures, and they appear to be calculated for uprooting plants, as well as tearing or stripping up branches or stems of shrubs or trees. In the case of uprooting, the nipper-like operation of the two great upper incisors, as opposed to the lower ones, would materially assist the extraction.

The number of molar teeth on each side often varies in different individuals, though there are never more than 28.

There are 56 vertebrae in all—7 cervical, 19 dorsal, 3 lumbar, 5 sacral, and 22 coccygian. The transverse apophyses of the atlas are very great and very wide, and without obliquity, so that their contour is nearly rectangular, which distinguishes them from those of the Hippopotamus; their extreme size distinguishes the atlas of the Rhinoceros from that of the Elephant still more clearly. The spinous process is only a large tubercle, and below the body of the vertebra is a small longitudinal crest. There are 19 pairs of ribs, 7 of which are true; they are easily recognised by their proportional thickness and the great arch formed by their curvature. The first pair are soldered together below. The sternum in the adult is composed of four bones; the first is compressed into a ploughshare-shape, and projects in a point in front of the first rib.

Of the anterior extremities the following parts are remarkable:—The scapula is oblong; its greatest width is at its upper fourth; its posterior border is elevated and thickened at this point. The crest has a very projecting apophysis at its upper third, directed a little backwards; this crest terminates at the lower fourth of the scapula, and consequently there is no acromion; a tuberosity occupies the place of a coracoid process, and the glenoid cavity is nearly round. This configuration distinguishes the scapula or blade-bone of the Rhinoceros from that of other great quadrupeds; that of the Elephant, for example, forms a nearly equilateral triangle, and the spine a great recurrent apophysis. The widely-crested humerus is very remarkable, and distinguishable from that of every other quadruped of the same size, but the carpus is formed after the same model as that of the Tapir and the Horse; though the Rhinoceros and the Tapir resemble each other more than they respectively

resemble the Horse in this part of the skeleton. The anterior face of the semilunar bone is square, and not pointed above, as in the Hippopotamus. None of the bones of the anterior extremities are liable to be confounded with those of animals of the same size; and though their greatest resemblance is to those of the Tapir, the smallness of those of the latter makes a sufficient distinction.

which result from the form of the zygomatic arches, the direction of the occipital crest, and that which the difference of the incisive bones produces on the front of the palate, it may be observed that the series of molars is longer in *R. Africanus* and *R. sinus*, and that it converges anteriorly with that of the opposite side. 4. The posterior surface is demi-elliptical, and higher than it is wide in *R. Indicus*,

Skeleton of *Rhinoceros Indicus*.

The posterior extremities present the following remarkable parts:—The pelvis is extremely wide, and that of the elephant alone among living quadrupeds resembles it; but the pelvis of the Rhinoceros is at once distinguished by its forked spine. The angle of the os ilium, which reaches the sacrum, is besides more elevated, and its neck much longer and narrower. The external edge of this bone is nearly as great as the internal, whilst in the Elephant it is much smaller. The crest of the pubis commences from the top of the ossa ilii. The oval holes are wider than they are long. The tuberosity of the ischium is very large above, and in the form of a hook. The femur is if anything more remarkable than the humerus; its upper part is extremely flattened from before backwards; the eminence which Cuvier calls the third trochanter projects extremely, and forms a hook, which ascends to touch a hook descending from the ordinary grand trochanter, so that there is an oval hole between these two eminences. The tibia, fibula, tarsus, and the upper part of the metatarsus are constructed upon the plan of those of the Horse; but the pulley of the astragalus is wider, more oblique, less deep, and its posterior internal angle is obliquely truncated; the astragalus touches the cuboid bone by a rather wide surface; the scaphoid and the third cuneiform bones are less flattened; the second cuneiform and the cuboid larger. In these points the Rhinoceros resembles the Tapir more than the Horse, and indeed were it not for size would be hardly distinguishable from the former; but it differs from both in having a larger and stouter calcaneum. Its anterior or astragalian surface is triangular. The astragalus has two large facets; that of the inside is prolonged into a tail-like process all along the lower edge of this surface, as in the Tapir. In the Horse the third facet towards the external angle is distinct. The facet, which touches the cuboid bone, is very small. The cuboid bone has a large and long protuberance behind, which does not exist in the Horse. On the inside of the foot is a similar one, produced by a supernumerary bone attached to the scaphoid, the internal cuneiform, and the internal metatarsial bones, which represent at once the first cuneiform and the thumb in its entirety. This bone exists only in the Tapir and in the Horse; but in the latter it is promptly soldered to the second cuneiform bone. The scaphoid bone then has three articular facets on its inferior or rather metatarsal face; the third cuneiform or internal bone is much smaller than the other. The phalanges are all wider than they are long; the second phalanx of the middle toe is especially short. The last are channelled like those of the hoof of a horse. (Cuv.)

The osteology of the various species of *Rhinoceros* differs very considerably. The following differences appear on examining the skull of the two-horned species of the Cape:—1. On its upper surface the horizontal contour of the bones of the nose is rounded in the Cape species, and almost extravagantly so in *R. sinus*, whilst in the one-horned species it is pointed. 2. The principal differences in the profile relate to the form of the incisive bones, which in *R. Indicus* advance as far as the bones of the nose, and have above a particular apophysis; in *R. Africanus* and *R. sinus* the incisive bones are each reduced to a small oblong piece. 3. On the lower surface, besides the differences

and rather wider than it is high in *R. Africanus* and *R. sinus*, in which last the occipital foramen is wider than it is high, whilst in *R. Indicus* those proportions are reversed.

The principal differences of the lower jaws are (besides the length which precedes the molars, which is much less in *R. Africanus* and *R. sinus* than in *R. Indicus*), 1st, that the series of molars is longer in the African species; 2nd, that the rising branches are much less high; 3rd, that the coronoid apophyses are much shorter, less pointed, and less directed forwards; 4th, that the dental branches are much more convex externally.

Skull of *Rhinoceros bicornis*.

The One-Horned Rhinoceros of Java (*R. Javanus*) resembles less, in the bones of the extremities, the *R. Indicus*, than does the *R. Africanus*; which, as Cuvier observes, is remarkable. But in the skull the resemblance to that of *R. Indicus* is striking, though there are still remarkable differences. The whole cranium, for instance, is less, and the zygomatic arches, the orbits, and the nasal bones, which terminate in a sharp point, are less developed. The post-orbital

Skull of *Rhinoceros Javanus*.

Teeth of *Rhinoceros Javanus*. (F. Cuvier.)

apophysis can hardly be traced. The occipital crest is less elevated; there is no apophysis on the superior edge of the incisive bones; the orbit has a more forward position; the posterior base of the zygomatic arch is less approximated to the occiput; the region of the external opening of the ear is wider; the descending part of the occipital arch, which is trenchant in *R. Indicus*, is here stout and obtuse. The posterior surface of the skull of *R. Javanus* is wider than it is high: in *R. Indicus* it is just the reverse; and the same difference exists in the dimensions of the occipital hole.

The osteology of this genus can be well studied in the museum of the Royal College of Surgeons of England, where there is a skeleton of the Sumatran two-horned species, and a fine collection of separate portions of the osseous system of the teeth and the horns of these animals.

The stomach of these animals is simple; their intestines are very long, and the cæcum is very large. Sparrman, who dissected a Cape Two-Horned Rhinoceros as well as his position and his Hottentot assistants would permit, remarks that the viscera most resemble those of a horse; though the stomach did not in the least resemble that of a horse, but rather that of a man or a hog. It was 4 feet in length and two feet in diameter; and to this viscus was annexed an intestinal tube 28 feet in length and 6 inches in diameter: at 3½ feet from the bottom was a large cæcum. The liver was 3½ feet in breadth, but in depth (taken as if the animal were in a standing position) 2½ feet. There was no gall-bladder nor any trace of it. The spleen was hardly a foot broad, but full 4 feet long.

The heart was a foot and a half in length, and the breadth was not much less. The right lobe of the lungs had an incision in it (probably made by the Hottentots who exenterated the animal, or by the shot, which passed through the great blood-vessels of the lungs, and mortally wounded the animal), but was in other respects undivided and entire: it was 2 feet in length. The kidneys were a foot and a half in diameter.

The hide of the Rhinoceros is perhaps as thick as, if not thicker than, that of any other pachydermatous animal. The horns, solid as they are apparently, consist actually of congregated parallel horny fibres.

We now proceed to give some account of the species of *Rhinoceros*: *R. Indicus* (*R. unicornis*, Linn.) has a single horn on the nose.

Skin naked, very thick, of a dull deep purplish-gray, marked with sub-elevated, rounded, and other inequalities, and remarkable for the deep folds which it forms behind and across the shoulders, and before and across the thighs, &c. There are a few stout, stiff, horny, and smooth hairs on the tail and on the ears.

The best early figure of *R. Indicus* known to us is that of Bontius, which, though somewhat exaggerated by the draughtsman about the lip, and furnished with little claws instead of broad nails, gives in general a correct idea of the animal.

Pennant, who is decidedly of opinion that this species is the Unicorn of holy writ, and the Indian Ass of Aristotle (p. 468), says that it loves shady forests, the neighbourhood of rivers, and marshy places; that it brings forth one young at a time, and is very solicitous about it; that it is quiet and inoffensive, but when provoked, furious, very swift, and very dangerous. "I know a gentleman," he continues, "who had his belly ripped up by one, but survived the wound."

The Rhinoceros described by Dr. Parsons came to London in 1739 from Bengal. It is stated that though but two years old, the expenses of his food and his voyage amounted to near 1000*l.* sterling.

The rhinoceros brought to this country in 1790 is the subject of an interesting account by Mr. Bingley, in his 'Animal Biography.' When it arrived it was about five years old, was tolerably tractable, would walk about at its keeper's command, and allowed the visitors to pat his back and sides. He was allowed twenty-eight pounds of clover, about the same quantity of ship-biscuit, and a great quantity of greens daily. Twice or thrice a-day five pails of water were given to him. The vessel out of which he drank contained about three pails, and each time as the animal drank the vessel was filled up. He never ceased his draught till the vessel was exhausted. He was fond of sweet wines, and it is stated that he would drink three or four bottles in a few hours.

*Rhinoceros Indicus*.*Rhinoceros Indicus*.

The species inhabits the East Indies, especially beyond the Ganges. It is recorded as having been found in Bengal, Siam, and Cochin-China. Shady forests, the neighbourhood of rivers, and marshy places are favourite localities. Their ordinary food consists of herbage and the branches of trees. The flesh is said to be not unpalatable. Our figure was taken from an animal which was living in the garden of the Zoological Society, but the horn was taken from a perfect specimen; for the animal, though a fine one, and in excellent general

health, from the time of its arrival and from the first growth of the horn constantly employed itself in rubbing it down, so as to prevent its proper increase.

R. Javanus (Cuvier) has one horn; folds of the neck obsolete; scutules of the skin angled at the margin, concave in the middle, and furnished with a few short bristles; margin of the ears and under side of the tail hairy.

Rhinoceros Javanus. (F. Cuvier.)

Dr. Horsfield, who had an opportunity during his residence at Surakarta, the capital of the Javanese empire, of examining an individual taken during infancy and kept in confinement, or rather in a state of domestication, gives a good figure of it, observing that the drawing from which the plate is taken, though deficient in some points that the skilful pencil of Mr. Daniell would have supplied from the living animal, exhibits, with scrupulous accuracy, its form and proportions. In 1817 this individual measured nine feet in length, and was four feet three inches high at the rump; and Dr. Horsfield remarks that the Rhinoceros figured by F. Cuvier (of which a reduced copy is given above), which was brought to Europe from the British possessions in India, was higher in proportion to its length, and its form was more unwieldy, the entire length being seven feet, and the height four feet ten inches. The head of the animal seen by Dr. Horsfield was strongly attenuated to the muzzle, and had a triangular form; the flexible lip was considerably lengthened, and the sides of the head were marked with protuberances or scutula, resembling those on the body, but no great roughnesses or folds were apparent. The marks of distinction afforded by the folds of the external covering were less evident than those afforded by the form of the body and the attenuated head; but the folds on the whole appeared less rough or prominent than in *R. Indicus*.

This animal is gregarious in many parts. Dr. Horsfield states that it is not limited to a particular region or climate, but that its range extends from the level of the ocean to the summit of mountains of considerable elevation. Dr. Horsfield noticed it at Tangung, near the confines of the Southern Ocean, in the districts of the native princes, and on the summit of the high peaks of the Priangan regencies. It prefers high situations.

The domesticated individual above alluded to by Dr. Horsfield was taken while very young, in the forests of the province of Keddu, and was conveyed to the residency at Magellan, in the year 1815 or 1816. By kind treatment it soon became domesticated to such a degree, that it permitted itself to be carried, in a large vehicle resembling a cart, to the capital of Surakarta. "I saw it," says the Doctor, "during its conveyance, and found it perfectly mild and tractable. At Surakarta it was confined in the large area or square which bounds the entrance to the royal residence. A deep ditch, about three feet wide, limited its range, and for several years it never attempted to pass it. It was perfectly reconciled to its confinement, and never exhibited any symptoms of uneasiness or rage, although on its first arrival barressed in various ways by a large proportion of the inhabitants of a populous capital, whose curiosity induced them to inspect the stranger of the forest. Branches of trees, shrubs, and various twining plants were abundantly provided for its food; of these the species of *Cissus* and the small twigs of a native fig-tree were preferred. But plantains were the most favourite food, and the abundant manner in which it was supplied with these by the numerous visitors tended greatly to make the animal mild and sociable. It allowed itself to be examined and handled freely, and the more daring of the visitors sometimes mounted on its back. It required copious supplies of water, and, when not taking food, or intentionally roused by the natives, it generally placed itself in the large excavations which its movements soon caused in the soft earth that covered the allotted space. Having considerably increased in size, the ditch of three feet in breadth was insufficient for confining it, but, leaving the inclosure, it frequently passed to the dwellings of the natives, destroying the plantations of fruit-trees and culinary vegetables which always surround them. It likewise terrified those natives that accidentally met with it, and who were unacquainted with its appearance and habits. But it showed

no ill-natured disposition, and readily allowed itself to be driven back to the inclosure, like a Buffalo. The excessive excavations which it made by continually wallowing in the mire, and the accumulation of putrefying vegetable matter, in process of time became offensive at the entrance of the palace, and its removal was ordered by the emperor to a small village near the confines of the capital, where, in the year 1821, it was accidentally drowned in a rivulet." ("Zoological Researches in Java.")

This species is the Warak of the Javanese, the Badak of the Malays and of the inhabitants of the western parts of Java. (Horsfield, "Zoological Researches in Java.")

Marsden, in his "History of Sumatra," states that the Rhinoceros, Badak, both that with a single horn and that with a double horn, are natives of the woods. He adds that he does "not know anything to warrant the stories told of the mutual antipathy and the desperate encounters of these two enormous beasts." The horn, he adds, is esteemed an antidote against poison, and on that account formed into drinking-cups.

R. Sumatrensis, Cuv. (*R. Sumatranus*, Raffles), has four great incisors, as in the two preceding species, but hardly any folds on the skin, which is hairy; a second horn behind the ordinary one.

The first satisfactory indication of the existence of this species occurs in Pennant, who imagined that the two-horned species of Sumatra was identical with *R. bicornis*, the only African species then known. He quotes the following remark of Mr. Charles Miller, who was long resident in Sumatra:—"I never saw but two of the two-horned Rhinoceros; but I believe they are not uncommon in the island, but are very shy, which is the reason they are but seldom seen. I was once within twenty yards of one. It had not any appearance of folds or plaits on the skin; and had a similar horn resembling the greater, and, like that, a little turned inward. The figure given by Dr. Sparrman is a faithful resemblance of that I saw."

The hide is rugose, covered with scattered stiff brown hairs; folds on the shoulders and croup but slightly marked; the skin generally rather delicate, and nearly without folds; head rather elongated; eyes small and brown; upper lip pointed and curved downwards; ears small and pointed, fringed with black short hairs; first horn bent backwards, second smooth and pyramidal, placed a little in front of the eyes.

It is a native of Sumatra.

Rhinoceros Sumatrensis. (F. Cuvier.)

R. Africanus, Cuv. (*R. bicornis*, Linu.), is of a pale yellow brown; horns unequal in length; neck surrounded with a furrow at the setting on of the head; eyes brown. Length 10 feet 11 inches. (Smith.)

The hide is pale yellowish-brown, with tints of purple upon the sides of the head and muzzle; the groins flesh-coloured; eyes dark brown; the horns livid-brown clouded with green; the hairs on the tip of the tail and the margins of the ears deep black.

Sparrman, in his description, exposes the errors of Buffon regarding both this species and *R. Indicus*; especially the opinion that the copulation of the latter takes place croupe à croupe. His poetical fancies too touching the impenetrable nature of the skin are freely and justly dealt with by the same learned Swede, who ordered one of his Hottentots to make a trial of this with his hassagni on one of those which had been shot. Though this weapon was far from being in good order, and bad no other sharpness than that it had received from the forge, the Hottentot, at the distance of five or six paces, not only pierced with it the thick hide of the animal, but buried it half a foot deep in its body.

Dr. Smith remarks that the present species, under the name of Rhinoster, has been familiarly known to the colonists of the Cape of Good Hope ever since 1652. In that year, when the Dutch first formed their settlement on the shores of Table Bay, this animal, he observes, was a regular inhabitant of the thickets which clothed the lower slopes of Table Mountain. He states that, like the Keitloa, this species feeds upon brushwood and the smaller branches of dwarf trees, from which circumstance it is invariably found frequenting wooded districts, and in those situations its course may often be traced by the mutilations of the bushes. "As it feeds but slowly," says Dr. Smith, "and besides passes much of its time in idleness, it

must be regarded as a very moderate eater, and considering that it appears to be fastidious in the choice of its food, it is fortunate for its comfort that it does not require more nourishment. Of the many shrubs which exist in the locality in which it resides, few comparatively appear formed for its choice, as it is to be seen approaching many and leaving them again without either injuring a branch or plucking a leaf."

Rhinoceros bicornis, female and young. (Smith.)

R. Keitloa (Smith) is of a pale brownish-yellow colour; the two horns subequal in length, the anterior one cylindrical, the posterior one compressed; anterior part of the upper lip produced and acuminate. Length, body and head, 11 feet and 1½ inches. Height 5 feet. Its figure nearly that of *R. bicornis*.

Dr. Smith remarks that the only species yet known with which the present could be confounded is the *R. bicornis* of authors. There are however, he observes, many and marked differences between them, of which the following are a few of the external and more palpable ones. In *R. Keitloa* the two horns are of equal or nearly equal length; in *R. Africanus* the posterior in neither sex is ever much beyond a third of the length of the anterior horn; the length of the head in proportion to the depth is very different in the two. The neck of *R. Keitloa* is much longer than that of the other, and the position and character of the cuticular furrows destined to facilitate the lateral motions of the head are very different. Besides these, Dr. Smith states that many other diagnostic characters might be instanced; such as the black mark on the inside of the thigh of the Keitloa, the distinctly produced tip of the upper lip, and the comparatively few wrinkles on the snout and parts around the eyes.

Rhinoceros Keitloa, male. (Smith.)

Dr. Smith thinks that it may with propriety be inferred that the Keitloa has not, for many years at least, been in the habit of generally extending its range higher than about 25° S. lat. He remarks that we have sufficient evidence that individuals of this species have approached Latakoo, or rather the country some 60 miles to the north of it, in the fact that Mr. Burchell, "whose merits as a traveller can be best appreciated by those who follow him in the same field, is at present in possession of the horns of an individual which was killed by his hunters." Dr. Smith further states that the natives at and around Latakoo are only acquainted with two species, namely, Borili (*R. bicornis* of authors), and Mohooloo (*R. simus*, Burch.); and those who were in the employ of the expedition declined, when they first saw the Keitloa, that it was not an animal of their country; and at once enlarged upon the points in which it differed from Borili.

The food of this species consists of small shrubs, or the more delicate branches of brushwood, in collecting which, Dr. Smith observes, the prolongation of the anterior extremity of the upper lip proves a useful assistant.

R. simus (Burch.) is of a pale gray-brown colour, tinged with yellow-brown; margins of the ears towards the tips, and tail both above and below at the extremity, clothed with stiff black hairs; mouth ox-like; two horns, the anterior one much the longest; eyes yellowish-brown. Length, body and head, 12 feet 1 inch. Height, at the shoulder, 5 feet 7 inches.

"Mohooloo, the name of this species among the Bechuannas," says Dr. Smith, "is considered by them to be one of the original animals of their country, and to have issued from the same cave out of which their own forefathers proceeded: in this respect they make no difference between it and Keitloa, with whose origin they do not profess to be acquainted."

Mr. Burchell, who added so much to our knowledge of the zoology of Africa, found, when he was in Latakoo, this species common there; and the natives told Dr. Smith that it was not unfrequently found even farther to the southward. The last-named author however tells us that it has almost ceased to exist, even in the situations where its discoverer met it; and the Doctor observes that this is accounted for by the danger to which it is exposed being now much increased from the general introduction of fire-arms among the Bechuannas. He also remarks that the form of the mouth at once suggests the kind of food upon which the animal probably subsists; and an examination of the contents of the stomach, principally grass, confirmed the inference. "Localities abounding in grass are therefore the haunts of the Mohooloo, and to enjoy them throughout the year, he is necessitated to lead a more wandering life than the two species already figured."

Rhinoceros simus. (Smith.)

The above species are those which are best known, although it is not improbable that others exist, and this is the impression of Dr. Smith. The following species are given in the 'Catalogue of the Specimens of Mammalia' in the British Museum:—

Family Elephantidae.

Tribe Rhinocerotina.

1. *Rhinoceros unicornis*, Linn., the Rhinoceros; *R. Indicus*, Cuv.; *R. Asiaticus*, Blum.; *R. incrimis*, Lesson.
2. *R. bicornis*, the Gargatan, or Rhinaster; *R. Africanus*, Desm.; *R. Brucei* and *R. Gordonii*, De Blainv.
3. *R. Keitloa*, A. Smith; Sloan's Rhinoceros.
4. *R. simus*, Burchell's Rhinoceros; *R. Burchellii*, Desm.; *R. Canus*, Griffith.

Fossil Rhinoceroses.

The Fossil Rhinoceroses hitherto discovered may be divided into three groups—1, those with a true or bony septum narium; 2, those without a bony septum; and 3, those with incisor teeth.

The greater portion of remains found in Northern and Central Europe and Asia belong to the first group; those found in Italy belong to the second.

The skulls of the Rhinoceroses belonging to the first group exhibit an essential difference when compared with those of the living species. Those of the former are longer and narrower in proportion; the width between the orbits is less; the bones of the nose are more elongated; the disc on which the anterior horn was seated is an oblong ovoid, whilst in *R. bicornis* it is a hemisphere. An analogous elongation exists in the place where the second horn was situated, whence Cuvier concludes that the horns of the Rhinoceros with a bony septum narium were very much compressed laterally. The same great zoologist remarks that in *R. bicornis* or *R. Africanus* (Cape Rhinoceros) the occipital crest is nearly over the occipital condyles, and the posterior surface of the occiput is nearly perpendicular to the axis of the head. In *R. Javanicus* this surface is inclined forwards, which renders the distance from the nose to the crest shorter than that from the nose to the condyle in a proportion of 19 to 25; and it

is much the same in *R. Sumatrensis*. In *R. Indicus* this forward inclination is still more remarkable, although the difference of the two lines is less in the proportion of 21 to 25, on account of the extreme height of this occipital surface. In all the fossil skulls, on the contrary, the occipital surface is strongly inclined backwards, and the distance from the nose to the crest much longer than that from the nose to the condyles. It would seem, says Cuvier in continuation, that in some fossil individuals the two horns did not touch each other; but in one from the neighbourhood of Rugby, which Cuvier saw in the Radcliffe Library at Oxford, and of which Mrs. Buckland made a drawing for his work, he is of opinion that the horns touched, for the discs on which they were seated are confounded in one rugose surface.

Skull of Fossil Rhinoceros. (Cuvier.)
a, profile; b, seen from below.

a, Crown of a sixth molar, but little worn, of a Fossil Rhinoceros; b, molar of a Fossil Rhinoceros, much worn, seen from above.

The skulls of the group of fossil rhinoceroses which have no bony septum malarium much resemble that of *R. bicornis*. As compared with the cranium of the ordinary fossil rhinoceros, which has the bony septum, the cerebral part of the skull is less prolonged and less thrown backwards; the orbit is placed above the fifth molar; the nasal bones terminate in a free point, and are not attached to the intermaxillary bones by a vertical septum; the intermaxillaries are much less prolonged and of a different conformation, offering none of the characters which render the other fossil skulls of this genus so remarkable. But though the skulls without the bony septum approach more to that of the *R. bicornis* than of any other living species, there are notwithstanding several differences. The bones of the nose in the last mentioned fossils are delicate, straight, and pointed; whilst those of *R. bicornis* are very thick and convex; the intermaxillaries of the fossil are much larger than those of *R. bicornis*, and the zygomatic arch is shorter and more convex towards the top; moreover there is a deeper depression between the part which supports the second horn and that which elevates itself to form the occipital crest.

The fossil rhinoceroses furnished with incisor teeth were much smaller than any known species, living or fossil.

The following fossil species have been recorded:—*R. tichorinus*, Cuv.; *R. incisivus*, Cuv.; *R. leptorhinus*, Cuv.; *R. minutus*, Cuv.; *R. elatus*, Croiz. and Job.; *R. pachyrhinus*, Cuv.; *R. hypselorhinus*, Kaup.; *R. Goldfussii*, Kaup.; *R. leptodon*, Kaup.

Two of these species are British, *R. tichorinus* and *R. leptorhinus*. In his 'British Fossil Birds and Mammals,' Professor Owen has described and distinguished these two species.

R. tichorinus, the Two-Horned Tichorine Rhinoceros, belongs to Cuvier's group with a closed septum malarium. The first notice of the fossil remains of the genus *Rhinoceros* occurs in a curious old tract

entitled 'Chartham News, or a brief relation of some strange boues there lately digged up in some grounds of Mr. John Somner of Cauterbury.' In this little work, which was printed and published in London in 1669, is an account of fossil bones found in digging a well at Chartham. These remains are now in the collection of the British Museum, and evidently belong to *R. tichorinus*. Remains of this species have been found very generally dispersed over the British Islands. "Although the remains of the great Tichorine Rhinoceros," says Professor Owen, "have not been found in such abundance in the caves, the unstratified drift, and the post-pliocene fresh-water deposits of Britain, as those of its more gigantic contemporary the Mammoth, the two-horned pachyderm seems to have been as extensively distributed over the land which now constitutes our island. The works of continental palæontologists demonstrate that this Rhinoceros was similarly associated with the Mammoth in the more recent deposits of France, Germany, and Italy."

The most remarkable specimens of this rhinoceros have been discovered in the northern latitudes of Asia. Twenty years previous to the discovery of the mammoth enveloped in ice [ELEPHANT], a Tichorine Rhinoceros had been discovered under the same circumstances. The following is Professor Owen's translation of Pallas's account of this discovery:—

"I ought here to mention an interesting discovery, which I owe to M. Le Chevalier de Bril. Certain Jakoutzki hunting this winter" (1771-2) "near Viloui, found the body of a great unknown beast. The Sieur Ivan-Argounof, inspector of Zimovia, caused to be transmitted to the Prefecture of the province of Jakoutzk, the head, a fore foot, and a hind foot of the animal, the whole of which were in an excellent state of preservation. He says in his 'Memoir,' dated the 17th of last January," (1772), "that they found, in the month of December, the animal dead, and already much decomposed, at about forty versts above Zimovié de Vilouiskoe, on the sand of the bank, at the distance of one toise from the water and four toises from another higher and more precipitous escarpment: it was about half buried in the frozen sand. They took its dimensions on the spot: it was three and three quarters Russian ells' (aunes de Russie, about eleven and a half English feet) 'in length, and they estimated its height at three and a half ells. The body of the animal, still retaining its corpulency,' (encore dans toute sa grosseur) 'was clothed with its skin, which resembled leather; but it was so far decomposed that they were unable to bring away more than the head and the feet. These I saw at Irkoutsk; they seemed to me, at the first view, to belong to a Rhinoceros, which had been in full vigour. The head, especially, was very recognisable, because it was covered by its skin. The skin had preserved all its exterior organisation, and one could see upon it many short hairs' (on y aperçoit plusieurs poils courts). 'The eyelids and eyelashes even had not entirely fallen into decay. I saw a substance in the cavity of the skull; and here and there, beneath the skin, were the remains of the putrified flesh. I remarked on the feet the very obvious remains of the tendons and cartilages, where the skin was wanting. The head had lost its horn, and the feet their hoofs. The situation of the horn, the fold of integument which surrounded it, and the separation' (of the toes?) 'which existed in the fore feet and hind feet are certain proofs of the animal being a Rhinoceros.' I have given an account of this singular discovery in the 'Memoirs of the Academy of St. Petersburg,' and refer my readers to that work to save repetition. They will there see the reasons in proof that a Rhinoceros has been able to penetrate near the Lena in high northern latitudes, and the circumstances that have led to the discovery in Siberia of the remains of so many strange animals."

One of the most remarkable points in this relation is the fact of this animal possessing short hairs, which probably, like those of the Mammoth, served as a protection against the cold, to which it was subject in a northern climate.

"Although the molar teeth of the *Rhinoceros tichorinus* present a specific modification of structure, it is not such as to support the inference that it could have better dispensed with succulent vegetable food than its existing congeners; and we must suppose therefore that the well-clothed individuals who might extend their wanderings northward during a brief but hot Siberian summer, would be compelled to migrate southward to obtain their subsistence during winter. Plants might then have existed with longer periods of foliation than those which now grow." (Owen.)

R. leptorhinus, Leptorhine Two-Horned Rhinoceros. Professor Owen has pointed out that the remains of this rhinoceros are frequently met with in the British Islands, though not so commonly as the last. A tooth from the upper jaw and other remains of this species have been found in the tertiary clay at Walton in Essex. Teeth have also been procured from the fresh-water beds near Cromer, on the coast of Norfolk. On the habits of this creature Professor Owen remarks:—"The habits of the less robust and less formidably armed species no doubt differed from those of the Tichorine Rhinoceros, which is more extensively distributed over England. Some naturalists have recognised different habits in the three or four species of Rhinoceros now living in Africa, and which differ from each other in form and structure much less than did the extinct Leptorhine and Tichorine Rhinoceroses of Europe."

Although the number of extinct species equals those which are now existing, no remains of this genus have ever been found in America or Australia. This peculiar form of pachydermatous creatures appears to have been confined from its first creation to the same great natural division of the world's surface to which the existing representatives of that form are still peculiar.

RHINOCEROS HORNBILL. [HORNBILLA.]

RHINOLOPHINA. [CHEIROPTERA.]

RHINOLOPHUS. [CHEIROPTERA.]

RHINOPHIS (Wagler), a genus of Serpents.

RHINOPITRUS. [ERPETON.]

RHINOPOMA. [CHEIROPTERA.]

RHINPIDURA. [MUSCIPIDÆ.]

RHINOPTERA, a name given by Latreille to the order previously named by Mr. Kirby *Strepsiptera*. This order embraces the genera *Xenos*, *Stylops*, *Elenchus*, and others. [STREPSIPTERA.]

RHISSOPTERA. [RHINOPTERA.]

RHIZANTHÆÆ, *Rhizantha*, *Rhizogens*, a small class of Plants, comprising the orders *Balanophoraceæ*, *Cytinaceæ*, and *Rafflesiaceæ*. They are parasitical plants, destitute of true leaves, in the place of which they are furnished with cellular scales. Their stem is either an snor-phous fungous mass or a ramified mycelium, and is very imperfectly supplied with spiral vessels, which are sometimes wholly deficient. They are of a brown yellow or purple colour, never green. They produce flowers which have genuine stamens and carpels, and are surrounded by a whorl of petaloid bodies. They possess ovules, but their seed is not known.

These plants have been regarded by Lindley, Endlicher, and other botanists, as sufficiently distinct to warrant their being placed in a class by themselves. Their flowers, stamens, and ovules, indicate their relation to the phanerogamic plants, whilst their mycelial stem, parasitic habits, and cellular structure ally them with the *Fungi* and other low forms of vegetation. Mr. Brown however is of opinion that the *Rhizantha* are but less developed forms of Exogenous Plants. He regards them as having affinities with *Aristolochiaceæ*, and other orders of Exogens. More recently Mr. Griffiths has adopted the views of Brown, and advanced a number of arguments in favour of their being degraded forms of higher plants, and not a permanently low form of vegetation. He thinks the relations of *Rhizantha* various. Thus he places *Mystroptalon* near *Proteaceæ* and *Santalaceæ*; *Sarcophyte* and *Balanophora* he places near *Urticaceæ*. Finally, he places *Thymia* between *Taccaceæ* and *Burmanniaceæ*.

The following are the orders of *Rhizanthææ* as recognised by Lindley:—

- Ovules solitary, pendulous; fruit one-seeded . . . *Balanophoraceæ*.
- Ovules 00, parietal; fruit many-seeded; calyx . . . } *Cytinaceæ*.
- 3-6-parted; anthers opening by slits . . . }
- Ovules 00, parietal; fruit many-seeded; calyx . . . } *Rafflesiaceæ*.
- 5-parted; anthers opening by pores . . . }

RHIZOBOLACEÆ, *Rhizobola*, a natural order of Plants, consisting of trees of very large size. The leaves are opposite, digitate, coriaceous, with a pointed stalk and no stipules; flowers large, regular, arranged in racemes, with their stalks pointed at the base and below the apex; the sepals are 5 or 6, more or less combined, imbricated in aestivation; petals 5 to 8, equal-sided, but unequal thickish, arising along with the stamens from a hypogynous disc; fruit of several combined indehiscent one-seeded nuts; seed reniform, exalbuminous, with a cord dilated into a spongy excrescence; radicle very large. The species are found in South America. They are large timber-trees, some of which yield edible fruit. It is from trees of this order that are produced the Souari (or Snurrow) Nuts of the shops, the kernel of which is one of the most delicious fruits of the nut kind that is known. An oil is extracted from them not inferior to that of the olive. The timber of the tree is used for ship-building. (Lindley, *Vegetable Kingdom*.)

RHIZOCARPEÆ. [MARSHACEÆ.]

RHIZODUS. [FISH.]

RHIZOMORPHA, a genus of Plants belonging to the natural order of *Fungi*, having altogether the appearance of the root of a tree. The species are found in damp cellars, old walls, mines, and other subterranean places, where they sometimes acquire a phosphorescent state, which renders them exceedingly curious objects. Nothing is at present known of their mode of reproduction or origin; but it is thought that they spring out of decaying wood buried in the ground. The genus *Rhizomorpha* is not included in Hooker's 'English Flora,' but it is mentioned by Mr. Berkeley, who wrote the mycological department of that work, as a fungous production, originating in tan-pits. Several species are mentioned by authors, of which *R. medullaris* is the most common. This is so like the root of a tree divided into numerous fibres, that it is probably often mistaken for it. Independently however of its cellular organisation, so different from that of wood, it may always be known by its musty smell.

RHIZOPHORA. [RHIZOPHORACEÆ.]

RHIZOPHORACEÆ, *Mangroves*, a natural order of Exogenous Plants, natives of the shores of the tropics, where they root in the mud, and form a close thicket down to the verge of the ocean. They are trees, or shrubs, with simple opposite leaves, having decidu-

ous interpetiolary stipules. The calyx is adherent, with 4-12 valvate lobes; petals 4-12; stamens twice or thrice as many; ovary 2-4-celled, with two pendulous ovules in each cell. The fruit is monospermal, indehiscent, crowned by the calyx. Seed exalbuminous, embryo germinating in the pericarp. There are 21 species and 5 genera. The bark of the trees is usually astringent, and is employed in tanning and as a febrifuge. The wood of several is described as being hard and durable. The following species of *Rhizophora* are the best known forms of the order:—

R. Mangle, the Common or Black Mangrove, is found abundant on the shores of the ocean, and within the delta of the Ganges, where it grows to a considerable size. The seed of this species, which is from one to two feet long, very quickly gives rise to a young tree, and, as mentioned by Browne in his 'History of Jamaica,' if the apex from whence the root issues be stuck only a little way in the mud, the leaves quickly unfold at the opposite end. The wood is dark-red, hard, and durable, and the bark is used for tanning leather.

R. Candel, Red Mangrove, or Paletuvier. The branches of this species, though they bend downwards, do not take root in the ground. The wood is heavy, of a deep-red, and takes a fine polish. The bark is used in dyeing red, is astringent, and used in the West Indies for the cure of fevers, as well as of the bites of venomous insects.

R. gymnorhiza grows to a considerable size where the spring-tides rise over it, as in the delta of the Ganges. The wood is yellow, hard, and durable; has a sulphurous smell, and burns with a vivid light; is chiefly used by the natives for fire-wood and for making posts for constructing their houses. The pith of the wood, boiled in palm wine or with fish, is used as food.

RHIZOPHYSA. [ACALEPHÆ.]

RHIZOSTOMA. [ACALEPHÆ.]

RHIZOSTOMIDÆ. [ACALEPHÆ.]

RHIZOTROGUS. [MELOLONTHIDÆ.]

RHODALITE, a Mineral which appears to consist of small rectangular prisms with square bases. Hardness about 2. Colour between rose-red and flesh-red. Specific gravity 2. Before the blow-pipe per se not altered. With carbonate of soda fuses into a greenish-blue transparent bead in the exterior flame, becoming yellow in the interior flame: with borax gives a transparent colourless bead; with phosphate of soda does not fuse. It is found in Ireland, occurring probably in an amygdaloidal rock. An analysis by Mr. Richardson gives—

Silica	55.9
Alumina	8.3
Peroxide of Iron, and trace of Oxide of Man- ganese	11.4
Lime	1.1
Magnesia	0.6
Water	22.0
	—99.3

RHODEA. [COAL PLANTS.]

RHODIOLA. [SEDUM.]

RHODIUM. [PLATINUM.]

RHODIZITE, a Mineral resembling *Boracite* [BORON] in its crystals, but it tinges the blow-pipe flame deep red. It occurs with the Red Tourmaline of Siberia. (Dana.)

RHODOCRINITES. [ENCINITES.]

RHODODENDRON, a genus of Plants belonging to the natural order *Ericaceæ*. The species are evergreen shrubs, very commonly cultivated in our gardens and shrubberies, and differing from *Azalea* principally in the stamens, being 10 instead of 5, in the corolla being campanulate, not tubular, and in the foliage being hard and evergreen. The species are nearly related to each other, and occur both in the New and Old Worlds.

R. Ponticum is the species to which most of the varieties of our gardens belong. The leaves are oblong-lanceolate, glabrous on both surfaces, attenuated towards the thick petioles, with a streak on the upper surface and of a wide lanceolate form, racemes short and corymbose. It is a native of Asia Minor in Pontus, and of Gibraltar, Spain, and the Caucasus, in wet places, in beech and alder coppices. The corolla is large, purplish, with ovate, acute, or lanceolate segments. The calyx minute, 5-toothed, somewhat cartilaginous. At one time it was supposed that it was this plant which rendered the honey of Asia Minor poisonous, but it has been ascertained that the effect is really produced by *Azalea Pontica*.

R. arboreum, True Rhododendron, has lanceolate leaves, acute, silvery beneath, tapering to the base; peduncles and calyxes woolly; segments of corolla 2-lobed, with crenulating curled margins, capsule 10-celled, tomentose. It is a native of the warmer parts of India, and is one of the most beautiful of all trees, but too delicate to bear the open air in England.

R. chrysanthum has acute leaves attenuated at the base, oblong, glabrous, reticulately veined, and of a rusty colour beneath; flowers and buds clothed with rusty tomentum; pedicels hairy; calyx hardly any; segments of the corolla rounded; ovary tomentose. It is a native of Siberia on the highest mountains, and of the Caucasus. The plant and its effects were first described by Gmelin and Steller, who mention it as used in Siberia for the cure of rheumatism; with us it is used in decoction as a substitute for colchicum.

Within the last few years a number of species of these beautiful plants has been found in the Himalayan Mountains by Dr. Joseph Hooker, who has described them in his 'Monograph of the Rhododendrons of the Sikkim Himalaya.' The most beautiful of these forms are the following:—

R. Falconeri, a white flowered species, never occurring below 10,000 feet above the level of the sea, is one of the most striking and distinct of the genus.

R. Dalhousiae is parasitical on the trunks of large trees, especially oaks and magnolias. It has large flowers, three to seven, in a terminal umbellate head, the spread of which is greater than that of the leaves. The calyx large, deeply-divided almost to the base into five ovate-elliptical very obtuse spreading foliaceous lobes; corolla very large, $3\frac{1}{2}$ inches to $4\frac{1}{2}$ inches long, and as broad at the mouth, campanulate, white, with an occasional tint of rose; in size and colour and general shape almost resembling that of the white Bourbon Lily, very frequently having the odour of the lemon.

R. barbatum, a tree from 40 to 60 feet high, branched from the base. Flowers of a moderate size, of a deep puce or blood-colour, collected into a compact globose head, from 4 to 5 inches in diameter. It is one of the most beautiful of the Himalayan species, and is readily distinguished by its having bristly petioles and numerous branches floriferous at their apices.

R. lancifolium is a shrub 6 or 8 feet high; the bark reddish, papery, easily separating and falling off. Branches spreading, tortuous, wrinkled, and knotted; flowers of a moderate size, collected into a rather dense head at the ends of the branches; corolla of a rich purple colour.

R. Wallitchi is a very distinct and handsome species, with lilac-coloured flowers. Its leaves are quite unlike any Indian species, and the flowers in colour and size resemble those of the much-cultivated *R. Ponticum*.

R. argenteum is a tree 30 feet high, having leaves very beautiful in the leaf-buds, erect and silky, at first enveloped in large scales, so closely imbricated and so large as to resemble the cones of some species of pine, the outer or lower scales broad and coriaceous, glabrous, coloured (reddish-brown), the innermost ones oblong spatulate, pubescent. The flowers are 2 to 3 inches long, 2 to $2\frac{1}{2}$ inches in diameter, always white.

Thirty-two species of the genus *Rhododendron* have been distinguished by De Candolle in the seventh volume of his 'Prodromus,' in 1839; the maximum of known species at the present time exists in Asia; for, commencing with Borneo and other Malayan islands in the tropics of the southern hemisphere, and proceeding north, we find them recorded in the mountain regions of all intervening countries that have been botanically investigated, even to northern and extreme arctic Siberia. As we proceed westward into Europe they gradually disappear, one only inhabiting Sweden and Norway, *R. lapponicum*, and that seems not to extend to the western coasts. No species grows in Mexico or near the coasts of Oregon or California, and none in the isthmus of Panama. Throughout the whole of Africa and Australia the genus is unknown, and it will be observed that it only enters the southern hemisphere through the medium of the Indian Archipelago.

Mr. Griffith in an excursion to one mountain in Bootan detected eight species, and Dr. Hooker, during a very limited sojourn in Sikkim, and notwithstanding great difficulties, was able to collect and describe a far larger number. These facts would lead to the conclusion that if the maximum of *Rhododendron* be in Asia, their headquarters are on the lofty ranges of the Eastern Himalayas, where the mild and moist atmosphere is eminently suited to their habits.

(Lindley, *Vegetable Kingdom*; Dr. Hooker, *Rhododendrons of the Sikkim Himalaya*.)

RHODONITE. [MANGANESE.]

RHODOPHYSA. [ACALEPHE.]

RHODOSPERMEE. [ALGÆ.]

RHODYMENIACEÆ, an order of *Algæ*, consisting of purplish or blood-red Sea-Weeds, with an expanded or filiform inarticulate frond, composed of polygonal cells, occasionally traversed by a fibrous axis; superficial cells minute, irregularly parted, or rarely disposed in filamentous series; fructification double; conceptacles external or half-immersed, globose or hemispherical, imperforate, containing beneath a thick pericarp a mass of spores affixed to a central placenta. The root is disc-like or branched, sometimes much unatted; frond very variable in habit and colour, either leafy or filiform, and much branched, never articulate; in some an intense scarlet, in some crimson, in others brown-red or purple, usually growing somewhat darker in dyeing. The species are widely dispersed; all our genera having representatives in very distant countries, with very various climates.

Rhodymenia is an ill-defined genus, and will probably be divided into several distinct genera; many of the species, especially of the section *Calophyllia*, are among the most splendidly coloured of crimson and carmine *Algæ*. Others, as *R. Hombroniana*, are clothed in royal purple; while others, like the sober dulso of our coasts, *R. palmata*, have often as much of brown as of purple in their attire.

Many of the *Rhodymeniaceæ* are valuable in an economic sense.

R. palmata, the Dulso of our coasts, is collected largely in Scotland and Ireland, and forms an important article of diet. Many of the

Gracilaria are largely used in the East as ingredients in soups and jellies, and also as substitutes for gluc. One of them *G. spinosa*, is the Agar Agar of the Chinese, and is largely collected both for culinary purposes, and as a component part of some of the strongest Chinese glues. It has recently been imported into England, and is occasionally used instead of carrageen moss in making jellies and blancmanges.

(Harvey, *British Algæ*.)

RHOMB SPAR, a Mineral, a variety of Magnesian Carbonate of Lime containing from 5 to 10 per cent. of oxide of iron or manganese.

RHOMBOIDES, a genus of *Mollusca*. [PYLORIDIA.]

RHOMBUS. [CONUS; PLEURONECTIDÆ.]

RHUBARB. [RHEUM.]

RHUS, the name of a genus of Plants belonging to the natural order *Anacardiaceæ*, and to the tribe *Sumachineæ*. One of the species, *R. cotinus*, appears to have been known to Pliny, who refers to its dyeing properties, and its place of growth, the Apennines, under the name of *Cotinus*. This genus has an extensive geographical range, from the south of Europe to the Cape of Good Hope. It is also found in Asia and North and South America. Most of the species are poisonous, but they are much cultivated as ornamental shrubs, especially on account of the beautiful red colour of their leaves in autumn. Many of them are used also for the purposes of dyeing and tanning; as an astringent principle, to which is frequently added an acid, is common to the whole genus.

The genus *Rhus* has the following characters:—Flowers bisexual, or polygamous; calyx small, persistent, 5-partite; petals 5, inserted under the margin of the disc, imbricate in æstivation; stamens 5, hypogynous; ovary 1-celled, sessile; fruit, a dry drupe; seeds solitary, exalbuminous; radicle opposite the hilum, and bent downwards along the edge of the cotyledons. Leaves alternate, simple, or compound; panicles axillary or terminal.

De Candolle enumerates about 90 species, to which other writers have made additions, but there is reason to believe that many of the new species are merely varieties. We shall here enumerate only a few of those which have interest on account of being cultivated, or their use in medicine and the arts.

R. cotinus, Venus-Sumach, or Wild Olive. Flowers hermaphrodite, arranged in loose panicles of a greenish-yellow colour; leaves simple, entire. This is a very ornamental shrub, and is one of the European species, growing wild in various districts of the south of Europe. It is made use of, like many other of the species, for tanning, in Italy, and is called *Scotino*. The wood is used by the modern Greeks for dyeing wool, which is said to be of a beautiful rich yellow. It is frequently cultivated on account of its beauty.

R. typhina, Fever-Rhus, or Stag's-Horn Sumach. Leaves with 8-10 pair of leaflets and an odd one, lanceolate-acuminate, serrated, pilose beneath. There are two forms of this plant: the one *R. t. arborescens*, in the form of a tree, from 10 to 25 feet in height; the other *R. t. frutescens*, shrubby, and only from 2 to 10 feet high. The young shoots are covered with down, which, with their somewhat crooked and stunted branches, give them the appearance of young stag's-horns; hence their name. The flowers are in dense spikes, at the ends of the branches, the pistilliferous ones developing themselves into woolly drupes, which are very conspicuous when ripe. It is found in every part of North America, and its dark-red leaves add much to the beauties of an American autumn. The fruit of this plant is exceedingly sour, and on this account it is frequently called vinegar plant, and is even used in some parts as a substitute for vinegar.

R. glabra, Smooth-Leaved Sumach. Leaf like the last, but broader and glabrous. Branches also glabrous. Fruit red, covered with silky hairs. This species, as well as another named *R. viridifolia* is considered by some botanists as only a variety of *R. typhina*. Like the last, this species is abundant in North America, over-running sometimes a whole district, and forming a troublesome weed. Its fruit is very sour, but may be eaten with impunity. Bees are very fond of the blossoms.

R. vernicifera, Varnish-Bearing Sumach, or Japan Varnish-Tree. Leaf with 5-6 pairs of leaflets, all ovate, long, acuminate, entire, glabrous above, velvety beneath. It is a native of Japan and Nepal. Its leaves are very large and beautiful, rendering it one of the handsomest of shrubs. According to Thunberg, this is the plant which yields the celebrated Japan Varnish.

R. venenata, Poison Sumach, or Swamp-Sumach. Leaf 6-7 pair of leaflets, almost glabrous, entire, lanceolate-acuminate, reticulated beneath. Fruit white. It is a native of North America from Canada to Carolina, and also in swampy districts in Japan. This plant is exceedingly poisonous, so virulent that it is said to affect some persons by merely smelling it. A touch will sometimes produce violent inflammation. It is a beautiful shrub, and well worthy of cultivation, but great care should be taken to prevent its being carelessly handled.

R. coriaria, Hide, or Elm-Leaved Sumach. Leaf 5-7 pairs of villous leaflets, elliptical, bluntly and coarsely toothed, petioles naked. Flowers in large loose panicles of a whitish-green. Drupes villous. This plant is a native of the south of Europe. It is extensively used for the purpose of tanning, and it is said that all the leather made in Turkey is tanned with the bark of this species of *Rhus*. The fruit is acid and astringent, and the seeds are often used as tonics for exciting the appetite.

R. Copallina, Gum-Copal or Mastich-Leaved Rhus.—Leaf glabrous above, slightly pilose beneath, 5-7 pairs of leaflets and an odd one, lanceolate and entire; petiole winged and jointed; root creeping; flowers yellowish-green, dioecious. It is a native of North America from New Jersey to Carolina.

R. radicans, Rooting Poison-Oak, or Sumach.—Leaf one pair of leaflets and an odd one, odd one petiolated, glabrous, entire. A native of America from Canada to Georgia. Its climbing habit, combined with the beautiful red colour of the leaf during the decline of the year, renders it one of the most picturesque of American plants. It frequently abounds in the forests, where it may be seen covering the tops of the highest trees. It climbs up walls and rocks, and runs upon the ground with equal facility, thus covering everything within the reach of its stems. De Candolle distinguishes three varieties: *R. vulgaris*, with a stem climbing by means of roots; *R. volubilis*, climbing without roots; and *R. microcarpa*, with fruit much smaller than the other two. Like the following species, it emits a juice which indelibly stains linen. It is equally poisonous with *R. venenata*. A detailed account of the effects of the poison of the genus *Rhus* may be seen in Professor Kalm's 'Travels in North America.'

R. toxicodendron, Common Poison-Tree, or Poison-Oak.—Leaf of one pair of leaflets and an odd one, with a petiole, inciso-angulate, pubescent; flowers greenish. It is found in woods, fields, and fences, in common with the last-named species, in North America, where they are both known by the same name. Many botanists consider the two only varieties of the same plant. This species is the type of the genus *Toxicodendron* of Tournefort. It was introduced into England in 1640, and first grown in the Bishop of London's garden at Fulham. This species is that which is most frequently used in medicine. [SUMACH, in ARTS AND SC. DIV.]

The less common species of this genus cultivated in Britain are—*R. pumila* (Dwarf Sumach), *R. viridiflora* (Green-Flowered Sumach), *R. pentaphylla* (Five-Leaved Sumach), *R. suarcolens* (Sweet-Scented Sumach), and *R. aromatica* (Aromatic Sumach).

RHYACOPHILA. [NEUROPTERA.]

RHYNCHÆA. [SCOLOPACHÆ.]

RHYNCHASPIS. [DUCKS.]

RHYNCHITES. [CURCULIO.]

RHYNCHOCINETES. [PALEMONIDÆ.]

RHYNCHOLITES. [NAUTILIDÆ.]

RHYNCHOSAURUS, a genus of Fossil Reptiles. It was found in the New Red-Sandstone of Grinsill in Warwickshire. (Owen.)

RHYNCHOSPORA, a genus of Plants belonging to the natural order *Cyperaceæ*. It has few-flowered spikelets, 6 or 7 glumes, the lower ones empty or smaller; about 6 bristles; the nut compressed, convex on both sides, crowned with the dilated base of the style. There are two British species; *R. alba*, not uncommon on turf bogs, and *R. fusca*, a rare species found in the south-west of England and in Ireland. (Labington, *Manual of British Botany*.)

RHYPHIDÆ, a family of Dipterous Insects called False Crane-Flies.

RHYZOPHYSA. [ACALEPHÆ.]

RIBAND-FISH. [GYMNETRUS.]

RIBES (a name formerly given to a species of *Rheum*), a genus of Plants forming the natural order *Grossulariaceæ*. As this genus is the only one in the order, its characters, geographical range, and affinities are described with the order. It is well-known as producing the Currant and Gooseberry, and also for affording many of the ornamental shrubs of our gardens.

De Candolle divides the genus *Ribes* into four sections, of which the following is an analysis:—

Shrubs with prickles:—

Peduncles 1-2-3-flowered. . . *Grossularia*.

Peduncles many-flowered . . . *Botrycarpum*.

Shrubs without prickles:—

Calyx campanulate . . . *Ribesia*.

Calyx tubular . . . *Symphocalyx*.

* *Grossularia*.

This section includes some handsome shrubs, as well as the species which produces the common Gooseberry. Of these we shall notice a few that are most commonly found cultivated in this country.

R. Oxycanthoides, Hawthorn-Leaved Gooseberry. Prickles infra-axillary, solitary; leaves glabrous, lobes dentate; peduncles short, bearing 1-2 greenish white flowers. It is a native of rocky districts in Canada, and bears a fruit very much resembling that of the common gooseberry both in appearance and taste. Like many other described species of large genera, it has been supposed to be referrible to a more common form, the *R. grossularia*.

R. nigrum, Snowy-Flowered Gooseberry. Prickles solitary, in pairs or threes; leaves glabrous, roundish, entire at the base; flowers two together in peduncles; sepals reflexed; stamens longer than the style. It grows to the height of 4 or 5 feet. It was found on the north-west coast of America by Mr. Douglas, who sent the seeds to England in 1826. The fruit is about the size of a black currant, of a deep red-purple colour. It is said to be of a superior flavour to the common gooseberry.

R. cynosbati, Dog-Bramble Gooseberry. Infra-axillary prickles 1-2;

leaves 3-4, lobed, pubescent; calyx campanulate, cylindric; petals shorter than stigma and stamens; berry prickly. This plant is found in Canada, according to Pursh, and was discovered in India by Royle, and in Japan by Thunberg. It differs little from another well-known species, *R. divaricatum*, which has the tube of the corolla somewhat narrower and the stamens longer. Two varieties of this plant are recorded: one with smooth fruit, a native of Hudson's Bay; the other with prickly branches and fruit, shorter peduncles, pubescent purplish flowers, from Lake Huron.

R. grossularia, Common Gooseberry. This plant is too well known to require any description here, and is probably the parent of many of the other recorded species of *Ribes*. It is found wild in almost every part of England and Scotland, growing on old walls, in hedges and woods, although a question might be raised as to its being aboriginal in this island. It seems to be truly indigenous in France, Germany, and Switzerland; and according to Dr. Royle, is found in the Himalays and on the banks of the Ganges. It has also been seen growing in North America, on rocks near the Falls of Niagara.

This plant does not appear to have been known to the ancients; and the earliest author who mentions it is Matthioli, an Italian botanist. It was recorded as existing in England by Turner, Parkinson, and Gerard; but Ray is the earliest writer who mentions it as a cultivated species. The Dutch were the first to cultivate the gooseberry successfully, but even up to the time of Miller it seems to have gained very little repute in England as a fruit for the table. From its extensive cultivation, it has received a great variety of names. In Cheshire and the north of England it is called Feaberry, in Norfolk Feabas, both of which names are corruptions of Fevor-berry, as, according to Gerard, it was at one time considered a specific against fevers. Grozzer is a common name for it in Scotland, which seems to be derived from the French name *Groseille à Macquereau*, which is again derived from the Latin *Grossularia*, and the use of the fruit as a sauce with mackerel. Its common name, 'gooseberry,' is derived from gorse-berry, because its prickles resembled those of the furze or gorse. Some derive this name from its berries being used as sauce for geese. [GOOSEBERRY, in ARTS AND SC. DIV.]

There are numerous varieties of this plant recorded, which chiefly vary in extent, size, and number of their prickles, and in the shape and size of their fruit and flowers.

** *Botrycarpum*.

This section includes four species intermediate between gooseberries and currants: they are however called by the former name. *R. orientale*, Eastern Gooseberry, with yellow green flowers, blowing in April and May. It is a native of Syria. *R. saxatile*, Rock Gooseberry, a native of Siberia, with greenish-purple flowers.

R. diacantha, Twin-Prickled Gooseberry. It flowers in May and June, having yellowish flowers and cuneated leaves. It grows wild in Dauria and other parts of Siberia. *R. lacustris*, Lake-Gooseberry, a native of moist places in Canada and Virginia, with flowers like a currant and prickles like a gooseberry.

*** *Ribesia*.

This section includes the greater number of the Currants, of which there are about 40 species.

R. rubrum, the Common Red Currant. The name Currant seems to be derived from the similarity of the fruit to the Corinth Raisin, or small grape of Zante, which are commonly called Corinth's, or Currants. This last is too well known to need a description. It is a native of Europe and Siberia, and the northern parts of North America, to the mouth of the M'Konzie, and is found in mountainous districts in the north of England and Scotland. Like most plants that are easily disseminated and occupy varied elevation, latitude, and soil, this species is subject to many varieties. Of these seven have been recorded by De Candolle, which vary in the shape, size, and covering of their leaves, as well as the size and colour of their fruit. The writer of the article '*Ribes*,' in London's '*Arboretum et Fruticetum Britannicum*,' observes, "The Common Red Currant is commonly treated by botanists as a distinct species, but we have no doubt whatever that *R. petraeum*, *R. spicatum*, *R. alpinum*, *R. prostratum*, and several other botanical species are essentially one and the same thing. We have arrived at this conclusion from the study of the plants in the very excellent collections of this genus which are in the garden of the Horticultural Society of London, and in the arboretum of the Messrs. Loddiges."

The Currant is not mentioned by Greek and Roman writers, but it is scarcely possible that its beautiful red and sweet berries should have been neglected by the people amongst whom they grew. In France they were cultivated long before the Gooseberry, but were first produced in perfection by the Dutch. Gerard mentions that they were cultivated in gardens in his time. [CURRANTS, in ARTS AND SC. DIV.]

R. nigrum, the Black Currant. Flowers whitish or yellowish-green. Calyx a rich brownish-red or pink colour. The stamens and petals frequently present a remarkable peculiarity: the usual number of each is 5, but should either the petals or stamens be increased in number the other is diminished; thus, if there are 7 stamens there will be but 3 petals, and if there are 10 stamens there will be no petals, and vice versa. The peculiar strong smell of the leaves of this

plant is very characteristic. The Black Currant has the same geographical range as the Red Currant, but is found more abundantly in the north than in the south of Europe. It is now common in Great Britain, but is probably not indigenous. It is found in Siberia, on the Caucasus, and in Sweden. It is indigenous in the woods of Russia as far as St. Petersburg, and in this district the fruit is found green, yellow, or even white. Species of *Ribes* are also found in India and South America with black fruit. There are three wild varieties—*R. bacca flarida*, with a dingy greenish-yellow fruit, supposed to be a hybrid between black and white currant; *R. bacca virida*, with green fruit; and *R. foliis variegatis*, with leaves streaked with yellow.

R. sanguineum, the Bloody or Red-Flowered Currant. Leaves cordate, serrated, villous beneath; racemes drooping, twice the length of the leaves; calyx with spreading segments. This is the most ornamental species of the genus, bearing large racemes of deep rose-coloured flowers, which are followed by berries of a bluish-black. It is a native of the north-west coast of America.

R. atropurpureum, the Dark Purple-Flowered Currant, is a native of the Altai and mountainous districts on the river Ural.

**** *Symphocalyx*.

The species of this section are cultivated entirely as ornamental shrubs. Of these, *R. aureum*, the Golden-Flowered Currant, is best known. It is a native of America. Of this plant there are three varieties—*R. præcox*, *R. villosum*, and *R. serotinum*. They are all beautiful shrubs, and deserve a place in every collection.

RIBGRASS. [PLANTAGINACEÆ.]

RIBWORT PLANTAIN, the common name of the *Plantago lanceolata*. [PLANTAGO.]

RICCIACEÆ, *Crystal-Worts*, a natural order of moss-like Plants or Herbs, inhabiting mud or water, swimming or floating, usually annual; their leaves and stems blended into a frond of a cellular structure, creeping, green or purple underneath, with a distinct epidermis, and a cavity of air-passages beneath it in some species.

These plants form a plain transition from *Thallogens* to *Acrogens*. Their spores are collected in large numbers within organs resembling the pistils of Phanogamous Plants. They have a distinct axis of growth, and an epidermis is distinctly formed with stomates for breathing with. The genus *Durinea* is regarded as forming the nearest transition to Liverworts. It fructifies under water, which is very seldom the case with the other *Crystal-Worts*.

Of the species hitherto known two-thirds have been observed in Europe, and the remainder in various parts of the world. Several species in North America, the Cape of Good Hope, and Brazil, appear to be very similar to those of Europe. There are 8 genera and 29 species.

(Lindley, *Vegetable Kingdom*.)

RICE. [ORYZA.]

RICE-BIRD, one of the names of the Paddy Bird, Paddee Bird, or Java Sparrow. It is the *Loxia oryzivora* of Linnaeus.

This well-known bird, whose plumage is well described by Buffon as being so well arranged that no one feather passes another, whilst all appear covered with that kind of bloom which is visible on plums, giving them a beautiful tint, has the bill very much developed; indeed, with the exception of *Pyrenestes* and perhaps *Coccothraustes*, this finch is the most remarkable of the race for the size and power of that organ.

The colour of this bird is bloomy lead-coloured; head and tail black; bill red; helly obscurely rosy; cheeks in the male snowy; legs flesh-coloured.

In Java, where it is called Glate, and the other parts of Asia where it is found, it has a very bad reputation on account of the ravages which it commits in the rice-fields with its powerful and sharp bill. In Sumatra the name of the bird is Boorong Peepee. It is often brought alive to this country, and confined in aviaries for the sake of its elegant shape and graceful colouring: its song, which is short and monotonous, does not much recommend it. This species must not be confounded with the Rice-Bird of America, *Emberiza oryzivora*, Linn. [BOO-O-LINK.] (See figures in next column.)

RICHARDIA, a genus of Plants belonging to the natural order *Araceæ*, of which only one species is known, the *R. Ethiopica*. It was introduced into this country from the Cape, under the name of *Calla Ethiopica*, in 1731. It is also found wild at St. Helena. It is one of the most beautiful of Aroideous plants. Its large spathe is pure white, surrounding a spadix which is coloured deeply yellow by its antheriferous flowers. *Richardia* is a hardy plant, bearing well our mildest winters, and growing in great vigour and beauty in the ordinary apartments of a house. It may be made to blossom all the year round.

RICHARDSONIA, a genus of Plants belonging to the natural order *Oimchonaceæ*, named by Houston in honour of Richardson, an English botanist of the sixteenth century. This genus was called *Richardia* by Linnaeus, but that name has been given to another plant. Most of the species of *Richardsonia* are natives of South America. They possess emetic properties, and under the name of White Ipecacuanha, &c., are used extensively as a substitute for the true Ipecacuanha (*Cephaelis Ipecacuanha*).

NAT. HIST. DIV. VOL. IV.

Rice-Bird (*Loxia oryzivora*, Linn., *Fringilla oryzivora* of Swainson and authors). Upper figure, female; lower figure, male. (Swainson.)

RICINULA. [ENTOMOSTOMATA.]

RICINUS, an apetalous genus of Plants belonging to the natural order *Euphorbiaceæ*. This word is derived from 'ricinus,' the Latin name for a species of insect which the fruit of this plant was supposed to resemble. (Pliny, 'Nat. Hist.,' xv. 7.) The common name of *Ricinus* is Palma Christi, a name applied to these plants by Brunfels, Matthioli, and other older botanists, on account of the form of its elegant lobate leaves. It was originally a native of Asia, but is now naturalised in Africa, America, and the south of Europe. The characters of this genus are:—Flowers monœcious; calyx 3-5-parted, valvate; no petals; filaments numerous, polyadelphous; style short; stigmas 3, bipartite, feathery; ovary globose, 3-celled, with an ovule in each cell; fruit capsular, trilocular; leaves alternate, stipulate, palmate, glands at apex of petiole; flowers in terminal panicles; trees, shrubs, or herbs, becoming arborescent.

R. communis, Common Palma Christi, is best known as producing castor-oil. It has peltate palmate leaves, with lanceolated serrated lobes; an herbaceous glaucous stem, of a purplish red-colour upwards, and flowers in long green and glaucous spikes springing from the divisions of the branches, the males from the lower part of the spike, the females from the upper; the capsules are prickly. It varies in size; in Britain it is seen seldom more than three or four feet in height, but in India it is a tree; and Clusius mentions it as measuring from two to four feet round its stem in Spain. Lindley refers several species distinguished by Willdenow to this form, namely, *R. viridis*, *R. Africanus*, *R. lividus*, and *R. inermis*. ('Flora Medica.')

R. communis will grow freely in this country, and when sown in pots or hot-beds early in the season, and transplanted in spring, it forms a very handsome border annual.

RIET-BOC. [ANTLOPEÆ.]

RIGGLE. [AMMODYTES.]

RING-BIRD. [EMBERIZIDÆ.]

RING-DOVE. [COLUMBIDÆ.]

RING-THRUSH. [MERULIDÆ.]

RING-TAIL. [FALCONIDÆ.]

RING-TAILED EAGLE. [FALCONIDÆ.]

RINGENT, a form of the corolla of plants. [FLOWER.]

RINGS, FAIRY, is a name given to certain spots which are observed amongst grass in fields, and which are characterised by being more

luxuriant than the surrounding herbage. They are of two kinds: either an entire knot of grass is more luxuriant than the rest, or the luxuriant grass grows in a circle or the segment of a circle around a comparatively barren spot. The name of fairy rings was originally given to these spots because they were supposed to be the places where the little fairies held their nightly revels. Recently a better cause has been assigned for their origin. They are now known to be those portions of the surface on which a species of fungus has grown, which by dying has afforded nutriment for the grass on the spot; and as the fungus grows in this particular place on account of something favourable to its development, it continues year after year to extend itself beyond the small circular space to which it was originally confined; but as the grass in the centre loses the stimulating influence of the decayed fungus, this part becomes comparatively barren, and thus the ring of luxuriant grass keeps on extending for many years, till the earth, no longer affording the circumstances necessary to the development of the fungus, it dies. There are several species of fungus that produce this effect. It was first noticed by Dr. Withering as occurring with the *Agaricus oreades*; but the Common Mushroom (*A. campestris*), the Gigantic Puff-Ball (*Bovista gigantea*), and many others may be seen in the act of forming these circles. It is very probable that most of the large *Fungi* would form these rings during their growth, provided the entire surface of the earth by which they were surrounded afforded the circumstances necessary to their growth.

RIOLITE. [Zinc.]

RIPIDOLITE, a variety of Chlorite. [CHLORITE.]

RIPPLE-MARK. In geology, the undulations on the surface of many rocks, which resemble the ridges and hollows left on mud and sand by the small waves of water, are thus termed.

The progress of geological induction has given an unexpected importance to the study of these undulations; for it is now certain that the right understanding of their origin is a very necessary element in reasoning on the deposition of stratified rocks and the displacements of the ancient bed of the sea.

The formation of small ridges and furrows, under the influence of water which ripples or undulates in small waves, may be conveniently witnessed and studied on the shores of comparatively quiet seas, on the margins of lakes, or along the sides and shallow beds of rivers. The ripple-mark thus produced is more or less permanent, according to the nature of the sediments on which it is impressed, and the circumstances which accompany and succeed the withdrawal of the water which formed it.

Loose coarse sand easily receives impressions from the superfluctuating water, which momentarily change under the varying influences of the waves: muddy sediments are less easily moulded, but the forms are less fleeting. It happens often that on the gradual retreat of the tide from broad muddy surfaces like those in the Bay of Morecambe, or along the shores of the Thames, the small rippling waves of the ebbing tide leave marks sufficiently durable to allow of being indefinitely preserved, if by any gradual operation some new sediments were gently overlaid.

A very small ripple leaves its mark on the subjacent sand or mud at only very small depths: larger waves are felt to a greater depth; and apparently the depth at which ripple-marks are formed may be judged of, within moderate limits of error, by the breadths of the ripple-marks. Wherever then we find among marine stratified rocks or sediments, of whatever date, undoubted ripple-marks such as shallow waters leave, those deposits contain clear proof of their having been formed at small depths; and when, as frequently happens, these are seen to be covered by other sediments hundreds or thousands of feet in thickness, the conclusion is just that in those situations the ancient sea-shore underwent a great subsidence, or the ocean-level experienced a great rise, after the formation of those now buried ripple-marks. There has been in those situations a change of the level of land or sea. Now, we find ripple-marked strata among the rocks of every geological age. As examples, we mention, among strata lower than the Mountain Limestone, the Fossiliferous Rocks (Grauwacke) near Killybegs, and near Linton in North Devon; in the sandstones of the Mountain Limestone Group, under Penyghent in Yorkshire; in the sandstone of the Coal-Formation at Elland in Yorkshire; in the sandstones of the New Red-Sandstone-Formation at Storeton near Liverpool; in the sandstones of the Oolitic Rocks near Scarborough and near Stamford; in the Wealden deposits at Horsted.

In most cases ripple-mark is found on sandstones or indurated clays of fine grain and frequent lamination, and it is most distinct on surfaces where a change of deposit happens, as where sandstones alternate with thin clay partings. Rarely, as in the Storeton quarries, impressions of quadrupeds accompany the ripple-mark; and it is even thought that marks of rain are preserved thereon.

(Babbage, *Ninth Bridgewater Treatise*; Playfair, *Huttonian Theory*; Lyell, *Principles of Geology*; De la Beche, *Theoretical Researches*.)

RISCOLUS. [PAGILORODA.]

RISSEA, M. De Freinville's name for a genus of Gasteropodous Mollusca, founded on some small shells observed by M. Risso of Nice, and described by M. Desmarest in 1814 in the 'Nouveau Bulletin de la Société Philomathique.'

Lamarck placed the few species known to him among the *Melania*, but without distinction. Delle Chiaje made known the animal struc-

ture of a Mediterranean species in his 'Memoirs on the Invertebrata of the Neapolitan Sea;' and Philippi recorded its generic characters in his 'Enumeratio Molluscorum Siciliæ,' from observations made upon two other Mediterranean species.

The animal has a subtriangular foot, truncated anteriorly, pointed posteriorly. Head probosciform, with a subulate tentacle on each side, at the external base of which the eye is placed on a little convexity; mouth prolonged into a short and truncated proboscis.

Shell elongated, turriculate, sometimes short and subglobular; aperture oval, semilunar, subcanaliculate, having the right lip thickened, and nearly always projecting forwards, and arched longitudinally; operculum horny, closing the aperture exactly.

M. De Blainville divides the genus into the following sections:—

A. Turriculated and Ribbed. Ex. *R. acuta*.

B. Subturriculated and Ribbed. Ex. *R. costata*.

C. Subturriculated; perfectly smooth. Ex. *R. hyalina*.

D. Subglobular. Ex. *R. cancellata*.

The same divisions are adopted by M. Rang.

There are about 70 recent species, which are very generally distributed, but are most abundant in the north temperate zone. They are found in North America, the West Indies, Norway, the Mediterranean, the Caspian, and in other seas. Messrs. Forbes and Hanley describe 27 species as inhabitants of the British seas. *Hydrobia Lynceus*, *Nematula*, and *Jeffreysia* are sub-genera.

One hundred species have been described as fossil. They are found in the Permian Rocks of Great Britain and Franco.

RIVER-HORSE. [HIPPOPOTAMUS.]

ROACH. [LEUCISCUS.]

ROAN-TREE. [PYRUS.]

ROBIN-REDBREAST. [ERYTHACA.]

ROBIN-HUSS. [SQUALIDE.]

ROBINIA, a genus of Plants belonging to the natural order *Leguminosæ*, named in commemoration of John Robin, a botanist in the time of Henry IV. of France. This genus is known by having an inferior perianth; teeth of calyx 5, lanceolate, two upper ones shorter and approximate; corolla papilionaceous; ovary with from 16 to 20 ovules; style bearded in front, and legume sub-sessile and many-seeded. They are North American trees, bearing nodding racemes of white or rose-coloured flowers. The genus *Robinia* formerly comprehended the plants now included under *Caragana*, from which it is distinguished by its long gibbous legume and unequally pinnate leaves.

The best known species of *Robinia* is the *R. pseudacacia*, the Bastard or False Acacia. It has stipular prickles, with loose pendulous racemes of white sweet-smelling flowers, which, as well as the legumes, are smooth. This tree, which is now so well known, was first grown in Europe by Vespasian Robin, the son of the botanist, after whom the genus was named, in the Jardin-des-Plantes at Paris.

It has always been known in America as affording an exceedingly hard and durable wood. It is there used for making posts, and occasionally trees are found large enough to be employed in ship-building; but its greatest consumption is for making trenails, by which the timbers of ships are fastened together, and for this purpose large quantities are used in the royal dockyard at Plymouth, which are imported from America.

Cattle are fond of the young shoots, and on this account it has been recommended to be cultivated as forage.

The roots and other parts of the plant, like many of its order (*Leguminosæ*), contain a saccharine principle, which accounts for the nutritive properties of the leaves. In St. Domingo the flowers are used for making a distilled liquor, which is said to be very delicious. It folds up its leaves at the approach of night.

There are two other species frequently cultivated in this country, *R. viscosa*, the Clammy Robinia, and *R. hispida*, the Hairy Robinia, or Rose-Acacia. The former is characterised by the sticky secretion with which it is covered, and which has been discovered to possess a peculiar vegetable principle. The latter, which is the smallest of the three species here mentioned, has very large flowers, and forms a very ornamental shrub when grown on an espalier rail or against a wall.

ROCAMBOLE. [ALLIUM.]

ROCELLA, a genus of Plants belonging to the family of Lichens. The species are used in dyeing, and are popularly called Orchil, or Archil. This name is derived from the Oricello of the Italians or the Spanish Orchella. It is often corrupted in commerce into Rocilla-Weed. Several species of Lichens are employed for the same purpose, which are distinguished according to the country whence they are imported, and also by manufacturers into Weed and Moss, the former name being applied to the Filiform Lichens of botanists belonging to the genus *Rocella*, to be treated of here, whilst the terms Moss and Rock-Moss are applied to the Crustaceous Lichens belonging to the genus *Lecanora*, which include the Cudbear and Parelle of dyers. [PARELLA.]

The character of the genus *Rocella* is as follows:—Thallus coriaceous-cartilaginous, rounded or plano, branched or lacinated; apothecia orbicular, adnate with the thallus; the disc coloured, plano-convex, with a border at length thickened and elevated, formed of the thallus, and covering a sublentiform black compact pulverulent powder, concealed within the substance of the thallus.

R. tinctoria, Dyer's Roccells, or Orchil. Thallus suffruticose, rounded, branched, somewhat erect, grayish-brown, bearing powdery warts; apothecia flat and horny, with a scarcely prominent border. A practical writer describes "the good kind as having a nearly white powder on its surface towards the centre; the under surface is of a gray colour, and is not hairy; if wetted, it does not turn of an orange colour; its edges are flat and thin."

R. fuciformis, the Flat-Leaved Orchil. Thallus flat, branched, nearly upright, grayish-white, bearing powdery warts; apothecia horny, bordered.

Both kinds are found on maritime rocks, or on dry stone walls exposed to the influence of the sea-breeze, as well on the coast of England as on the shores of the Mediterranean and the East Indies. [ORCHIL, in ARTS AND SC. DIV.] The more arid the situation, the better is the quality of the lichens. The presence of the colouring-matter is ascertained by steeping the weed broken up in small pieces in diluted solution of ammonia, in a bottle half filled with liquid, which should be kept corked, but frequently opened in a temperature not exceeding 150° Fahr.

1, *Roccella tinctoria*; a, warts on the thallus. 2, *Roccella tinctoria* (East India). 3, *Roccella fuciformis*; b, apothecia.

ROCHEA (named after La Roche, a French botanist), a genus of Plants belonging to the natural order *Crassulaceæ*. It has a 5-lobed calyx; petals 5, united into a gamopetalous hypocrateriform corolla, with a short tube, equal in length to the spreading limb or shorter than it; stamens 5, alternating with the petals, a little exserted; glands and carpels 5. The species are fleshy simple succulent shrubs. The leaves opposite, connate at the base, thick, and white. The flowers are disposed in terminal corymbs, without any bracts. A large number of the species are cultivated in our gardens and green-houses.

ROCINELLA. [ISOPODA.]

ROCK-CRYSTAL. [QUARTZ.]

ROCK-FISH, a name for the Black Goby. [GONIUS.]

ROCK-MANAKIN. [RUPTICOLINÆ.]

ROCK-PLANTS are those plants which are distinguished by growing on or among naked rocks, and are confined to no particular region or latitude. De Candolle ('Dictionnaire des Sciences Naturelles,' vol. xviii.) observes that they pass by insensible gradations into the plants that inhabit walls, rocky and stony places, and even gravelly places, from which they pass into those that are found particularly on sands and barren soils. Most of the plants growing on rocks have but a small development of root, as they derive their nutriment principally from the air, through the medium of their leaves and stems. A large number of the *Cryptogamia*, especially Mosses and Lichens,

belong to this class. Many of these plants present a remarkable diversity, according to the nature of the rocks on which they grow.

[VEGETABLE KINGDOM.]

ROCK-ROSE. [CISTUS.]

ROCK-SALT. [SODIUM.]

ROCK-SNAKE. [BOIDE.]

ROCKET. [ERUCA.]

ROCKET, SEA. [CAKILE.]

ROCKET, YELLOW. [BARBAREA.]

ROCKLING. [MOTELLA.]

ROCKS, in Geology, are any aggregation or collection of minerals or fragments of mineral matter, whether they are crystalline or amorphous, hard or soft, compact or loose. On this account they vary exceedingly in character, and no simple definition will give an idea of a rock as distinct from other objects around. The causes which produce them are the great agents of all geological change. They may be merely mechanical heaps, chemical crystallisations, and contain in them organic beings or not. Their exceedingly mixed character makes it difficult to classify them, independent of their age, as arranged in the various geological strata. [GEOLOGY.]

The most prevalent classification of rocks in actual use is founded on one leading feature of their origin and history. Rocks are of igneous origin (Pyrogenous Rocks), or of aqueous origin (Hydrogenous Rocks), and thus make two great classes; the former being often considered, with reference to the circumstances of their occurrence in two divisions, namely, hypogene or Plutonic rocks (as granite), and volcanic rocks (as obsidian); the latter being distinguished into fresh-water and marine deposits, the result of chemical, vital, and mechanical agencies exerted in water. Many cases are known of an alteration of these hydrogenous rocks by contact with Plutonic or volcanic masses: by this change they acquire the name of Metamorphic Rocks. Thus clays and sandstones are hardened, and have their structure altered so as to resemble clay-slate, quartz-rock, or jasper; and chalk and limestone are rendered crystalline.

Adopting as the best and most applicable the fundamental distinction of pyrogenous and hydrogenous rocks, the student will find by experience that the best if not the only good way of describing and recognising rocks, is by attending to their elementary composition. The granitic, porphyritic, amygdaloidal, or other structures of igneous rocks, are so many variable circumstances due to particular accidents in the fusion or cooling of the masses, and belong more or less to all of them, as the compact, oolitic, arenaceous, and other characteristic textures of hydrogenous rocks, mark peculiarities of their aggregation or solidification.

Mr. Scrope has successfully shown, in his 'Synopsis of Volcanic Rocks' ('Journal of Science, vol. xxi.), that these various compounds may be easily and philosophically classed by consideration of the relative abundance of two minerals seldom absent from any of them, namely, felspar and augite. (The felspar is sometimes replaced by leucite, hedyne, olivine, or melite; the augite by hornblende or titaniferous iron.) Hence we have only three great groups:—

Felspathic	Trachyte.
Augite-Felspathic	Graystone.
Augitic	Basalt.

To each of these belong many varieties, and many gradations of granitic, porphyritic, amygdaloidal, and other structures. [LAVA.] By a similar method we may class the older or Plutonic rocks of fusion, as:—Felspathic—granite, porphyry, felspar rock, claystone, eurite, pitchstone; Augite-Felspathic—sienite, euphotide; Augitic—sienite, hypersthene rock, greenstone, basalt, wacké, melaphyre.

The hydrogenous rocks of most importance may be classed according to their arenaceous, argillaceous, calcareous, or other basis, as:—

Arenaceous, uniform, as sandstones, sands; aggregated as conglomerates, pudding-stones.

Argillaceous, uniform, as clay and shale; containing fragments, as some clay conglomerates.

Argillo-Calcareous, as marls properly so called.

Calcareous, as chalk, limestone.

Calcareo-Magnesian, as dolomite.

Haloid, as gypsum, rock-salt.

Carbonaceous, as coal, lignite.

Ferruginous, as ironstone.

Cupriferous, as the kupferschiefer.

Finally, all these hydrogenous rocks are liable to local changes, by contact or proximity with the rocks of fusion. These metamorphic rocks may be classed according to the same form as those which are unaltered. We give below authentic examples of several cases of metamorphism:—

1. Arenaceous Rocks, metamorphic by induration, as along greenstone dykes in Arran, and Salisbury Crags. Similar effects happen beneath iron-furnaces, and when the effect is in extreme the result is quartz rock.

2. Argillaceous Rocks, metamorphic by induration, and a certain confluence of grains. In extreme cases the result is a kind of clay-slate, or hone-slate, or Lydian stone, with cubic pyrites, and rarely garnets, imbedded. An example of the latter occurs at Plas Newydd.

3. Calcareous Rocks, metamorphic by re-arrangement of particles.

Thus granular or saccharoid limestone is found by the side of the basaltic dykes in Antrim, on the greenstone of Teesdale, near the hypersthene of Sky, &c. The limestone among primary strata is of similar appearance, though not in contact with igneous rocks.

4. Carbonaceous Rocks. Coal becomes coke or anthracite near basaltic dykes.

Examinations of this kind have shown that ordinary sedimentary rocks altered by heat acquire aspects and structures and compositions resembling almost exactly those most common among the earliest or primary strata, as quartz rock, clay-slate, garnet mica-slate, garnet gneiss, granular marble, &c.; and it is therefore a probable inference that in all such cases of strict resemblance those ancient rocks have undergone on a great scale, and under the general influence of the intense heat of the earth, the changes which are certainly proved to have happened locally, from limited agencies, on substances of similar chemical quality. Very careful investigations on these points are however still needed to fix limits and give precision and certainty to the inferences from phenomena. [BASALT; GRANITE; GRAUWACKE; GNEISS; LAVA; MICA-SCHIST; PORPHYRY; STRATIFICATION.]

RODENTIA, an order of Animals belonging to the class *Mammalia*, embracing the Rats and Mice, Hares, Rabbits, Guinea-Pigs, and other well-known animals.

The following is Mr. Waterhouse's arrangement of these animals:—

front only, so that their posterior border being worn away more than their anterior edge, they are always kept set like a chisel; their prismatic form causes them to grow from the root in proportion to the wearing down of their cutting edge; and this disposition to grow or push forward from the root is so strong, that if one of them is lost or broken, its antagonist, meeting with no opposition to keep it within bounds, develops itself so as to become monstrous. [BEAVER.] The lower jaw is articulated by a longitudinal condyle, so as to have no horizontal movement except from behind forwards, and vice versa, convenient for the action of gnawing; the molars consequently have flat crowns, the enamelled eminences of which are always transversal, so as to be in opposition to the horizontal movements of the jaw, and to be better adapted for trituration.

The genera in which these eminences are simple lines, and which have the crown of the tooth very flat, are more exclusively frugivorous; those which have the eminences divided into blunt tubercles are omnivorous; and, finally, the small number of those which have points more willingly attack other animals, and approximate a little to the *Carnivora*.

The form of the body of the Rodents is in general such that their hinder parts exceed their anterior ones, so that they leap rather than walk; this disposition in some of them is as excessive as in the Kangaroos.

These animals have two great incisor teeth in each jaw, separated from the molars by a wide space, with which they could hardly seize a living prey, or rend flesh; they could not even cut aliments, but they might serve for reducing them by continued labour into fine molecules—in a word, for gnawing them; whence the term Rodents, or Gnawers, applied to this order. With these weapons they attack the hardest vegetable productions, and frequently feed on wood and bark. The better to effect this object, these incisors have enamel in

The intestines of the animals of this order are very long; their stomach simple or slightly divided; and their cæcum often very voluminous, even more so than the stomach. The *Myoxi* (Dormice) want the cæcum.

The brain of the Rodents is nearly smooth and without convolutions; the orbits are not separated from the temporal fossæ, which have but little depth; the eyes are entirely directed laterally; the zygomatic arches, delicate and curved below, announce the weakness of the jaws;

the fore arms have scarcely any rotatory motion, and their two bones are nearly united; in a word, the inferiority of these animals shows itself in the greater part of the details of their organisation. Nevertheless, the genera which have the strongest clavicles enjoy a certain dexterity, and use their fore feet for carrying their food to their mouth; others again (the Squirrels) climb trees with facility. ('Règne Animal.')

Preparations of the structure of these animals may be seen in the museum of the Royal College of Surgeons.

The following animals are arranged by Cuvier under the order *Rodentia* :—

The Squirrels (*Sciurus*, Linn.), namely, the Squirrels properly so called (*Sciurus*, Cuv.); the Flying Squirrels (*Pteromys*); and the Aye-Aye (*Cheiromys*).

The Rats (*Mus*, Linn.), namely, the Marmots (*Arctomys*, *Spermophilus*); the Dormice (*Myoxus*, Gm.); the Spiny Rats (*Echimus*, *Hydromys*, *Capromys*); the Rats properly so called (*Mus*, Cuv.); the Jerbilles (*Gerbillus*, *Meriones*); the Hamsters (*Cricetus*); the Field-Rats (*Arvicola*, Lacép.), subdivided into the Ondatras (*Fiber*, Cuv.), the ordinary Field-Rats (*Arvicola*, Cuv., *Hypudaeus*, Ill.), and the Lemmings (*Georychus*, Ill.); *Otomys*, and the Jerboas (*Dipus*, Gm.).

The Jumping Hares (*Hemylus*, F. Cuv.; *Pedetes*, Ill.).

The Rat-Moles (*Spalax*, Guld.).

Bathyergus (*Oryctères*, F. Cuv.).

Geomys (*Pseudostoma*, Say; *Ascomys*, Licht.).

Diplostoma, Raf.

The Beavers (*Castor*).

The Couias (*Myopotamus*, Com.).

The Porcupines (*Hystrix*, Linn.), namely, the Porcupines properly so called (*Hystrix*, Cuv.); *Atherurus*, Cuv.; *Erethizon*, F. Cuv.; and the Coendous (*Syntherisma*, F. Cuv., *Cercolabes*, Brandt).

The Hares (*Lepus*, Linn.), namely, the True Hares (*Lepus*, Cuv.), and *Lagomys*, Cuv.

The Capybara (*Hydrochærus*, Erxl.).

The Guinea-Pigs (*Anema*, F. Cuv.; *Cavia*, Ill.).

The Mocoos (*Kerodon*, F. Cuv.).

The Agoutis (*Chloromys*, F. Cuv.; *Dasyprocta*, Ill.); and

The Pacas (*Calogenys*, F. Cuv.).

In this work the genera and species of *Rodentia* have been described under the following heads:—CHINCILLIDÆ, HYSTRICIDÆ, LEPORIDÆ, MURIDÆ, SCURIDÆ, BEAVER, ONDATRA, CŒLOGENTS, AGOUTI, and KERODON.

ROEBUCK. [CERVIDÆ.]

ROEMERIA (named after Dr. John James Römer, professor of botany at Landshut; he was author of several botanical works, and died in 1820), a genus of Plants belonging to the natural order *Papaveraceæ*. It has 4 petals, numerous stamens, 2-4 sessile stigmas, an elongated 2-4 valved 1-celled capsule with distinct placentas. The species are annual herbs yielding a yellow juice, with violet flowers.

R. hybrida, Hybrid-Roemeria, has a 3-valved erect pod with a few rigid leaves at its extremity. This plant is a native of Europe and the north of Africa, in cultivated fields and vineyards, especially on the coasts of the Mediterranean. It is also found in England in chalky corn-fields in Cambridgeshire and Norfolk. Although now having the appearance of a native, this plant has been probably introduced into this country. Two other species, *R. refracta* and *R. bivalvis*, have been described: the first a native of Tauria, the second of Syria.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*.)

ROLLER. [CORACIAS.]

ROMANZOVIITE. [GARNET.]

ROMEINE, a Mineral occurring crystallised in square octohedrons, in groups of minute crystals. Colour hyacinth, or honey-yellow. Hardness, scratches glass. It is found at St. Marcel, in Piedmont.

Its analysis by Damour gives :—

Antimonious Acid	79.17
Lime	16.65
Protoxide of Manganese	2.16
Protoxide of Iron	1.19
Silica	0.60

—99.77

RONDELETIA, a genus of Plants belonging to the natural order *Rubiaceæ*, named after Rondelet, a French botanist of the 16th century. It is characterised by having a calyx with a subglobular tube. Corolla superior, funnel-shaped, ventricose at the throat; segments 4-5, ovate-obtuse, spreading; anthers 4-5, sessile within the corolla; ovary 2-celled; style filiform; stigma bifid; capsule round, crowned with the limb of the calyx. Seeds minute, numerous, or few when abortive. The genus, as formerly constituted, included many shrubby trees which occur in India (Roxb., 'Fl. Indica'), but these have been referred by modern botanists to *Adenosacme*, *Greenia*, and *Wendlandia*. The present genus *Rondeletia* occurs chiefly in America and the West Indies.

ROOK. [CORVIDÆ.]

ROOT is that part of a plant which is sent downwards into the earth, at the same time that the stem is sent upwards into the air. Every part of the plant which exists underground is not root, as

large portions of the stem itself may remain under the surface of the earth; and large buds, called huds, also exist underground. These parts have been often confounded with the root. The creeping root, and some forms of the tuberous and hulsous roots of older botanical writers, are only so many different forms of the stem. [EXOGENS.]

The root is distinguished by certain structural peculiarities, by which it may be easily known from the stem. First, its ramifications are irregular, not having the symmetrical form of branches, nor are they developed like branches from huds. Secondly, roots generally produce no leaf-buds. When they do appear, which occasionally occurs, they are called adventitious huds. Thirdly, roots never have leaves, scales, or other appendages developed upon their surface; and fourthly, the cuticle of roots is never found to possess stomates, which are frequently very numerous on various parts of the stem.

The smaller divisions of roots are called fibrils, which consist of a little bundle of ducts or spiral vessels, surrounded by woody fibres, lying in a mass of cellular tissue. At the apex of the fibril the cellular tissue is loose and devoid of cuticle, from which cause it absorbs more rapidly the fluid by which it is surrounded than the other parts of the root. Although the terminations of the roots cannot be considered as special organs, they have been named by De Candolle spongelets, or spongioles, in reference to their absorbing power.

The relation between the size and extent of the roots and that of the branches varies very much. In some tribes, as the *Conifere* and *Palmaceæ*, the roots are very insignificant compared with the size of the stem. In other plants the roots are much the longest, as in the lucern, &c. In the greater proportion of trees the roots extend wider than the branches, but do not penetrate so deep as the stem is high.

The internal structure of the root resembles that of the stem, but in Exogens the roots do not possess a central pith. The cellular tissue of many roots is exceedingly abundant, and on this account they are used as articles of diet. Many of these roots, by attention to their culture, may be increased in size; and the growth of esculent roots is an object of importance in the kitchen-garden. The principal esculent roots are: the Jerusalem Artichoke (*Helianthus tuberosus*); Turnip (*Brassica Rapa*); Carrot (*Daucus Carota*); Parsnip (*Pastinaca sativa*); Red-Beet (*Beta vulgaris*); Skirret (*Sium Sisarum*); Scorzonera, or Viper's-Grass (*Scorzonera Hispanica*); Salsafy, or Purple Goat's-Beard (*Tragopogon porrifolius*); Radish (*Raphanus sativus*). Besides these, which are commonly cultivated, there are many of our native plants which possess roots yielding a nutritive matter, and are occasionally used as articles of diet. The Arrow-Head, Common Arum, Bitter Vetch, or Mouse-Peas, Earth-Nut, Meadow-Sweet, Pilewort, Silver-Weed, Solomon's Seal, and Common Comfrey, are recorded as yielding edible roots. ('Cyclopædia of Gardening.')

During dry seasons and in dry situations the roots of many plants swell and become tuberous, which seems to be a provision for supplying nutriment to the stem and its appendages.

Roots are called annual, biennial, or perennial, according to their duration. When a root perishes after its first year's herbage and flowering, it is annual; if after the second year's herbage and first year of flowering, it is biennial. If a root endures for many years, although its herbage may perish every year, it is perennial.

There are various forms of roots distinguished by botanists. The Fibrous Root possesses a multitude of small divisions of the fibrillæ, as is seen in the *Poa annua* and many other grasses. The Nodulose Root presents occasional dilatations, as in the *Phleum nodosum*. A Premorse Root is one in which the extremity of the primary axis has perished, or its development has been prevented by the extension of fibrillæ from its sides, as in the Devil's-Bit Scabious (*Scabiosa succisa*). The Fusiform Root is seen in the carrot and turnip; such plants are also called Tap-Rooted. The term Tubercules is applied by some to the roots of the Orchis and Dahlia; the former are palmated, or lobed, the latter are fasciculated.

Although most if not all the higher plants possess roots, amongst many of the lowest forms they are not to be distinguished. The lower plants which float about in water, as the *Oscillatoria*, *Diatoma*, &c., and which consist of little more than simple cells, possess no appendages which can be called roots. In many of the *Conferve* a downward development of the cells of cellular tissue, attaching them to the objects on which they grow, has been observed. Some of the Lichens, as the *L. esculentus* of Pallas, and the lower forms of *Pungi*, as the Tremellas, &c., possess no roots. Many of the floating water-plants, as the *Aldrovanda vesiculosa*, do not develop roots, and derive their nourishment from the medium in which they live by the direct contact of the cellular tissue. In fact we find that the simple cells of cellular tissue in the lower plants perform all those functions which, as we ascend in the scale of organisation, are performed by particular parts of the plant. In the Charas and the *Marchantia*, the roots become more evidently developed, and the downward growth of the cells is more observable than in the *Conferve*. On the lower surface of the *Marchantia*, prolongations of the cellular tissue are observed, which Meyen calls root-hairs or capillary fibrils. In the *Equisetaceæ* and Ferns the roots become more perfectly developed, and their surface is almost entirely covered with capillary fibrils. These fibrils are developed on almost all roots, and perform the function of absorption.

In many plants the roots, instead of being covered with the capillary fibres, present a condensed membrane, which also incloses the roots as in a sheath, and extends to the point of the root where the fibrils commence their growth. This structure occurs in most water-plants, and in the roots of those plants which are accidentally projected into water, and in some land-plants. It drops off with increasing age, in the same manner as the root-hairs. It is also seen in aerial plants, as the *Orchidaceæ*. Meyen considers this sheath a modification of the root-hairs, and hence infers that it performs the same functions. (Meyen, 'Neues System der Pflanzen-Physiologie,' Band ii.)

What the absorbent vessels are to the animal, the roots are to the plant, and a difference between plants and animals has been pointed out as dependent on the relative situation of their organs of absorption. The animal derives its nutriment, by means of its absorbents, from an internal reservoir, the stomach; whilst the plant derives its nutriment from an external reservoir, the earth. The spongioles of the roots, as we have already stated, are the active agents in the absorption of nutritious matter from the soil. By some botanists it is supposed that no other part of the root absorbs except the spongiole; but from the observations of Meyen and others it appears that the capillary fibrils and the epidermis of the root have also the power of absorbing fluid, though not in so high a degree as the delicate point of newly-developed tissue situated at the extremity of the fibrilla. [ABSORPTION; ENDOSMOSIS.]

Roots do not absorb everything that is presented to them. It was long ago ascertained by Davy that plants did not absorb particles of charcoal and other substances that he diffused through water. Experiments also by Meyen, Link, and others, prove that the colouring matter of various infusions is not taken up by the roots, and that when this has been supposed to have taken place, it has arisen from mistaking a deposition of the colouring matter on the outside of the tissue for an absorption into it.

When the roots of plants are placed in solutions of gum, sugar, starch, &c., they thrive if the solutions are thin; but if thick solutions of these substances be prepared, the plants die in them. Experiments of this kind were performed by Sir H. Davy, who attributed the non-absorption of the thick solution, and the death of the plant, to the blocking-up of the pores of the vegetable tissue by the thick matter.

When plants are submitted to solutions of various poisonous agents, they take up very varying proportions. De Saussure instituted a series of very careful experiments for the purpose of ascertaining the quantities of earthy and alkaline salts taken up by the roots of plants. For this purpose he prepared solutions of the hydrochlorates, nitrates, sulphates, and acetates of soda, potassa, and copper, and having submitted plants of *Polygonum* and *Bidens* to them, he found that the plants constantly absorbed a larger proportion of the water than of the salt, and that the salts were taken up in different proportions. The salts were not absorbed in proportion to their innocuous qualities, as the sulphate of copper, which was the most poisonous, was absorbed in largest quantity. De Saussure concludes that it was not the properties of the salts that determined their relative absorption, but that it depended upon the relative consistence of the solutions. Plants absorb poisons much more quickly when their roots are injured by being torn or cut, and do not suffer much by exposure to weak solutions of poisonous matters. This is a point of some practical importance, and will explain how it is that vegetation does not suffer when exposed to poisonous solutions.

Another function which has been attributed to the roots is that of excretion. Du Hamel first called the attention of botanists to this subject; he found that the roots of plants grown in water gave out a brackish secretion, and looked upon it as a secretion from the fluids of the plant. Brugmans followed up this point, and, in conjunction with Coulon, came to the conclusion, from the experiments they made, that the secretion given out from the roots of plants was a process of a similar nature to the rejection of the excrements in animals, and that these secretions acted beneficially in the nutrition of some plants, and injuriously in others. At the suggestion of De Candolle, M. Macaire prosecuted some researches on this subject, which were published in 1832 ('Mémoires de la Société de Genève,' tome v., p. 287). He confirmed the views of Brugmans and Coulon, and examined more attentively the nature of the different excretions given out by plants of different orders. Thus he found that the *Leguminosæ* gave out a gum and carbonate of lime; *Graminacæ* deposited a matter containing hydrochlorates and carbonates of alkalies and earths, and containing but little gum; *Cichoracæ*, an abundant brown matter analogous to opium; *Euphorbiacæ*, a gum-resinous matter. It was inferred that these excretions were matters injurious to the plant, which were thus thrown off from the system. This inference seemed to be confirmed by an experiment of Macaire's, in which, having divided the roots of a plant of *Mercurialis annua* into two parcels, he plunged the one into a glass with solution of acetate of lead, and the other into a glass of pure water; in a short time it was found that the acetate of lead had not only been taken up by the roots from the one glass, but that it had been excreted by them into the other.

These researches were considered to offer a satisfactory explanation of the practice of rotation of crops in agriculture; the rotation being

required on account of the excretions of a plant being injurious to itself, but beneficial to another, as the excretion of one plant is the food of another. [ROTATION OF CROPS, in ARTS AND SC. DIV.]

A far more rational explanation of the phenomena of rotation is to be found in the fact, that every plant requires certain inorganic products, as well as carbonic acid and ammonia, for its nutrition. These inorganic matters are supplied by the soil. When the same plant is grown for several years in succession in the same spot, it at last exhausts the soil of the inorganic matters necessary to its growth. By growing crops of another kind, and which do not require the same constituents in the same soil, opportunity is given for the ingredients required by the first plant to accumulate in the soil.

It is now a well-known fact that certain plants will not grow without certain inorganic constituents. Thus the plants of the sea and the sea-shore require chloride of sodium, but those which grow inland demand the salts of potash. The Grasses and Palms all require silica wherewith to form their stems, and the *Cerealæ* need phosphatic salts.

Just as these facts have become known, our agriculture has assumed a more scientific character, and every farmer at the present day is aware of the necessity of adding manures containing inorganic matters to his fields. It is on this account that Guano, Coprolites, and the superphosphate of lime or materials containing it, are added so constantly to the soil. [GUANO; COPROLITES; PHOSPHATITE.] That the necessity of rotation depends upon the exhaustion of these constituents of the soil, is rendered also probable by the fact that some soils grow the same crop continually for many years, which it may be supposed depends upon an abundant supply of the inorganic constituents of the soil. Again, from recent experiments it has been found, that by supplying artificially the inorganic food of plants to the soil, that the same crop may be grown any number of years in succession.

It is upon a knowledge of the nature of the food of plants that all agriculture must depend, and the principal source of this supply of this food is the soil, and the organs which take up this food are the roots. It is not however the chemical nature of the soil alone that demands notice, but also its physical properties. The great constituents of the food of plants are carbonic acid, ammonia, and water, and these are absorbed by the soil before they are supplied to the plant. According as the soil is capable of absorbing these constituents, will depend to a considerable extent its power of growing all plants. It is on this account that the absorbent nature of the soil in relation to the important elements of the food of plants, should be inquired into. The following table by Schubler of the absorbing power of different substances in relation to water, will serve as an indication of the importance of studying the physical properties of soils in general (Schielden, 'Principles of Scientific Botany') :—

Kinds of Earth.	1000 grains of Earth distributed over a surface of 30 square inches, absorbed in			
	12 hours. Grains.	24 hours. Grains.	48 hours. Grains.	72 hours. Grains.
Quartz-Sand . . .	0	0	0	0
Limestone-Sand . . .	2	3	3	3
Gypsum . . .	1	1	1	1
Loam Clay . . .	21	26	28	28
(Letztartiger Thon) . . .				
Muddy Clay . . .	23	30	34	33
(Lehmartiger Thon) . . .				
Resonant Clay . . .	30	36	40	41
(Klangartiger Thon) . . .				
Pure Gray Clay . . .	37	42	48	49
Fine Calcareous Earth . . .	26	31	35	35
Fine Magnesia . . .	69	76	80	82
Humus . . .	80	97	110	120
Garden Mould . . .	33	43	50	52
Field Mould . . .	16	22	23	23
Slaty Marl . . .	24	20	32	33

Besides the function of absorption, the roots serve other purposes in the economy of the plant. It is by means of the roots that a plant maintains its position in the earth; and if for the increasing nourishment of the plant an increase of the absorbing surface is required, it is no less necessary that, for the purpose of maintaining its stem erect and firm, an extension of its holdfasts should take place. In many instances the root appears to serve merely the purpose of holding the plant in the ground, as in the mosses and many of the plants belonging to the orders *Crassulacæ* and *Cactacæ*. By means of the roots the temperature of plants is kept below that of the atmosphere in summer, and above it in winter. This arises from the roots absorbing fluids from some depth below the surface of the earth, where its temperature is not much affected by the changes in the atmosphere. It is thus that the inhabitants of tropical climates are supplied with fruits whose delicious juices, pumped up from the earth, are much cooler than the atmosphere, and thus afford the most refreshing articles of diet.

ROOTSTOCK. [STEM.]

RORQUAL. [CETACEA.]

ROSA (from the Latin *Rosa*, through the medium of the French Rose; the Latin *Rosa* and the Greek *Ῥόδον* are evidently the same), the name of the most universally admired and cultivated genus of plants, forming the type of the natural order *Rosaceæ*.

The Rose was known in early times, and was as great a favourite among the nations of antiquity as it is in modern times. The Rose is found generally in almost every country of the northern hemisphere, both in the Old and New World: from Sweden to the north of Africa; from Kamtschatka to Bengal, and from Hudson's Bay to the mountains of Mexico. It is not found in South America or in Australia. All the species are included between 70° and 19° N. lat. It is found more generally on dry and free soils than on those which are wet and tenacious. In the north of Europe it occurs with single flowers, but in Italy, Greece, and Spain more frequently double.

The characters of the genus *Rosa* are—calyx 5-parted, tube fleshy, urceolate; petals five; stamens numerous, attached to the calyx and corolla; ovaries attached to the inner surface of the tube of the calyx; style long, stigma projecting beyond the mouth of the calyx; achenia numerous, hard. The species are mostly shrubs with alternate pinnate leaves and beautiful odiferous flowers. There are few better marked genera amongst plants than this, but as of all plants it has been the greatest favourite, and thus surrounded by the greatest variety of external influences, its species and varieties are the most difficult to distinguish.

Dr. Lindley, in his '*Rosarum Monographia*,' arranges the species under eleven divisions, the first of which, including but one species, has since been made into the genus *Lowea*. We shall here give the remaining divisions, and point out the species which, on account of their ornamental flowers or uses, are most frequently cultivated.

1. *Feroces*, with branches permanently tomentose and naked fruit. They are generally low shrubs, remarkable for thick hoary branches clothed with numerous prickles, and hence their name. There are only three species belonging to this division, of which *Rosa ferox*, the Hedgehog-Rose, is most common.

2. *Bracteata*.—The species of this division have not only their branches, but also their fruit clothed with a persistent tomentum. They have mostly bright-green leaves, and their organs of fructification are in the highest state of development of any of the genus. They belong to the class of evergreen roses. *R. bracteata*, the Macartney Rose, is a native of China, and was introduced into this country by Lord Macartney. It has upright branches, 5-9-leaflets, stout prickles, with large white terminal solitary flowers, and large globose orange-red fruit. It is a handsome plant, flowering abundantly late in the season. *R. microphylla*, Small-Leaved Rose, resembles *R. bracteata*, but differs in being smaller, and having prickly fruit and ovate-obtusate leaves.

3. *Cinnamomeæ*, distinguished by their long lanceolate leaflets, without glands, bracteated flowers, and delicate disc, but little thickened. The shoots are either with or without setæ. There are several species in this division, but comparatively few are known out of the herbarium. *R. lucida*, the Bright-Leaved Rose; *R. laxa*, Loose or Spreading Carolina Rose; and *R. Carolina*, the True Carolina Rose, belong to this division.

4. *Pimpinellifolia*.—Branches either crowded with nearly equal prickles or unarmed; leaflets ovate or oblong; bracts absent; sepals connivent and persistent. Although this division approaches the last in artificial characters, it is essentially different in habit. *R. spinosissima*, the Scotch Rose, is a dwarf, compact, green bush, with creeping roots; it has unequal prickles, flat, glabrous, simple serrated leaflets, and small, solitary, white, or bluish-coloured flowers. It is found native in the mountainous districts and sea-coasts of all Europe, and also in the Caucasus. It was the only rose found by Sir W. Hooker in Iceland. A great number of varieties are found in the gardens of Britain, produced from the wild plant found in the North of England and Scotland. *R. sulphurea*, the Double-Yellow Rose, and *R. alpina*, the Boursalt Rose, are also examples.

5. *Centifolia*, clothed with bristles and prickles; flowers bracteate; leaflets oblong or ovate, rugous, disc thickened, closing the throat; sepals compound. This division comprehends those species which have ever been most interesting to the florist, as also probably those that were earliest known. Although the garden varieties of this division would probably amount to several hundred, there are only three species.

R. centifolia, the Hundred-Leaved Cabbage, or Provence Rose, is known by its large unequal prickles, glandulous leaflets, pendulous flowers, and oblong fruit. This rose has been said to be a native of France, but this is doubtful. It has been found wild in thickets on the eastern side of the Caucasus. It is the same plant as the *R. provincialis* of Miller. A botanical variety of this species, the *R. centifolia mucosa*, is the parent of the beautiful family of moss-roses.

R. Gallica, the French Rose, has equal small prickles, erect flowers, ovate sepals, and globose fruit. It is found wild about Montalbanum, Walzenberg, and Geneva, also in Austria, Piedmont, and the Caucasus. This is supposed to be the species to which Pliny refers ('Hist. Nat.' xxi. 18, 25, 72, 73). *R. pumila* of Jacquin is a variety of this species. Hundreds of varieties of this rose are found cultivated in gardens.

A great number of varieties of roses found in gardens are hybrids between *R. Gallica* and *R. centifolia*. They mostly combine the long

graceful shoots of the last with the rich crimson hues of the first. Hybrids are also produced between *R. Gallica* and *R. Indica*, but differ from the last in not being perpetual. They have a pleasing glossy sub-evergreen foliage.

R. Damascena, the Damask Rose, has unequal prickles; the larger ones falcate, sepals reflexed, fruit elongated. This plant is supposed to have been originally brought from Damascus, and to be a native of Syria. It is much cultivated in gardens, and has not fewer varieties than the two last.

6. *Villosæ*.—Root-shoots erect; prickles nearly straight; leaflets ovate or oblong, with diverging serratures, sepals persistent, connivent; disc thickened, closing the fauces. The best known species of this division is the *R. alba*, White Rose; it has rugose glaucous leaves, with simple serratures and acicular unequal prickles, by which it may be distinguished from both *R. tomentosa* and *R. canina*, with which it is liable to be confounded. It is a native of Piedmont, Cochinchina, Denmark, France, and Saxony. Its flowers are very large, exhaling a delicious fragrance. *R. Hibernica*, the Irish Rose, belongs to this division, and is interesting to the botanist as being entirely confined to Ireland.

7. *Rubiginosæ*.—Unequal and sometimes bristly prickles, ovate or oblong leaflets, with glands and diverging serratures, persistent sepals, thickened disc, and arched root-shoots. To this division belongs the *R. rubiginosa*, Eglantine, or Sweet Briar. It is common in Britain in bushy places on a dry gravelly soil. *R. lutea*, the Austrian Briar, is nearly allied to the latter.

8. *Canina*.—With equal hooked prickles; oval eglandulose leaflets, with connivent serratures, deciduous sepals, and thickened disc closing the throat. To this division belong many of the varieties called Autumnal or Perpetual Roses, on account of their blooming late in the season and continuing in flower a long time. Of the roses in this group that have afforded varieties for the garden, the *R. Indica*, Chinese Rose, stands first. There is a hybrid variety between this species and the *R. odorata*, which is well known in gardens under the name of *R. Indica odorata*, Tea-Scented China Rose. This rose is the parent of a great number of sorts in gardens.

The Bourbon Rose (*R. Bourboniana*) is a natural hybrid between *R. Indica* and a variety called Red Four-Seasons. This hybrid was found amongst a number of the latter plants in a hedge in the Isle of Bourbon. It was brought to Paris, and has since produced many beautiful varieties.

The Noisette Rose was grown from seeds produced from *R. moschata* impregnated with *R. Indica*. It was first reared in America.

R. Lawranceana, the Miniature or Lawrance Rose, named after Miss Lawrance, who published a collection of drawings of roses, belongs to this division. It was first brought from China, and is probably only a dwarf variety of *R. Indica* or *R. sempervirens*, which it closely resembles in structure.

R. canina, the Dog-Rose, is one of the most common species of the division in this country, and from its varying characters has given origin to a great number of names supposed to represent species. This is the species used for making conserve of roses.

9. *Systyle*.—Styles cohering in an elongated column; stipules adnate. The habit of the plants of this division is nearly the same as that of the last. *R. arvensis*, the Field or White Dog-Rose, belongs to this group. It is a very common plant in many parts of England, adorning the hedges with its elegant snowy blossoms. It has cord-like shoots, unequal falcate prickles, leaflets glaucous beneath; diverging stipules, and ovate crimson fruit. The varieties of this and allied species, as *R. multiflora* and *R. sempervirens*, produce the climbing roses of the garden, of which there are a great number now to be had.

R. moschata, the Musk-Rose, is one of the oldest inhabitants of our gardens. It is found native in the North of Africa, and in the temperate and warm provinces of Spain.

10. *Banksianæ*.—Nearly free subulate stipules, usually deciduous; ternate shining leaflets and climbing stems. This is the last division of the species of roses. The most remarkable species in this group is the *R. Banksianæ*, Banksian Rose, named after Lady Banks. It is a native of China, and has very numerous double sweet-scented nodding flowers, which are arranged in umbel-like corymbs.

The roses are used in the arts for obtaining their delicious perfume, which is called Attar of Roses. The petals are also used in medicine. [ROSE, in ARTS AND SC. DIV.]

(Lindley, *Monographia Rosarum*, 1820; Miss Lawrance, *A collection of Roses from Nature*, 1799; Redoute and Thory, *Les Roses*; Guilleman, *L'Histoire Naturelle de la Rose*, 1800; Thory, *Prodrome de la Monographie du Genre Rosier*, 1820; T. Rivers, of Sawbridgeworth, *Rose-Amateur's Guide, with Descriptive Catalogue of Roses*, 1836 (a very excellent account of the garden varieties and their cultivation); Sir J. B. Smith, the article 'Rosa,' in Rees's *Cyclopædia*; Don, 'Genus Rosa,' in Miller's *Gardener's Dictionary*.)

ROSA'CEÆ. [ACALEPHEÆ.]

ROSA'CEÆ, a natural order of Polypetalous Exogenous Plants, with 4-5-lobed calyx; 4 or 5 regular petals; indefinite perigynous stamens; exalbuminous seeds; and alternate stipulate leaves. The plants of this order are allied to *Chrysobalanaceæ*, from which they may be distinguished by their styles proceeding from the side of the ovary near the apex, and not from the base, and by their regular

petals and stamens. They are distinguished from *Fabacee* (*Leguminosae*) by their regular petals and stamens, and especially by the odd segment of the calyx being posterior, and not anterior, as in that order. The genera of this order may be arranged under four groups or sub-orders, the principal distinctions of which will be seen in the following analysis:—

Carpels numerous.
Ovaries superior. *Rosaceae* (proper).
Ovaries inferior. *Pomeae*.

Carpels solitary.
Fruit a drupe. *Amygdaleae*.
Fruit a nut. *Sanguisorbeae*.

Rosaceae proper include the true *Roses* (*Rosae*), the *Cinquefoils* (*Potentillae*), the *Spiraeas* (*Spiraeae*), and the *Neuradas* (*Neuradeae*). They are herbaceous plants or shrubs. This family includes about 570 species and 20 genera, principally inhabitants of the temperate and cold zones of the northern hemisphere of the New and Old World; a very few are found on high land within the tropics, and a small number in the southern hemisphere. None of the plants of this section of the order are unwholesome; they are characterised by the presence of an astringent principle, which has led to the use of many of them in medicine. [*ROSA*; *POTENTILLA*; *SPIRÆA*; *FRAGARIA*; *GEUM*; *DRYAS*.]

Spiraea argentea.

a, flower, showing the perigynous arrangement of the stamens; b, fruit, showing its apocarpous structure; c, one of the follicles separate from the fruit.

Pomeae are known by the adhesion of their ovaries to the sides of the calyx, forming the fruit called a Pome. Their ovula are always in pairs. The tendency of the flowers of this family to revert to their normal state frequently affords instructive examples of morphological changes. The fruit of many of the species contains a considerable quantity of malic acid, which gives to the fruit its peculiar flavour. The Apple, Pear, Medlar, Quince, Service-Tree, and Mountain-Ash belong to this family. They are inhabitants of Europe, Northern Asia, the mountains of India, and North America. [*PRUS*; *CYDONIA*; *AMELANCHIER*; *CRATÆGUS*; *COTONEASTER*; *MESPILUS*.]

Amygdaleae have but a single carpel, which when ripe is a drupe; but they are also distinguished amongst *Rosaceae* by their leaves containing hydrocyanic acid, and their bark yielding gum. They are natives exclusively of the northern hemisphere, where they are found in cold or temperate climates. Many of the species are poisonous, on account of the hydrocyanic acid they contain. They yield, however, some of our most valued fruits, as the Peach, Nectarine, Plum, Apricot, Cherry, and Almond, which last is the seed of the *Amygdalus communis*. [*AMYGDALÆE*; *AMYGDALUS*; *PRUNUS*.]

Sanguisorbeae are not only known by their solitary carpels, but they are destitute of petals and have a hard thickened calyx. They are found wild in heaths, hedges, and exposed places in Europe, North and South America beyond the tropics, and the Cape of Good Hope. Their principal property is astringency, and some of the species may be used as fodder. [*SANGUISORBA*; *POTERIUM*; *AORIMONIA*.]

ROSCOEAE, a genus of Plants belonging to the natural order *Scitamineae* or *Zingiberaceae*, which was named by Sir J. E. Smith, in honour of the historian of the Medici, who elucidated the plants and remodelled the genera of the *Scitamineae* in his beautiful work on that family. The species have been figured by Smith, Wallich, and Royle.

The genus consists of only a few species, which are confined to the Himalaya Mountains, and is characterised by having spathaceous flowers, a single-leafed tubular calyx, corolla ringent, limb double, the outer tripartite, with the upper segment erect and arched. Inner limb

two-lipped, ovary inferior, style inclosed in the furrow of the anther, which is two-lobed, incurved, surrounding the style with an appendage split at the base.

The species of *Roscoeae*, belonging to so tropical a family as the *Scitamineae*, are generally accounted showy stove plants; but they are found only on the slopes of the Himalayas during the rainy season, when there is moisture with uniformity of temperature. *R. alpina* is found at as great an elevation as 9000 feet above the level of the sea, and on places whence the snow had just melted, like the snowdrop in early spring in European countries.

ROSE. [*ROSA*.]

ROSE-BEETLE. [*CETONIADÆ*.]

ROSEMARY. [*ROSMARINUS*.]

ROSE-ROOT. [*SEDUM*.]

ROSE-WOOD. [*TRIPTOLEMEA*.]

ROSELITE, a rose-red Mineral related to Cobalt Bloom. [*COBALT*.]

ROSIN. [*TURPENTINE*.]

ROSITE, a Mineral occurring in small grains, without crystallisation. Fracture splintery, and in the larger grains somewhat foliated. Surface of the fracture shiving. Colour faint rose-red to brownish-red; the former more common. Subtransparent. Hardness 2.5. Specific gravity 2.72. It is found in Södermanland.

Its analysis by Svanberg gives—

Silica	44.901
Alumina	34.506
Peroxide of Iron	0.688
Oxide of Manganese	0.191
Potash	6.628
Lime	3.592
Magnesia	2.493
Soda	a trace
Water	6.333

—99.337

ROSMARINUS, a genus of Plants belonging to the natural order *Lamiaceae*. It is one of the genera belonging to this order that are perennial and possess the character of shrubs. It is known by the following characters:—Calyx ovate, campanulate, with two lips, the upper of which is entire, and the lower two-parted; corolla not ringed in the inside; the throat slightly inflated with two lips, equal, the upper one emarginate, the lower two-parted, the middle lobe very large and hanging down; stamens two; filaments slightly toothed at the base; style with the upper lobe very short.

R. officinalis, the Common Rosemary, is an inhabitant of the southern parts of France, Spain, and Italy, the basin of the Mediterranean, and some parts of Asia Minor. It is a very leafy shrub, growing to the height of three or four feet; the leaves are sessile, linear, quite entire, revolute at the edge, and covered with white hairs beneath; the flowers are few, and in short axillary racemes; the corolla has a dull leaden blue or white colour, with the tube protruding a little beyond the calyx; the flower-leaves or bracts are shorter than the calyx. The cultivated and garden plants differ very much in the shape and number of their leaves, on which account Miller described them as two species, the *R. angustifolia* and the *R. latifolia*. The size of the leaves varies according to the soil and situation in which the plant grows. It is generally observed that the broader and longer the leaves, the more vigorous is the plant. The Rosemary abounds in the district of Narbonne in France, where it is used to form hedges for gardens, &c. It is supposed to be the aroma of this plant gathered by the bees that gives to the honey of this district its peculiarly fine flavour.

ROSSIA, a genus of Cephalopodous *Mollusca*, named by Professor Owen in honour of Sir John Ross, who found one of the first specimens in the Arctic Seas. It belongs to the family *Tenuthidae*, and has a rounded or oval body, furnished on each side with a suborbicular fin; a large head, with eyes covered by an epidermic expansion, and pierced by a very small hole; arms ten, two tentacular and retractile, eight corneous, flexible, small, and sub-spatulate. There are five species, of which two are British, *R. macrosoma* and *R. Oweni*. These have been both taken in Ireland, and the latter also near Bonchurch, in the Isle of Wight.

ROSTELLARIA. [*STROMBIDÆ*.]

ROSTELLUM, a botanical term applied occasionally to very different parts: 1, it is most frequently used as a diminutive of rostrum, to express any small beak-shaped process; 2, it is applied to the short beak-shaped process found on the stigma of many violets, as *Viola hirta*, *V. odorata*, *V. canina*, &c.; and *Orchidaceae*, as *Orchis*, *Spiranthes*, *Liatris*, &c.; 3, some writers have also used this term to indicate the radicle or descending element of the embryo of the seed.

ROSTRUM, a botanical term applied to any rigid prolongation of remarkable length, or to any additional process at the end of any of the parts of a plant.

ROTATE, a botanical term applied to either the calyx or corolla, when the tube is very small or entirely wanting, and the petals or sepals are united and spreading.

ROTATORIA. [*ROTIFERA*.]

ROTCHIE. [*AUK*.]

ROTELLA. [*TROCHIDÆ*.]

ROTHOFFITE. [*GARNET*.]

ROTIFERA, Wheel-Animalcules, a class of animals placed by Ehrenberg among the *Infusoria*, under the name of *Rotatoria*. They have acquired these names on account of the apparent rotation of the disc-like organs which surround their mouths and which are covered by cilia. These creatures are very minute, and although some of the larger forms may be detected by the naked eye, their organisation can only be seen by the aid of the microscope. We are indebted to Leeuwenhoek for the discovery of their existence and the first account of their structure and habits. In the 'Philosophical Transactions' for 1702, he gave an account of the discovery of what is now called *Rotifer vulgaris*, one of the most common forms of these animals. He afterwards described another form, *Meliceria ringens*.

Subsequent observers added to the discoveries of Leeuwenhoek, so that in 1824 Bory St. Vincent described 80 species. In 1838 Ehrenberg published his great work on the *Infusoria*, and there describes 189 species of *Rotifera* in 55 genera. Although classed by Ehrenberg with the *Polygastrica*, their organisation is much higher and more complicated, and the only claim they appear to have to be classed together is the fact of their minute size. [INFUSORIA.]

The *Rotifera* are very widely diffused on the surface of the earth. They inhabit both fresh-waters and the ocean, and are found in the cold, temperate, and tropical parts of the earth. Although capable of swimming freely they are generally found near or attached to the leaves of plants. They are found constantly present in ponds and streams in which *Ceratophyllum*, *Callitriche*, *Valisneria*, and other fresh-water plants abound.

A curious point in their history, which first attracted the attention of Leeuwenhoek, is their power of retaining their vitality after having been more or less perfectly desiccated. This property is undoubtedly possessed by the ova of the lower animals, especially those which are called 'winter eggs'; but it does not appear to be very generally possessed by animals of an organisation as high as the *Rotifera*. Professor Owen states that he has observed the revivification of one of these wheel animalcules after having been kept four years in dry sand.

The *Rotifera* have usually an elongated form, although some of them are nearly as broad as they are long. In most instances they are covered with a lorica or double envelope, the outer layer of which is often of a horny consistence. Some of them build for themselves a little case, or tube, in which they live, but this must not be confounded with their proper envelope. When the lorica is soft the animal has considerable power of elongating and contracting its body, as seen in *Rotifera vulgaris*. Many of the species are furnished with an elongated tail, which is often supplied with pincer-like organs, to enable them to remain stationary whilst feeding. Those which form tubes are usually fixed.

The rotatory organs, or wheels, are fleshy retractile lobes, covered with vibratile cilia, and are capable of being contracted or expanded. These organs are moved by means of a muscular system. Muscular hands are observed attached to the tegumentary system, and also to that part of the digestive system connected with the rotatory organs. The fibres of these muscles have been observed to present the striæ which are characteristic of voluntary muscles.

The digestive system consists of a mouth, jaws, frequently a dilatation which may be regarded as a stomach, and an intestinal tube which has an anal orifice. The jaws generally consist of two semi-circular pieces, to which are attached one or more teeth, which act upon a central plate. The number of teeth varies, and also the form and character of the jaws in different species.

The *Rotifera* have no true circulating or respiratory organs, although Ehrenberg has described certain parts of their structure as such. In most of the species minute vessels can be seen, which terminate in blind sacs or cæca. In these cæcal branches a vibratile body exists, which keeps up a peculiar flickering movement, and it is to these bodies that Ehrenberg has given the name of 'gills.' This system of vessels is regarded by Mr. Huxley and other observers as a true aquiferous or water-vascular system. Connected with the respiratory apparatus, according to Ehrenberg, is an organ projecting from the under surface of the mouth, which he has called the 'calcar,' 'siphon,' or 'respiratory tube.' Ehrenberg describes it as a tube, and supposes currents to pass from it. It is connected with the nervous ganglion. Dujardin and Huxley have not observed either currents or an orifice in this organ.

All observers agree that the *Rotifera* possess a nervous system, which presents itself in the form of a pair of cephalic ganglia, from which proceed nervous filaments. The extent of the development of the nervous system is a subject for further inquiry. The red spots which Ehrenberg calls eyes are subject to considerable variations in appearance. Mr. Huxley says he observed them in young *Laciniularia*, but not in adult individuals.

The existence of sexes in a species of *Notommata* has been clearly made out by Mr. Brightwell of Norwich. The male however is much smaller and less developed than the female. All observers agree that the parts to which Ehrenberg has assigned the functions of male organs are not so. Certain caudate bodies have been described by Kölliker as *Spermatozoa*, but their nature is doubted by other observers. Mr. Huxley describes in *Laciniularia* certain 'vacuolar thickenings,' which he suggests have been previously mistaken for male organs, ganglia, &c. Ovarial organs are easily made out in most of the species.

The ova are of two kinds. Mr. Huxley says in *Laciniularia* they consist, first, of bodies which resemble true ova in their origin and subsequent development, and which possess only a single vitellary membrane; second, of bodies half as large again as the foregoing, which resemble the ephippium of *Daphnia*: like it they have altogether three investments, and which do not resemble true ova either in their origin or subsequent development; which therefore probably do not require fecundation, and are thence to be considered as a mode of asexual reproduction. Professor Williamson has described very fully the development of the true ova in *Meliceria ringens*, from which it appears the young after they are hatched do not pass through any of those larval changes which are characteristic of animals both higher and lower in organisation. All the changes which take place occur in the ovum.

The position of the *Rotifera* in relation to the other forms of animal life has been the subject of much discussion. Dr. Graut was one of the earliest writers to take them out of the *Radiata*, and place them amongst *Articulata*. The relation of such forms as *Stephanoceros* to the Ciliobrachiate Polyps is very evident. In his 'Mémorial on Laciniularia,' Mr. Huxley gives his reasons for regarding these creatures as permanent larva-forms of *Echinodermata*. After referring to the various forms of *Rotifera*, and their homologous organs, he thus concludes:—

"We may say, therefore, that the *Rotifera* are organised upon the plan of an Annelid larva, which loses its original symmetry by the unequal development of various regions, and especially by that of the principal ciliated circle or trochal band; and it is curious to remark that, so far as the class of the *Rotifera* can be considered to be made out (approximately), the dioecious forms belong to the latter of the two modifications of the type which have been described, while the monœcious forms belong to the former.

"It is this circumstance which seems to me to throw so clear a light upon the position of the *Rotifera* in the animal series. In a Report in which I have endeavoured to harmonise the researches of Professor Müller upon the Echinoderms, 'Annals of Natural History,' 1851, I have shown that the same proposition holds good of the latter in their larval state, and hence I do not hesitate to draw the conclusion (which at first sounds somewhat startling) that the *Rotifera* are the permanent forms of Echinoderm larvæ, and hold the same relation to the Echinoderms that the Hydriform *Polypi* hold to the *Medusæ*, or that *Appendicularia* holds to the *Ascidians*.

"The larva of a *Sipunculus* might be taken for one of the *Rotifera*; that of *Ophiura* is essentially similar to *Stephanoceros*; that of *Asterias* resembles *Laciniularia* or *Meliceria*. The pre-trochal processes of the *Asterid* larvæ *Brachiolaria* are equivalent to those of *Brachionus*.

"Again, the larvæ of some *Asterid* forms and of *Comatula* are as much articulated as any *Rotifera*.

"It must, I think, have struck all who have studied the Echinoderms, that while their higher forms, such as *Echiurus* and *Sipunculus*, tend clearly towards the dioecious *Annelida*, the lower extremity of the series seemed to lead no-whither.

"Now, if the view I have propounded be correct, the *Rotifera* furnish this wanting link, and connect the Echinoderms with the *Nemertidæ* and *Nematoid* worms.

"At the same time it helps to justify that breaking up of the class *Radiata* of Cuvier, which I have ventured to propose elsewhere, by showing that the *Rotifera* are not 'radiate' animals, but present a modification of the Annulose type—belong, in fact, to what I have called the *Annuloida*, and form the lowest step of the Echinoderm division of that sub-kingdom."

Dr. Leydig, in a paper in the 'Zeitschrift für Wissenschaftliche Zoologie,' vol. vi., on the other hand, regards the relations of *Rotifera* as much more with the *Crustacea* than with the Worms. The points of resemblance to which he draws attention are:—

1. Their external figure and hard tegument, which more nearly resembles the carapace of the *Crustacea* than the rings of the *Articulata*.
2. Their muscular structure, which resembles that of many *Crustacea*.
3. Their nervous system resembles that of many *Entomostraca*, as *Daphnia*.

4. The alimentary canal resembles that of *Daphnia*.

5. The resemblance in the character of their ova, the *Entomostraca* having two kinds of ova, as the *Rotifera*.

6. The development of *Rotifera* and Entomostracous *Crustacea* correspond.

Leydig concludes a very able paper by proposing to call the *Rotifera* Ciliated Crustaceans.

With regard to the arrangement of the *Rotifera*, we give that of Ehrenberg, which, although exceedingly defective, served to make these creatures known amongst naturalists:—

Order 1. *Rotatoria nuda*.

Order 2. *Rotatoria lorica*.

Section I. *Monotrocha*.

Ciliary Circle simple and entire, and not variable.

Monotrocha nuda.

Monotrocha lorica.

1st Fam. *Ichthydina*.

A. No eyes.

a. Body smooth.

* Tail simple, truncated,

and flexible.

Gen. *Ptygura*.

- ** Tail bifurcate and very short.
Gen. *Ichthyidium*.
- aa. Dorsal part of the body hairy.
Gen. *Chaetonotus*.
- B. Two eyes.
Gen. *Glenophora*.

Section II. *Schizotrocha*.

Ciliary Circle simple, divided in parcels.

- Schizopoda nuda*.
1st Fam. *Megalotrocha*.
- A. One eye.
Gen. *Microdon*.
- B. Two eyes, which are effaced with age.
Gen. *Megalotrocha*.
- Schizopoda loricata*.
1st Fam. *Floscularia*.
- A. No eyes. The envelope of the body gelatinous.
a. Rotatory organs bilobate or quadrilobate.
Gen. *Lacinularia*.
- aa. Rotatory organ multifold.
* Rotatory organ quinquefid, mandibles dentate.
Gen. *Stephanoceras*.
- ** Rotatory organ with 6-8 divisions, mandibles edentate.
Gen. *Floscularia*.
- B. Two eyes, which are effaced with age. Envelope of the body membranous and granular. Rotatory organ bilobate or quadrilobate.
Gen. *Melicerta*.

Section III. *Polytrocha*.

Several small Ciliary Circles.

- Polytrocha nuda*.
1st Fam. *Hydatina*.
- A. No eyes.
a. Mandibles dentate.
Gen. *Hydatina*.
- aa. Mandibles edentate.
* Mouth direct, terminal.
Gen. *Euteroplea*.
- ** Mouth oblique, inferior.
Gen. *Pleurotrocha*.
- B. A single eye.
b. Eye frontal, tail bifurcate.
Gen. *Furcularia*.
- bb. Eye dorsal.
* Tail simple, hairy.
Gen. *Monocerca*.
- ** Tail bifurcate.
† Frontal cilia similar.
Gen. *Notommata*.
- †† Frontal cilia dissimilar.
§ With cilia and styles.
Gen. *Synchaeta*.
- §§ With cilia and hooks.
Gen. *Scaridium*.
- C. Two eyes.
c. Eyes frontal.
* Tail bifurcate.
Gen. *Diglena*.
- ** Tail simple, front with two cirri.
Gen. *Triarthra*.
- cc. Eyes dorsal.
* Tail simple.
Gen. *Rattulus*.
- ** Tail bifurcate.
Gen. *Distemma*.
- D. Three eyes.
d. One eye dorsal, and two frontal.
Gen. *Eosphora*.
- dd. Three dorsal eyes.
Gen. *Norops*.
- E. Several eyes.
e. Eyes in a circle on the neck.
Gen. *Cycloglena*.
- ee. Eyes in two cervical groups.
Gen. *Theorus*.
- Polytrocha loricata*.
1st Fam. *Euchlanidota*.
- A. No eyes.
a. Cuirass depressed.
* Tail bifurcate.
Gen. *Lepadella*.
- aa. Cuirass compressed.
* Tail simple.
Gen. *Monura*.
- ** Tail bifurcate.
Gen. *Colurus*.
- B. One eye.
b. Cuirass depressed.
* Tail simple.
Gen. *Monostyla*.
- ** Tail bifurcate.
Gen. *Euchlanis*.
- bb. Cuirass swollen or angular.
* Tail hairy and simple.
Gen. *Mastigocera*.
- ** Tail bifurcate or trifurcate.
† No cornicle.
Gen. *Salpina*.
- †† Corniculated.
Gen. *Dinocharis*.
- C. Two eyes (frontal).
c. Head nude.
Gen. *Metopidia*.
- cc. Head hooded.
Gen. *Stephanops*.
- D. Four frontal eyes.
Gen. *Squamella*.

Fig. 1.

Notommata centrura. The branchial apparatus (b, c, a) omitted on the left side. (The letters correspond with those of fig. 2.)

Zygotrocha.

Two small ciliary coronae.

- Zygotrocha nuda*.
1st Fam. *Philodina*.
- A. No eyes.
a. Tail bifurcate and corniculate (a frontal proboscis).
Gen. *Callidina*.
- aa. Tail bifurcate, not corniculate.
* Rotatory organs, supported on frontal pedicles of great length (no frontal proboscis).
Gen. *Hydria*.
- ** Rotatory organs sessile and lateral (no frontal prolongation).
Gen. *Typhlina*.
- B. Two eyes.
b. Eyes frontal.
* Tail bifurcate, and with two pairs of horns (thus becoming six-pointed); a frontal proboscis.
Gen. *Rotifer*.
- ** Tail trifid, and with a single pair of horns (thus becoming five-pointed); a frontal proboscis.
Gen. *Actinurus*.
- *** Tail bifurcate, and without horns; no frontal prolongation.
Gen. *Monolabis*.
- bb. Eyes dorsal.
(Tail bifurcate, and with ten pair of cornicles; a frontal prolongation).
Gen. *Philodina*.
- Zygotrocha loricata*.
1st Fam. *Brachionura*.
- A. No eyes.
Gen. *Notus*.
- B. One tail.
b. No tail.
Gen. *Anuraea*.
- bb. Tail bifurcate, flexible.
Gen. *Brachionus*.
- C. Two eyes (frontal).
Gen. *Pterodina*.

Fig. 2.

*Drachionus ureolaris.*

c, cilia rotatoria; *p*, pharynx; *e*, stomach; *ap*, appendages to stomach; *ov*, ovary; *o*, eye; *m*, muscles; *g*, tail; *b*, internal branchiae; *ca*, branchial canal.

From the previous observations on structure it will be seen that this arrangement is open to many objections.

Dujardin, who was one of the earliest observers that pointed out the defects of Ehrenberg's arrangement, has proposed the following:—

Order I. *Systolides*.—Fixed by a pedicel.

Family 1. Floscularians.

Family 2. Melicerians.

Order II. Swimming *Systolides*.

Family 3. Brachionians.

Family 4. Furcularians.

Family 5. Albertians.

Order III. *Systolides*.—Alternately swimming and fixed.

Family 6. Rotifers.

Order IV. Crawling *Systolides*.

Family 7. Tardigrades.

Leydig has proposed an arrangement of his own, which is preferable to either of the above.

Ciliocrustacea.

Animals with a jointed body and a ciliary apparatus at the cephalic extremity. The nervous system consisting of a cerebral ganglion, and filaments radiating from it. Digestive and respiratory systems much developed. No heart or blood-vessels. Sexes separate. The female produces 'summer' and 'winter-ova.' Many undergoing metamorphosis.

A. Figure between clavate and cylindrical.

I. With elongated transversely-ringed attached Foot.

1. *Floscularia proboscidea*, Ehrenberg; *F. ornata*, Ehr.; *F. appendiculata*, n. s.
2. *Stephanoceros Eichhornii*, Ehr.; *S. glacialis*, Perty.
3. *Ecistes crystallinus*, Ehr.
4. *Conochilus volvox*, Ehr.
5. *Lacimularia socialis*, Ehr.
6. *Limnias ceratophylli*, Schrank.
7. *Tubicularia najas*, Ehr.
8. *Meliceria ringens*, Schrank.

II. With elongated jointed Foot, retractile, like a telescope.

1. *Callidina elegans*, Ehr.; var. *C. rosea*, Perty; *C. cornuta*, Perty.
2. *Hydrias cornigera*, Ehr.
3. *Typhlina viridis*, Ehr.
4. *Rotifer vulgaris*, *R. citrinus*, *R. erythraeus*, *R. macrurus*, *R. tardus*, Ehr.
5. *Actinurus neptunius*, Ehr.
6. *Monolabis conica*, Ehr.
7. *Philodina erythrophthalma*, *P. roseola*, *P. macrostyla*, *P. citrina*, *P. aculeata*, *P. megalatrocha*, Ehr.

III. With elongated jointed non-retractile Foot.

1. *Scardium longicaudum*, Ehr.
2. *Dinocharis Pocillum*, *D. tetractis*, *D. paupera*, Ehr.

IV. With a short Foot and long Pedal Forceps.

1. *Notommata* (?), *N. tigris*, *N. longisetæ*, Ehr.
2. *Monocerca rattus*, *M. bicornis*, *M. valga*, Ehr.
3. *Furcularia gibba*, *F. forficula*, *F. gracilis*, Ehr.
4. *Microdon clavus*, Ehr.

V. With short Foot and Pedal Forceps, which are of equal length with or somewhat shorter or longer than the Foot.

1. *Hydatina senta*, *H. brachydactyla*, Ehr.
2. *Pleurotrocha gibba*, *P. constricta*, *P. leptura*, Ehr.
3. *Furcularia Rheinhardtii*, Ehr. (probably not a *Furcularia*, but a *Notommata*).
4. *Notommata tuba*, *N. petromyzon*, *N. saccigera*, *N. copeus*, *N. centrura*, *N. brachyota*, *N. collaris*, *N. najas*, *N. aurita*, *N. gibba*, *N. ausata*, *N. decipiens*, *N. felis*, *N. parasita*, *N. tripus*, Ehr.; *N. tardigrada*, n. sp.; *N. vermicularis*, Duj.; *N. roseola*, *N. onisciformis*, Perty.
5. *Lindia torulosa*, Duj.
6. *Synchaeta pectinata*, *S. baltica*, *S. oblonga*, *S. tremula*, Ehr.
7. *Diglena grandis*, *D. forcipata*, *D. aurita*, *D. catellina*, *D. conara*, *D. capitata*, *D. caudata*, Ehr.
8. *Rattalus lunaris*, Ehr.
9. *Distemma forficula*, *D. setigerum*, *D. marinum*, *D. forcipatum*, Ehr.
10. *Triophthalmus dorsalis*, Ehr.
11. *Eospora najas*, *E. digitata*, *E. elongata*, Ehr.
12. *Cyclogena lupus*, *C. elegans*, Ehr.
13. *Theorus vernalis*, *T. uncinatus*, Ehr.

Note.—Ehrenberg's genus, *Enteroplea hydatina*, is the male of *Hydatina senta*; and his *Notommata granularis* stands in the same relation to *Notommata brachionus*, which latter genus however is placed far more correctly under the genus *Brachionus* than under *Notommata*. *Diglena granularis*, Weisse, lastly, is the male of *D. catellina*, Ehr.

VI. Without Foot.

1. *Albertia*.

Includes the *A. vermiculus*, found by Dujardin in the abdominal cavity of the Earthworm, and in the intestine of the *Limacina*; and *A. crystallina*, discovered by Schultze in the intestine of *Nais littoralis*.

B. Figure sacciform.

I. Foot short.

1. *Notommata clavalata*, *N. myrmeleo*, *N. syrinx*, Ehr.
2. *Diglena lacustris*, Ehr.

II. Foot absent.

1. *Notommata Anglica*, Dalrymple; *N. Sieboldii*, n. sp.
2. *Polyarthra platyptera*, Ehr.
3. *Triarthra longisetæ*, *T. mystacina*, Ehr.
4. *Ascomorpha helvetica*, Perty; *A. Germanica*, n. sp.

C. Figure compressed.

a. Depressed from above downwards.

I. With a foot.

1. *Euchlanis triquetra*, *E. Hornemanni*, *E. luna*, *E. macrura*, *E. dilatata*, *E. Lynceus*, Ehr.; *E. emisetata*, n. sp.; *E. bicarinata*, n. sp. (*E. bicarinata*, Perty, I consider a *Salpina*.)
2. *Lepadella ovalis*, *L. emarginata*, *L. salpina*, Ehr.
3. *Monostyla cornuta*, *M. quadridentata*, *M. lunaris*, *M. carinata*, Ehr.
4. *Metopidia lepadella*, *M. acuminata*, *M. triptera*, Ehr.
5. *Stephanops lamellaris*, *S. muticus*, *S. cirratus*, Ehr. (Dujardin declares that *S. muticus* is *Lepadella ovalis*.)
6. *Squamella bractea*, *S. oblonga*, Ehr.
7. *Notogonia Ehrenbergii*, Perty.
8. *Notus quadricornis*, Ehr.
9. *Brachionus pala*, *B. amphicerus*, *B. urceolaris*, *B. rubens*, *B. Mülleri*, *B. brevispinus*, *B. Bakeri*, *B. polyacanthus*, *B. militaris*, Ehr.
10. *Pterodina patina*, *P. elliptica*, *P. clypeata*, Ehr.

II. Foot absent.

ROTTBOELLA, a genus of Plants belonging to the tribe *Rottboellieae*, of the very natural and extensive family of Grasses, named by Mr. Brown in honour of C. F. Rottbüll, a professor of botany at Copenhagen, who died in 1797, and who published several works, one in particular on exotic species of *Gramineæ* and *Cyperaceæ*. The genus is distributed throughout Asia, especially India, Australia, and the tropical islands, and extends also to Egypt. The species are usually tall, erect, and flat-leaved, with the spikes round and jointed; spikelets two in each joint, pressed close to or sunk into a hollow in the rachis; of these one is sessile, the other stalked. The species are not relished by cattle, with the exception of *R. glabra*, of which they are said to be fond in India.

ROTTEN-STONE, a Mineral, occurring massive. Fracture uneven. Colour grayish, reddish, or blackish brown. Dull, earthy, and opaque. Soft, soils the fingers, and is fetid when rubbed or scraped. It is found near Bakewell, Derbyshire; in Wales; and at Albany, in the state of New York. It is employed in polishing metals, &c. The analysis by R. Phillips gives—

Alumina	86
Silica	4
Carbonaceous matter	10
—100	

ROTTLE'RA, a genus of Plants named in honour of Dr. Rottler, belonging to the natural family *Euphorbiaceæ*. It is characterised by having male and female flowers upon different plants. Male: Calyx 3-5-partite; corolla none; stamens 30 to 40, inserted into the convex receptacle; filaments free or united at the base. Female: Ovary 2-3-4-celled, each 1-seeded; style deeply 2-3-4-partite, laciniated; capsule 2-3-4-coccous, each 1-seeded. The genus, which is found in the tropical parts of Asia and throughout India, contains handsome moderate-sized trees. *R. tetraecocca* grows in Silhet, and yields a hard and valuable timber. The capsules of *R. tinctoria*, a native of the Coromandel coast, and extending to the forests of Northern India, are covered with short stiff hairs, which when rubbed off have the appearance of a powder of a fine red colour, which is employed in India in dyeing silk of a scarlet colour, and therefore forms an article of commerce in that country. Dr. Royle states that this strigose pubescence is also employed in India as an anthelmintic in the same way that cowage is, and, like it, probably acts mechanically in expelling intestinal worms.

ROUD. [*LEUCISCUS*.]

ROULOUL. [*TETRAONIDÆ*.]

ROUNDTAIL. [*SALMONIDÆ*.]

ROWAN-TREE. [*PYRUS*.]

ROXBURGHIA. [*ROXBURGHIAEÆ*.]

ROXBURGHIAEÆ, *Roxburgh-Worts*, a natural order of Plants belonging to the class *Dictyogens*. The species are twining shrubs with tuberous roots; reticulated leaves, coriaceous, and with parallel secondary veins connecting several primary ribs; flowers large and showy, solitary, fœtid; perianth of four large petaloid divisions; stamens 4, hypogynous; anthers adnate, opening inwards, pointed, with connectives projecting far beyond the cells, which separate from the latter as far as their bases; pericarp 1-celled, 2-valved, with two clusters of seeds at the base. Seeds attached to long cords covered with loose hairs just below the seeds; embryo taper, in the axis of fleshy albumen, with the plumule lying within a slit. The plants of this small order are natives of the hot parts of India. There is but one genus—

Roxburghia, the roots of a species of which are prepared with lime water, candied with sugar, and taken with tea. The flavour is insipid. (Lindley, *Vegetable Kingdom*.)

ROYDSIA, an Indian genus of Plants allied to the natural order *Cappariaceæ*, named by Dr. Roxburgh in compliment to Sir J. Royle. The genus consists of a single species indigenous in the forests of Silhet, where, with a stout stem and numerous branches, it climbs over the trees to a great extent, and flowers in the month of March, diffusing a strong but pleasant odour from its numerous blossoms arranged in axillary racemes or terminal panicles. The leaves are alternate, oblong, coriaceous, smooth on both sides, and without stipules. The calyx is 6-partite and of a pale-yellow colour; corolla none; stamens numerous, with the filaments inserted on the spex of a short column; ovary pedicelled, 3-celled, with two rows of ovules in each, attached to the axis; drupe berried, of the size of a large olive, orange-coloured; pulp abundant and yellow; nut oblong, single-celled and 3-valved; seed solitary, conformable to the nut. The plant is figured in Roxburgh's 'Coromandel Plants,' p. 289, and is well-suited to the hothouses of this country.

ROY'LEA, a Himalayan genus of Plants belonging to the natural order *Lamiaceæ*, and tribe *Balloteæ*, named by Dr. Wallich in compliment to Dr. Royle, author of the 'Illustrations of the Botany of the Himalayan Mountains and of Cashmere,' who first found it on the

Sirmore Mountains. The plant forms a handsome shrub, with many branches and an abundance of pale-green glaucous leaves. It is characterised by having the calyx ovate, tubular, 10-nerved, and semi-quinquefid; corolla shorter than the calyx, 2-lipped, lips unequal; stamens 4, didynamous, ascending under the upper lip; anthers bilocular; style bifid.

R. elegans, the only species known, is called Putkuroo by the natives of the mountains where it is indigenous, and is employed by them as a febrifuge. It is suited to the shrubberies of this country.

ROYSTON CROW, the common English name for the Hooded-Crow, *Corvus Cornix*, Linn. [*CORVIDÆ*.]

The subjoined illustration is omitted in the article *CORVIDÆ*.

Royston Crow (*Corvus Cornix*).

RUBELLAN, a Mineral, which occurs in small hexagonal plates, not elastic. Colour reddish-brown. Hardness 2 to 2.5. Lustre pearly. Transparent, opaque. Specific gravity 2.8 to 3.1. Found at Schima, in the Mittelgebirge, Bobemia. The analysis by Klaproth, gives:—

Silica	45
Alumina	10
Oxide of Iron	20
Lime	10
Potash and Soda	10
Volatile Matter	5
—100	

RUBELLITE. [*TOURMALINE*.]

RUB'IA, a genus of Plants belonging to the natural order *Galiaceæ*, containing about 40 species, found both in Europe and Asia. This genus is characterised by flowers monopetalous, superior; tube of the calyx ovate-globose, limb scarcely any; corolla sub-campanulate, rotate, 5-partite; stamens 4-5, short; styles 2, short; berries 2, 1-seeded.

R. tinctorum, Madder, has been long known, and was employed in medicine even in the time of Hippocrates, but is valued chiefly as a dye. It has a diffuse brittle-branched stem, angular, very rough, with sharp hooks; leaves 4 or 6 in a whorl, lanceolate or oblong-lanceolate, mucronate, somewhat membranous with pinnated veins; flowers small and white; lobes of the corolla ovate-lanceolate, apiculate; anthers ovate-oblong; stigmas conical. It is a native of Europe and Asia Minor, but is now extensively cultivated in Holland and France; the culture has likewise been attempted, and successfully, in this country, but the English madder could not be sold so cheap as the foreign; it is therefore still largely imported, chiefly from Holland, France, Italy, and Turkey, though since cochineal has become cheaper, it is much used for the same purposes. It is employed by dyers and calico printers as a red and scarlet dye. It has also the singular property of turning red the bones and secretions of fowls and other animals fed on it.

R. cordifolia (*R. Munjista*), the Munjeet of India, a native of Nepal, &c., possesses very similar properties, and is imported into England from Calcutta. The root is used as a substitute for that of *R. tinctorum*; it is known in commerce under the name of East India Madder, and is also employed in medicine. Like Madder, Munjeet was probably known from very early times, as Rodeus is given as the Greek name in Persian works on *Materia Medica*. *R. Chilensis* and *R. Reiban*, both natives of South America, are also esteemed there as dyes.

Lindley, *Vegetable Kingdom*.)

RUBICELLE. [*SPINEL*.]

RUBUS (the Latin *Rubus*, a Bramble), a genus of Plants belonging to the natural order *Rosaceae*, and to the section *Potentilleae* of the suborder *Rosaceae* proper. This genus, like that of *Rosa*, has proved a source of difficulty and difference amongst botanists. Some writers on the British Flora have described upwards of twenty-five species, whilst others have reduced them to four or five, or even two.

The following excellent description of this genus from Hooker's 'British Flora' has been drawn up by Mr. Borrer, who has investigated the British species with more success than any other botanist:—

"Shrub-like Plants or Herbs, with perennial Roots. The latter offer nothing very peculiar. In some species of the former the stem is upright, or merely curved at the top; but in the greater number it is either prostrate, or, as is more generally the case, assurgent, arched, and decurved; and the ends of the shoot and of the side branches, if it produce any, unless prevented by circumstances from reaching the ground, take root in the latter part of the year. In the winter the shoot is partially destroyed, the part next to the original root surviving to produce flowering branches during the ensuing summer, and usually dying after the fruit has been perfected; young shoots meanwhile springing up by its side. The rooted ends also become distinct plants at various distances from the parent root, often many yards. This mode of growth adds much to the difficulties in the discrimination of the species; since an acquaintance with both the leafy shoot and the floriferous stem, formed in the second year from its remains, is necessary. The best characters are found in the figure, the arms, and the leaves of the former. The leaves in all the British species of this division are, occasionally at least, quinate, and, with one exception, digitate, or somewhat pedate from a partial junction of the stalks of the two lateral pairs of leaflets; the margins serrated, for the most part unequally and irregularly; the prickles on the leaf-stalks more curved than those of the stem. In some species the inflorescence is remarkable, but in general the panicle varies so much as to afford no good distinction, nor can the arms of the calyx nor the form of its segment be depended on. The petals in all are delicate and crumpled, and in several species very considerable in size and width. There are some differences in the fruit, but they are rarely discriminative. In examining the figure of the leaves, the central leaflet is to be regarded; the lateral ones are always smaller and of a narrower proportion. In several species the leaves occasionally survive a mild winter, and are found the next season subtending flowering branches. The leaves of these branches are of less determinate figure; the number of their leaflets is reduced as they approach the inflorescence, and their place is supplied in the upper part of the panicle by first trifid and then simple bracteas, formed by the coalescence of the stipules. These last are usually long and narrow, entire, or sometimes toothed or jagged, and issue from the petiole, for the most part, a little above its base. They afford no distinguishing characters." This description applies equally to the foreign species as to those of Britain. The essential characters of the genus are:—calyx 5-cleft; petals 5. Fruit superior, of several single-seeded juicy drupes placed upon a protuberant spongy receptacle. The species are universally diffused over the mountainous and temperate regions of the Old and New World.

Nearly 200 species of this genus have been described. Babington, in his 'Manual of British Botany,' gives 43 species as British, Hooker and Arnott in the 'British Flora' give but 9 species, whilst Dr. Bell Salter, in the 'Supplement' to the same work, makes 22 species. This will be sufficient to show the difficulty of determining the species in this genus.

1. Species having minute leaves, and 3 to 7 leaflets.

R. idaeus, Common Raspberry, or Mount Ida Bramble. [RASPBERRY, in ARTS and SC. DIV.] The whole plant is villose, stem round, with slender recurved prickles; leaves pinnate, with 3 or 5 ovate serrated leaflets, tomentose beneath; flowers drooping; petals obovate, wedge-shaped, entire, conniving, shorter than the calyx; carpels numerous, tomentose. It is a native of woods in Europe, from Norway and Sweden to Spain and Greece. It is found also in Asia on the Himalayas, in the north of Africa, and in America from Canada to Pennsylvania. It is found abundantly in almost every part of Great Britain and Ireland.

R. suberectus, Upright Bramble, is known by its nearly upright, not rooting, obsolete angular stem, uniform few and small prickles, lower pair of leaflets sessile or nearly so, and panicle nearly simple. The stems are between three and four feet high. The fruit consists of a number of small dark-red aggregated carpels, which have something the flavour of the raspberry, and hence recommended for cultivation. It is a British species, and grows on boggy heaths, by the sides of streams, &c., chiefly in mountainous districts of the North.

R. micranthus, Small-Flowered Bramble, has an upright, round, branched stem, pinnate leaves, with 5-7 oblong, ovate, doubly serrate, tomentose beneath, and green above leaflets, with small reddish-purple flowers arranged in corymbs, and black fruit. It is a native of Nepal, and one of the most gigantic of the genus, attaining a height of 8 or 9 feet. It is easily distinguished by its nearly erect, smooth, dark mahogany-coloured shoots, and very long pinnate leaves. The shoots sometimes attain a length of 20 feet. There are two other species, *R. distans* and *R. asper*, found with this in Nepal, which have been grown in this country.

R. occidentalis, the Western Bramble, is a native of Canada and the

West Indies, and was introduced into this country in 1696. It has umbellate flowers, and fruit like the raspberry, but black, and grows to the height of 4 or 6 feet.

2. Digitate leaves, with from 3 to 5 leaflets.

R. cæsius, the Gray Bramble, or Dewberry. Stem trailing, round or nearly so, glaucous: prickles straight, unequal, passing insensibly into setæ, the length of the largest rarely equalling the diameter of the stem; leaves digitate, of 3 or more rarely 5 ovate leaflets, the outermost sessile; calyx embracing the fruit. It is a native of Europe and the north-east of Asia, in woods and hedges. Many of the species described by botanists may be referred to this; the most important of these are *R. Sprengelii*, *R. dumetorum*, *R. foliolosus*, *R. flagellaris*, and *R. coryliflorus*. The last, the Hazel-Leaved Bramble, is admitted as a species by most British botanists. It is known by its stem being decurved and roundish, prickles straight, passing into setæ; leaves digitate, with five ovate leaflets; fruit spreading or reflexed. It is generally a much larger and stronger plant than *R. cæsius*. Dr. Lindley refers several of the species of the German botanists, Weihe and Nees, to the *R. coryliflorus*, which he admits as a genuine species.

R. spectabilis, Showy Bramble, is one of the handsomest of the genus. It has a glabrous stem, not bearing prickles; leaf of three ovate, acute, doubly and unequally serrated leaflets, downy beneath; flowers of an agreeable purplish colour, on terminal peduncles. It is a native of America.

R. fruticosus, Shrubby Bramble, or Common Blackberry, is one of the most common species of the genus. It has a 5-angled erect stem, rather tomentose, bearing recurved prickles, 3-5 leaflets, each on a secondary petiole; rose-coloured or white flowers arranged on a panicle; reflexed sepals, almost without prickles; purplish black fruit. It is a native of almost all Europe, in hedges, thickets, and woods. There are no less than ten generally admitted varieties of this species, and some botanists make many more. The fruit of this species and its varieties are well known as blackberries, or bumblekites, and also scald-berries, from their supposed power of giving scald-head to children.

R. arcticus, the Arctic Bramble, is the smallest species of the genus. It has three glabrous obtusely-serrated leaflets, no runners, stem bearing only one flower, and without prickles, the petals notched. It is a native of the mountainous and colder regions of Europe. Its stem never attains a greater height than six inches, and is furnished with from three to four leaves, with a single large deep rose-coloured flower, which is succeeded by a purplish-red fruit highly prized for its flavour among the Swedes.

3. Leaves singly lobed, not digitate or pinnate.

R. odoratus, the Sweet-Scented Bramble. It has an upright stem, with large showy red flowers, numerous ovate velvety carpels, and red fruit. It is a native of North America, in the woods of Canada, and the Alleghanies. It grows to the height of 4 or 5 feet, and is called *odoratus* on account of the fragrance of its foliage. Another American species, resembling the last, is the *R. Nutkanus*, the Nootka-Sound Bramble. It flowers from May to October.

R. chamæmoris, the Cloud-Berry, is known by its dioecious flowers, simple-lobed leaves, and herbaceous single-flowered stem without prickles. It grows in great abundance on the Scotch Highlands, and, under the name of Roebuck-Berries and Knot-Berries, the fruit is gathered in great quantities by the inhabitants of those districts. It is the badge of the clan of McFarlane.

RUBY. [SPINEL.]

RUD, or RED EYE. [LEUCISCUS.]

RUDBECKIA, a genus of Plants dedicated by Linnæus to the memory of his predecessors the Rudbecks, father and son, in the botanical chair at Upsal. It belongs to the natural order *Compositæ*, and possesses many species. Some of these are well known in gardens. The are herbaceous, biennial, and perennial.

RUDISTES. [HIPPIURITES.]

RUE. [RUTA.]

RUELLIA, a genus of Plants belonging to the natural order *Acanthaceæ*, which was so named by Linnæus in compliment to J. Ruelle, physician of Francis I., who wrote commentaries on Dioscorides, as well as some other botanical works. The genus, as formerly constituted, embraced a great many Indian species, which are now distributed among some other genera. The species are distributed through the tropical parts of Asia, including the tropical and subtropical parts of Australia. It includes many highly ornamental plants, as are also those which have now been excluded from it; all are easily cultivated, and often to be seen in our hot-houses. Some of the species which have now been removed to other genera are found at considerable elevation on the sides of the Himalaya Mountains; of these the most remarkable is *Æchmanthera* formerly *Ruellia gossypina*, which has its stems covered with a thick coating of white tomentum, which probably enables it to withstand a greater degree of cold than most others of the family.

The leaves of *R. strepens* are subacid. A valuable dye, called Room, is obtained in Assam from a species of *Ruellia*.

RUFFE, a Bird. [SCOLOPACIDÆ.]

RUFFE, a Fish. [CERNUÆ.]

RUMEX, a genus of Plants, from 'rumex,' a sort of spike, spear, or

halberd, which the shape of its leaves resembles. It belongs to the natural order *Polygonaceæ*. Most of the species of this genus are well known as troublesome weeds to the agriculturist, under the name of Docks and Sorrels. Some of them have been used in medicine, but their incomplete flowers and inelegant appearance have caused their almost entire neglect in the garden. The essential characters of the genus are:—Calyx with 6 sepals, the outer 3 slightly coherent, the inner ones enlarged after flowering; stamens 6; styles 3, reflexed; stigmata 3 and cleft; fruit a 3-cornered nut, with a lateral embryo and superior radicle. In the descriptions of this genus by botanists, the three inner sepals are often designated as corolla, but it is more consistent with what we know of the general structure of the order *Polygonaceæ* to refer it to the apetalous or incomplete sub-class of *Exogena*, and thus to consider the flower of *Rumex* as destitute of corolla. *Rumex* is nearly allied to *Rheum*, but may be distinguished from that genus by its 3-cornered carpels not having wings, and by the embryo of the seed being lateral, not central as in *Rheum*. The wings that are observed upon the fruit of some species of *Rumex* are produced by the calyx.

R. acetosa, Common Sorrel, is known by its granular valves, dioecious flowers, oblong awl-shaped leaves, with converging (often notched) lobes. It is indigenous in this country, and it is also common in meadows and grassy pastures throughout Europe, from Lapland to Greece. It flowers early in June. The leaves are used in decoction as a febrifuge.

R. hydrolapathum, Great Water-Dock, is distinguished by having sepals petaloid, nearly entire, unequally tuberculated; lanceolate leaves acute at each end; almost leafless whorls. It is found growing in marsh-land ditches, stagnant waters, and the margins of great rivers throughout Europe, as well as in North America from Pennsylvania to Virginia. It is by far the largest and most conspicuous of our indigenous docks; flowering from July to August. This seems to have been the plant known under the name of *Herba Britannica* to Pliny (xxv., c. 3, 8), Galen, and others, and which was employed, on account of its astringent properties, in various diseases in which those remedies are indicated.

R. crispus, Curled Dock, is a common weed all over Europe. It has a tapering yellowish root. Stem two or three feet high, angular, furrowed, somewhat zigzag, smooth to the touch, paniced, and leafy. Leaves lanceolate-acute, strongly undulated, and crisped at the edges, smooth, of a lightish green-colour, the radical ones on long stalks, the uppermost narrower and nearly sessile. Clusters of numerous rather crowded tufts, or whorls, of drooping pale-green flowers, in the lower part leafy. The nut contracted at each end, with three blunt or tumid angles. This common weed has the reputation of being in decoction or ointment a cure for the itch; the root, which is astringent, is the part used.

There are 13 British species described in Babington's 'Manual,' which are commonly known by the names of Sorrel, or Dock. Besides the species just described, several others are used in medicine.

R. obtusifolius, the root of which, in powder, is employed as a dentifrice.

R. alpinus, Monk's Rhubarb, the root of which is thick, fleshy, and purgative.

(Lindley, *Flora Medica*.)

RUMINANTIA, Cuvier's name for his eighth order of Mammifères. They constitute the *Pecora* of Linnaeus.

Cuvier remarks that this is perhaps the most natural and the best defined of the class; for these animals have the air of being nearly all constructed on the same model; and the camels alone present some small exceptions to the common character. [CAMELUS; LLAMA.]

The first of these characters, observes the great French zoologist, is the possession of incisor teeth in the lower jaw only, and these are nearly always eight in number. They are replaced above by a callous rim (bourrelet). Between the incisors and the molars is a wide space, where are found, in one or two genera only, one or two canines. The molars, nearly always six in number on each side of the upper and lower jaws, have their crown marked with two double crescents, the convexity of which is turned inwards in the upper and outwards in the lower teeth.

The four feet are terminated by two toes and two hoofs, which oppose to each other a flattened surface, so that they have the appearance of a single hoof which has been split; whence these quadrupeds have obtained the name of animals with divided or bifurcate hoofs, &c.

Behind the hoof there are sometimes two small processes or spurs, the vestiges of the lateral fingers. The two bones of the metacarpus and the metatarsus are united into a single one, the cannon bone, but in some species there are also vestiges of the lateral metatarsians and metacarpians.

The name Ruminants indicates the singular faculty possessed by these animals of masticating a second time their food, which they return into the mouth after a previous deglutition, a power which is the result of the structure of their stomachs, four of which they always have. Of these stomachs the three first are so disposed that the aliment can enter at the will of the animal into any one of the three, because the œsophagus terminates at the point of commu-

The First Stomach or Paunch (Rumen, Penula, Magus Venter, Ingulvies—Panse of the French) is much the largest in the adult animal, but not so in the recently born calf or lamb. It is divided outwards into two bag-like appendages at its extremity, and it is slightly separated into four parts on the inside. The internal coat of this stomach is beset with innumerable flattened papillæ. Here are received the masses of herbage rudely broken up by the first mastication, and here it is (though they sometimes, but seldom, occur in the second) that the morbid concretions of a globular or elongated but rounded figure are generally found. These concretions are composed of three sorts of substances—of hairs, of the fibrous parts of plants, or of stony matter. The first of these are formed, particularly in the cow, by the animal's own hair, or that of another cow or ox licked off and gradually accumulated in the stomach. Sometimes these are hairy externally, but generally they are covered with a dark polished coat. The *Ægagropilæ* found in the Chamois consist of vegetable maccrated fibres. The stony concretions have received the name of Bezoar Stones. They were formerly believed to be antidotes to poisons, and to possess other extraordinary virtues.

The herbage in the stato above noticed is transmitted into the Second Stomach, Honey-Comb Bag, Bonnet, or Klug's-Hood (Retikulum, Ollula—Bonnet of the French), the walls of which are furnished with laminae somewhat resembling the cells of bees; this, which is small and globular, may be considered as an appendage of the first stomach or paunch, but is distinguished from that by the elegantly arranged polygonal and acute-angled cells, forming superficial cavities on its internal coat. Here the herbage is arrested, imbibed, and compressed into small masses or balls, which are thence returned successively into the mouth for remastication. During this operation the animals remain in a state of repose,

"Some ruminating lie,"

until all the herbage swallowed has undergone the action of the molar teeth a second time. The aliment thus remasticated is transmitted into the third or smallest stomach, the Manyplus (Manyplies)—(Echinus, Conclave, Centipellio, Omasus, Psalterium—Feuille of the French). This stomach is distinguished from the two former, both by its form, which has been fancied to resemble a hedgehog rolled up (whence the name Echinus), and its internal structure, the longitudinal laminae of its walls resembling in some degree the leaves of a book (whence the name Feuille). These numerous and broad duplicatures of its internal coat lie lengthwise and vary in breadth in regular alternato order, amounting to some forty in the sheep, and about a hundred in the cow.

From the third stomach the food is transmitted into the fourth, the Red (Abomasus, Faliscus, Ventriculus Intestinalis—Caillette of the French), which is next in size to the first stomach or paunch, of an elongated pyriform shape, and with an internal villous coat similar to that of the human stomach, with large longitudinal wrinkles. This last is, so to speak, the true organ of digestion, analogous to the simple stomach of ordinary animals.

We will now proceed to inquire how this complicated machine is connected together, and how it acts.

Blumenbach observes that the first three stomachs are connected with each other, and with a groove-like continuation of the œsophagus, in a very remarkable way. The latter tube enters just where the paunch and the second and third stomachs approach each other; it is then continued with the groove, which ends in the third stomach. This groove is therefore open to the first stomachs, which lie to its right and left. But the thick prominent lips which form the margin of the groove admit of being drawn together so as to form a complete canal which then constitutes a direct continuation of the œsophagus into the third stomach. The functions of this very singular part will vary according as we consider it in the state of a groove or of a closed canal. In the first case, the grass, &c., is passed, after a very slight degree of mastication, into the paunch as into a reservoir. Thence it goes in small portions into the second stomach, from which, after a further maceration, it is propelled, by a kind of antiperistaltic motion, into the œsophagus, and thus returns into the mouth. It is here ruminated and again swallowed, when the groove is shut, and the morsel of food, after this second mastication, is thereby conducted directly into the third stomach. During the short time which it probably stays in this situation between the folds of the internal coat, it is still further prepared for digestion, which process is completed in the fourth or true digestive stomach. (Lawrence's 'Blumenbach.') In notes to the same work it is stated that the shutting of the groove when the food is again swallowed after rumination supposes a power of voluntary motion in this part, and indeed, it is added, the influence of the will in the whole affair of rumination is incalculable. It is not confined to any particular time, since the animal can delay it according to circumstances when the paunch is quite full. It has been expressly stated of some men, who have had the power of ruminating (instances of which are not very rare), that it was quite voluntary with them. "I have known," continues Blumenbach, "two men who ruminated their vegetable food: both assured me that they had a real enjoyment in doing this, which has also been observed of others; and one of them had the power of doing it or leaving it alone according to circumstances."

Whilst the Ruminants remain at the teat and live upon nothing but

milk, the fourth stomach is the largest of all. The first stomach or paunch only develops itself into its enormous volume in proportion as it receives supplies of herbage.

The intestinal canal of these animals is very long, but little enlarged or sacculated in the great intestines. The cæcum is moderately long and smooth.

The student will find a series of preparations illustrative of the structure of the alimentary canal of the *Ruminantia* in the Museum of the Royal College of Surgeons of England. The structure of the particular forms of these animals will be found under the articles ANTILOPEÆ, BOVIDÆ, CAMELUS, CAPRÆÆ, CERVIDÆ, LLAMA, OVEÆ, and GIRAFFA.

Cuvier makes the Ruminants consist of two divisions:—first, those without horns; secondly, those with horns.

The first division embraces the Camels (*Camelus*, Linn.), or the Camels properly so called, and the Llamas; and the Chevrotains (*Moschus*, Linn.). Secondly, all the rest of the Ruminants, of the male sex at least, have two horns or prominences, more or less long, projecting from the frontal bones, which is not found in any other family of mammals.

In some these prominences are covered with a case of elastic substance, composed, as it were, of agglutinated hairs, which grows in layers, and during the whole life of the animal. The name horn (corne) is particularly applied. The bony prominence or core which this case envelops, grows, like it, during the whole life of the animal, and is never shed. Such are the horns of oxen, sheep, goats, and antelopes.

In others the prominences are invested only with a hairy skin, which is continued from that of the head, and is never destroyed during life. These prominences are never shed.

Finally, in the great genus *Cervus*, Linn., the prominences covered during a certain period with a hairy or velvety skin resembling that of the rest of the head, have at their base a ring of bony tubercles, which, as it increases, compresses and obliterates the nutrient vessels of that skin, which, when the horn is complete, dries and is removed. The naked bony prominence separates in due time from the skull, to which it grew, falls, and the animal becomes defenceless. But new horns soon begin to bud, ordinarily, and while the animal is in the vigour of life, larger than the preceding ones, and destined to fall in their turn. These horns, purely osseous and subjected to periodical changes, are termed by the French Bois, and are known in England by the name of Antlers.

Mr. Swainson divides the *Ungulata* into the following five tribes:—*Ruminantes*, *Pachydermes*, *Anoplotheres*, *Edentates*, and *Solipedes*.

The *Ruminantes* are thus arranged:—

1. Sub-typical group.—Horns sheathing; form gracile, slender.

Family *Antilopidæ*. [ANTILOPEÆ.] (Sw.—*Capridæ*, Smith.)

Genera.—*Dicranocerus*, Sm.; *Agocerus*, Sm.; *Oryx*, Sm.; *Gazella*, Sm.; *Antelope*, Sm.; *Redunca*, Sm.; *Tragulus*, Sm.; *Raphicercus*, Sm.; *Tetracerus*, Leach; *Cephalophus*, Sm.; *Neotragus*, Sm.; *Tragelaphus*, Sm.; *Nemorhædus*, Sm.; *Rupicapra*, Ant., Sm.; *Aplocercus*, Sm.; *Capra*, Auct.; *Ovis*, Auct.; *Damalis*, Sm.; *Acronotus*, Sm.; *Boselaphus*, Sm.; *Strepsicercus*, Sm.; *Portax*, Sm.

2. Typical.—Horns sheathing; form heavy, robust.

Family *Bovidæ*, Sm. [BOVIDÆ.]

Genera and Subgenera.

1. *Alex*, Sm. (Subgenera *Rangifer*, Sm.; *Dama*, Sm.)
2. *Cervus*, Linn., Sw. (Subgenera *Rusa*, Sm.; *Axis*, Sm.)
3. *Capreolus*, Sm. (Subgenus, *Mazama*, Sm.)
4. *Subulo*, Sm.
5. *Styllocerus*, Sm.

3. Aberrant. Horns solid, deciduous. (*Cervidæ*, Sm.; *Cervus*, Linn.) [CERVIDÆ.]

Horns wanting; fore legs shorter than the hinder. (*Moschidæ*, Sw.) [MOSCHIDÆ.]

1. *Moschus*, Linn.

Horns very short, covered with a skin. (*Camelopardæ*, Sw.) [GIRAFFA.]

1. *Camelopardalis*, Antiq.

The tribe *Solipedes*, which immediately follows the Camelopards, consists of the genera *Camelus*, *Auchenia*, and *Equus*. Thus the Camels and Llamas, with which Colonel Smith, following Cuvier, commences the Ruminants, are placed by Mr. Swainson at the conclusion. With the exception of this and a few other modifications, the two arrangements are similar.

RUMINATION. [RUMINANTIA.]

RUMPHIA, a genus of Plants named by Linnæus in honour of George Eberhard Rumph, is only known from a figure of Rheede, published in his 'Hortus Malabaricus', vol. iv., t. 11, who describes it as being found in Parabaroo and other provinces of Malabar. It has not been seen by any modern botanist. It is usually referred to the natural family of *Terebinthaceæ*, and to the sub-order *Bursereæ*. It

has a tubular trifold calyx, 3 oblong petals of the corolla; stamens 3, equal to the petals, and exserted. The ovary is single, 3-cornered; style one; drupe coriaceous, turbinate, 3-furrowed, with the nut 3-celled, 3-seeded. But Messrs. Wight and Arnott remark, that as each apparent stamen may be composed of several filaments, this doubtful genus would be brought near *Byttneriaceæ*.

RUNNER. [STEM.]

RUNNING. [LOCOMOTION IN ANIMALS.]

RUPELLARIA. [LITHOPIAGIDÆ.]

RUPICAPRA. [ANTILOPEÆ.]

RUPICOLINÆ, a sub-family of Insectorial Birds allied to the Manakins and generally arranged under the family *Pipridæ*. Mr. Swainson places both *Calyptomena* and *Rupicola* in the sub-family *Ampelina*, or Typical Chatterers; and *Rupicola*, in his arrangement, immediately precedes the sub-family *Piprina*, Manakins, which he considers as subtypical. Mr. G. R. Gray ('Genera of Birds') places *Rupicola* and *Calyptomena* at the head of the *Ampelina*, the fourth sub-family of the *Ampelidæ* in his method.

Rupicola (Briss.).—Bill moderate, robust, rather vaulted and curved at the point, upper mandible as wide as it is high, compressed at the base and notched at the point; lower mandible shorter, straight, and sharp; nostrils oval, lateral and hidden by the feathers of the elevated crest which covers the head. Feet large, strong, tarsi partially clothed with feathers, feet syndactyle, outer toe connected with the middle toe beyond the first joint; hallux very strong, and armed with a crooked nail. Wings short, rounded; fourth and fifth quills longest.

The species are found in central and South America.

R. aurantia, Vieillot. It is the *Pipra Rupicola* of Linnæus, *Rupicola Cayana* of Swainson, *R. elegans* of Stephens, and Rock Manakin and Cock-of-the-Rock of English ornithologists.

The male is about the size of a Ring-Pigeon (*Columba palumbus*), very bright orange-yellow; a crest, which is compressed and elevated, rises from the head with a helmet-like air, and is varied at the summit with brown and bright-yellow; there is some white at the bend and on the middle of the wing, which is filiform at the first quill; the tail-feathers are short, reddish-black bordered with yellow; bill and feet rosy-white. Female rather smaller, and with a less elevated crest; colour entirely dirty bistre-brown.

This beautiful bird inhabits Guyana, especially about the rocks which border the small river Oyapock, and is becoming daily more rare.

The Cock-of-the-Rock flies swiftly, and is a very shy bird. The nest is made of twigs and dry herbage; and there the female lays two white eggs about the size of those of a pigeon. The food consists of the smaller wild fruits.

Cock-of-the-Rock (*Rupicola aurantia*).

R. Peruviana (Dumont), the Chichia Lacca of the Mexicans. Male.—Bright-orange, like the preceding, but the quills and tail-feathers are deep-black and the middle wing-coverts are bright gray-ash. The crest is of a uniform colour, wanting the deeper-coloured semicircular line, and not of a helmet-like contour. The tail-feathers are long.

The Peruvian Cock-of-the-Rock was for some time considered to be a mere variety of *R. aurantia*, but it differs in being of larger size, in colour, in the length of the tail-feathers, in the absence of the filiform wing-feathers, and in the crest, which is not circular as in the preceding species.

It has been brought to Europe from Lima.

Peruvian Cock-of-the-Rock (*Rupicola Peruviana*).

Calyptomena (Raffles); *Rupicola* (Temminck).—Bill depressed and wide at the base, curved or hooked at the point, and nearly hidden by the feathers of the erect and compressed crest. Wings large and very broad, first quill shortest, third longest, lesser quills notched at their tips. Tail and feet very short, hind toe as long as the tarsus, outer and middle toe connected up to the second joint.

C. viridis (Raffles). This very singular and beautiful bird is about 6½ inches in length. Its colour is a brilliant green, like that of the parrots. It is the Burong Tampo Pinang of the Malays. It is a native of Singapore and the interior of Sumatra.

Sir Stamford Raffles states that this species is found in the retired parts of forests, and as it is of the colour of the leaves, and perches high, it is not easily procured. He further tells us that the stomach contained nothing but vegetable substances, chiefly wild grains.

Dr. Horsfield observes that the bill greatly resembles that of the genera *Rupicola*, *Pipra*, *Phibalura*, *Pardalotus*, *Platyrrhynchus*, and *Procnias*.

Calyptomena viridis.

RUPPELLIA (Milne-Edwards), a genus of Crustacea belonging to the family Cancridæ (Canceriens Argués), established on the *Cancer tenax* of the German zoologist and traveller Rüppell, and considered by M. Milne-Edwards as the type of the small group which leads to the genera *Ozius* and *Eriphia*.

The form of the carapace approximates closely to that of *Xantho* and *Ozius*; dorsal buckler slightly curved, and about once and a half as wide as it is long; the orbits are nearly circular, and are directed

upwards and forwards. The internal antennæ bend back directly outwards, as in *Xantho*, &c.

R. tenax, *Cancer tenax*, Rüppell, has the upper border of the orbit marked by two fissures separated by a small tooth; there is a fissure at its external angle, and two teeth at its lower borders. Length about two inches. It is a native of the Red Sea.

Ruppellia tenax.

a, abdomen of male; b, abdomen of female; c, pedipalps.

RUPPIA, a genus of Plants belonging to the natural order Juncaginaceæ. This genus was named by Linæus after Henry Ruppilius of Giessen, an active botanist, and author of 'Flora Juncensis.'

R. maritima, Sea Ruppia, is found in salt-water pools and ditches; it has a slender filiform leafy stem, with linear leaves, which are furnished with sheaths sometimes narrow and small, at other times inflated. Its flowers, which are two in number and green, are seated one above another on opposite sides of a short spadix, which is included in a sheath or spathe; it has large sessile anthers 1-celled; the ovaries are four minute grains seated in the centre between the stamens, which are sessile and two in number. When the plant has flowered the spadix lengthens to the height of five or six inches or more, and becomes spirally twisted, as if to bring the fruit to the level of the water, in which the flowers are always immersed. After this the ovaries begin to swell, and their base is elongated into a footstalk, as the fruit ripens, one or two inches long. When the fruit is perfectly ripe it becomes an ovate acuminate drupe. It is a native of Great Britain.

R. rostellata has the cells of the anthers nearly round. The whole plant is very slender; the leaves rather filiform than linear; sheaths small and close; nut obliquely ascending. It is found in salt marshes in Great Britain.

(Babington, *Manual of British Botany*.)

RUSCUS, a genus of Plants belonging to the natural order Liliaceæ, known by the common name of Butcher's Broom. The species of this genus are evergreen, and on this account are frequently introduced for undergrowth in shrubberies. The genus is known by its dioecious flowers, of which the barren flowers have a perianth of 6 single leaves, 3-6 anthers with the filaments combined at the base; in the fertile flowers the same perianth with a tubular nectary, single style, fruit superior, 3-celled, cells 2-seeded.

R. aculeatus, Common Butcher's Broom, is found wild in Britain. It has ovate attenuated leaves, very acute, rigid, bearing the flowers upon the middle of their upper surface; flowers solitary, rarely 2 together, subtended by a flat subulate scarious 1-nerved bract. It is found in bushy places and woods. The Butcher's Brooms of Europe were once celebrated as aperients and diuretics on account of their bitter subacid mucilaginous roots.

R. hypophyllum had considerable reputation at one time. Its seeds are very horny, and when roasted are said to form a pleasant substitute for coffee.

(Lindley, *Vegetable Kingdom*; Babington, *Manual of British Botany*.)

RUSH. [JUNCUS.]

RUSH DUTCH. [EQUISETACEÆ.]

RUSH, FLOWERING. [BUTOMACEÆ.]

RUTA, a genus of Plants belonging to the natural order Rutaceæ. The following is a description of this genus:—Calyx 4-partite, deciduous, shorter than the petals, which are four and unguiculate, with the limb vaulted. Stamens eight, longer than the petals;

filaments subulate, glabrous; anthers ovate, obtuse. Receptacle broader than the ovary, marked round with eight nectariferous pores, bearing the petals and stamens at the base. Carpels 4, partly combined by means of the central axis (gynobase) into one 4-lobed ovary, ovules 6-12 in each cell. Styles 4, distinct at the base, united upwards into a single pistil which is attenuated towards the apex. Stigmas 4. Capsules 4, partly united, dehiscing internally at the apex. Seeds dotted. The species of this genus are suffrutescent, herbaceous, or perennial plants, with alternate exstipulate pinnated or decompound leaves covered with pellucid dots. The flowers are yellow, rarely white, and disposed in terminal corymbs or racemes. De Candolle enumerates 24 species of *Ruta*, of which comparatively few are generally known or cultivated.

R. graveolens, Common Rue, is a glaucous hairless erect herb or half-shrubby plant, with a strong heavy unpleasant smell, growing to the height of about two feet. The leaves are supradecomposed, alternate, their lateral lobes linear or nearly so; the terminal ones obovate; they and all other parts of the plant are covered with transparent dots. Carpels terminal, leafless, trichotomous, cymose; petals four, wavy concave, a little irregularly toothed. Fruit roundish, warted, four-lobed, each lobe opening into two valves.

Rue is sometimes called Herb-Grace, or the Herb of Grace, and in some parts of England Ave-Grace. This name is said to have been given to it on account of its use in exorcisms. In company with rosemary it has been used from time immemorial as an emblem of remembrance and grace on account of its evergreen foliage. The stamens are remarkable for their presenting an instance of vegetable irritability. When the time is come for the pollen to be introduced into the stigma, and thus presented to the ovules, the stamens, which are hard and rigid, and almost at right angles with the style, approach the stigma one by one, and after remaining in contact with it long enough to discharge their pollen, they return back to their original position parallel with the petals. [RUE, in ARTS AND SC. DIV.]

RUTACEÆ, a natural order of Polypetalous Exogenous Plants, characterised by the possession of hypogynous stamens, two or three times as many as the petals, cohering carpels with from 3 to 5 valves, an entire ovary with several cells, imbricate calyx with four or five divisions, symmetrical hermaphrodite flowers with petals either wanting or as many as the lobes of the calyx, mostly twisted in aestivation. Fruit capsular, the sarcocarp mostly separating from the endocarp. Leaves without stipules, opposite, or alternate, simple, deeply lobed or pinnate, and covered commonly with pellucid resinous dots. They are trees, small shrubs, or herbaceous plants.

Ruta graveolens.

a, lobed fruit surrounding the central axis; b, section of a seed, showing the embryo lying in the centre of the albumen; c, flower, showing a double row of stamens, concrete carpels, and rim of the disc.

This order embraces the *Rutaceæ* and *Diosmeæ* of A. de Jussieu, which are now made the principal sections of *Rutaceæ*. *Rutaceæ* are known by their seeds containing albumen, and by the sarcocarp of the fruit not being separable from the endocarp. In *Diosmeæ* the seeds have no albumen, and the sarcocarp and endocarp are separable into distinct bodies when the fruit is ripe. A. St. Hilaire says that the observation of the adhesion of the sarcocarp and endocarp in *Rutaceæ* has been made on unripe specimens of the plants, and that when ripe they are as separable as in *Diosmeæ*. Whatever may be the real state of the case, the two sections are too obviously related in structure and general properties to permit of so slight differences elevating them into the importance of distinct natural orders. *Ruta-*

NAT. HIST. DIV. VOL. IV.

ceæ agree with *Aurantiaceæ* in their dotted leaves, definite stamens, and fleshy disc. With *Xanthoxylaceæ*, *Simarubaceæ*, and *Humiriaceæ* they have also many points of analogy. They are closely allied to *Zygophyllaceæ* through *Peganum*, which Jussieu and other writers place amongst *Rutaceæ*. They are found in the south of Europe, and in our hemisphere extend as far as the limits of the Old World. *Diosma* and allied genera are found at the Cape of Good Hope. Australia possesses *Boronias*, *Phebaliums*, *Correas*, &c.; and great numbers are found in the equinoctial regions of America.

Many of the plants of this order emit a powerful and usually offensive odour from the glands that cover their whole surface. These glands are sometimes so full of a volatile oil, that in hot weather the atmosphere surrounding the plant becomes charged with it, so that a lighted taper brought near the plant will cause the air to inflame. This is especially the case with *Dicamnus*. The *Diosmas*, or Bucku Plants, are used in medicine as antispasmodics. The celebrated Angostura Bark is produced by a plant (*Galipea officinalis*) [GALPEA] belonging to this order. [RUTA; FRAXINELLA; DIOSMA.]

RUTILE. [TITANIUM.]

RYACOLITE, a Mineral resembling *Albite*. It contains 10 per cent. of soda. It comes from Mount Soruma and the Eifel.

RYE. [SECALE.]

RYE-GRASS. [LOLIUM.]

RYNCHÆA. [SCOLOPACIDÆ.]

RYNCHOPS (Linnaeus), a genus of Aquatic Palmipede Birds. The word would be more correctly written *Rhyuchops* (*Ῥύγχος*), and indeed is so spelled by most ornithologists; but the word stands in the last edition of the 'Systema Naturæ,' published by Linnaeus, as it appears at the head of this article, and the genus is arranged at the end of the *Anseres*, coming immediately after *Sterna*, which last is preceded by *Larus*.

This genus has been variously placed by zoologists. It has the following generic characters:—Bill longer than the head, straight or nearly so, compressed, and in form resembling the blade of a knife, truncated, and with the appearance of having been broken at the point; upper mandible much shorter than the lower, and with a groove into which the lower mandible is received; nostrils unangular, median. Feet moderately long, slender. Wings very long; the first quills longest.

The extraordinary structure of the bill in this bird immediately fixes the attention. In appearance it looks, at first sight, like a worn or imperfect organ: in reality it is an instrument of the nicest adjustment as applicable to the purposes which it has to execute. Buffon, as was too frequently his wont, condemns an organisation which he did not understand, and indeed could never have accurately examined. On account of the peculiarities of its bill the bird is popularly called the Scissors Bill.

The upper mandible at its base overlaps the lower with its edges; but the upper edge of the under mandible, which consists of a thin flattened plate or blade, is received in a groove with elevated sharp edges, on the lower surface of the upper mandible: this groove diverges at the base, and thus comes to overlap the lower at the gap as above noticed. Catesby speaks of it as "a wonderful work of nature," and accurately describes it. "The under mandible," says he, "is more compressed than the upper, and very thin, both edges being as sharp as a knife, and is almost an inch longer than the upper mandible, which has a narrow groove or channel into which the upper edge of the lower mandible shuts."

Bill of *Rynchops*.

Bill of *Rynchops*: the mandibles closed, and seen from below.

R. nigra is the Bec-en-Ciseaux and Coupenr d'Eau of the French; Shearwater, Cut-Water, Skinner, and Black Skimmer, of the Anglo-Americans; and Piscator of the Chilians.

The male is about 19 inches in length; the closed wings extend beyond the tail 4 inches; alar stretch 44 inches. Length of the lower mandible 4 inches; of the upper mandible 3½ inches; both red, tinged with orange, and tipped with black. Upper part of the head, neck, back, and scapulars, black; wings the same, except the secondaries, which are white on their inner vanes, and also tipped with white. Tail forked, the two middle feathers about an inch and a half shorter than the exterior ones, all black, broadly edged on either side with white; tail-coverts white on the outer sides, black in the middle. Front, cheeks and neck below the eye, throat, breast, and all the lower parts, white. Legs and webbed feet red-lead colour.

The female is only 16 inches long, and 39 inches in alar stretch; similar with the male in plumage, except in the tail, which is white-shafted and broadly centred with black.

There are oblique stripes on the lower mandible, which become most apparent in the dead and dry specimen.

It is a native of the tropical and temperate parts of America.

Cut-Water (*Rynchops nigra*).

Linnaeus thus succinctly and truly describes its habits:—"Volando aquae superficiem radit, ex illa insecta pisciculosque, mandibulo inferiore introducta, extrahit; victitatio conciliis." Catesby says:—"These birds frequent near the sea-coasts of Carolina. They fly close to the surface of the water, from which they seem to receive somewhat of food. They also frequent oyster-banks, on which I believe they feed; the structure of their bills seems adapted for that purpose."

Wilson thus describes their mode of taking food on the wing:—"The Sheerwater is formed for skimming while on the wing the surface of the sea for its food, which consists of small fish, shrimps, young fry, &c., whose natural haunts are near the shore and towards the surface. That the lower mandible, when dipped into and cleaving the water, might not retard the bird's way, it is thinned and sharpened like the blade of a knife; the upper mandible, being at such times elevated above the water, is curtailed in its length, as being less necessary, but tapering gradually to a point, that on shutting it may suffer no opposition. To prevent inconvenience from the rushing of the water, the mouth is confined to the mere opening of the gullet, which

indeed prevents mastication taking place there; but the stomach, or gizzard, to which this business is solely allotted, is of uncommon hardness, strength, and muscularity, far surpassing in these respects any other water-bird with which I am acquainted. To all these is added a vast expansion of wing, to enable the body to sail with sufficient celerity while dipping in the water. The general proportion of the wing of our swiftest hawks and swallows to their breadth is as one to two; but in the present case, as there is not only the resistance of the air but also that of the water to overcome, a still greater volume of wing is given, the Sheerwater measuring nineteen inches in length, and upwards of forty-four inches in extent. In short, whoever has attentively examined this curious apparatus, and observed the possessor, with his ample wings, long bending neck, and lower mandible occasionally dipped into and ploughing the surface, and the facility with which he procures his food, cannot but consider it a more playful amusement, when compared with the dashing immersions of the tern, the gull, or the fish-hawk, who to the superficial observer appear so superiorly accommodated. The Sheerwater is most frequently seen skimming close along shore, about the first of the flood. I have observed eight or ten in company passing and repassing at high water, dipping with extended neck their open bills into the water with as much apparent ease as swallows glean up flies."

Mr. Nuttall states that the Cut-Water, or Black Skimmer, is a bird of passage in the United States, appearing in New Jersey (to the north of the sea-coast of which he believes it is unknown) from its tropical quarters early in May; and he thinks that it probably passes the breeding season along the whole of the southern coast of the United States. In New Jersey it "resides and breeds in its favourite haunts, along the low sand-bars and dry flats of the strand in the immediate vicinity of the ocean. Their nests have been found along the shores of Cape May about the beginning of June, and consist of a mere hollow scratched out in the sand, without the addition of any extraneous materials. The eggs are usually three in number, oval, about one inch and three-quarters to two inches by one inch and a quarter, and nearly pure white, marked almost all over with large umber-brown blotches and dashes of two shades, and other faint ones appearing beneath the surface. In some eggs these particular blotches are from half an inch to an inch in length. As the birds, like the terns and gulls, to which they are allied, remain gregarious through the breeding season, it is possible to collect half a bushel or more of the eggs from a single sand-bar, within the compass of half an acre; and though not very palatable, they are still eaten by the inhabitants of the coast. The female only sits on her nest during the night, or in wet and stormy weather; but the young remain for several weeks before they acquire the full use of their wings, and are during that period assiduously fed by both parents: at first they are scarcely distinguishable from the sand by the similarity of their colour, and during this period may often be seen basking in the sun, and spreading out their wings upon the warm beach. The pair, retiring to the south in September, or as soon as their young are prepared for their voyage, raise but a single brood in the season." ('Manual of the Ornithology of the United States and of Canada,' vol. ii.)

The same author states that this species is met with in the equatorial regions of America, where it is resident as far as Surinam, but never penetrates into the interior, being, properly speaking, an oceanic genus.

M. Lesson remarks that, though this bird closely approaches the species belonging to the Antilles, it is still possible that it may be distinct from it.

RYTINA. [CETACEA.]

S

SAARA. [DRACONINA.]

SABADILLA. [CEBADILLA; HELONIAS.]

SABATIA, a genus of North American Plants, belonging to the natural order *Genitaceae*. The genus is known by a 5-12-parted calyx, rotate 5-12-parted corolla, withering on its capsule, revolute anthers, stigma with two straight arms, becoming at length spirally twisted, and a 1-celled capsule, with the valves turned a little inwards. There are several species of *Sabatia*, all of which are characterised by the possession of a pure bitter principle, and on this account they are extensively used, in North America, in intermittent and remittent fevers, and as tonics. The species most commonly used is the *S. angularis*.

SABELLA. [TUBICOLAE.]

SABELLARIA. [TUBICOLAE.]

SABIA, a genus of Plants named by Mr. Colebrooke from the Indian name, *Sabja*, of one of the species. It is usually referred to the natural family *Terebinthaceae*, but it is now attached as an anomalous genus to the group *Anacardiaceae* which is separated from them. The species form ornamental climbing-shrubs, with smooth lanceolate alternate leaves suited to the shrubberies of this country.

SABINEA (named by De Candolle, in honour of Joseph Sabine, F.R.S.), a genus of Plants belonging to the natural order *Leguminosae*. The violet flowers of *S. Florida* are considered poisonous.

SABLE. [MUSTELIDÆ.]

SACCHARITE, a Mineral resembling granular felspar, of a greenish-white colour, and with the constitution of *Leucite*. It is found in Silesia.

SA'CCHARUM, a genus of Plants belonging to the natural order *Graminaceae*. One of the species yields the well-known product sugar, and is called the Sugar-Cane.

The Sugar-Cane was introduced by the Saracens into the south of Europe, but the period is not well ascertained. Gibbon says they introduced it into Sicily soon after they got possession of the island. About the year 1420 sugar was much cultivated by the Portuguese in Madeira. In 1503 we read of sugar being imported from the Canaries, and in 1506 sugar-canes were carried thence to Hispaniola in the West Indies. But, besides the Indian cane, another, and a much more prolific kind, that of *Otaheite*, was introduced into the West Indies about 1791, and about the same time, or in 1796, the China sugar-cane was introduced into India. The Chinese and Indians seem both therefore to have had independent means, that is, distinct plants from which they could extract sugar; and, as history shows, they did so at very early periods. [SUGAR, in ARTS and SC. DIV.]

The genus *Saccharum* contains numerous species, which are usually easily distinguished by their highly ornamental nature, by the light

and feathery or rather silk-like inflorescence. The species are widely distributed through the tropical parts of the world. The genus is distinguished by the spikelets being all fertile and in pairs, one sessile, the other stalked, articulated at the base, 2-flowered, the lower floret neuter with one palea, the upper hermaphrodite with two paleæ. Glumes 2, membranous. Paleæ transparent, awnless; those of the hermaphrodite flowers minute, unequal. Stamens 3. Ovary smooth; styles 2, long; stigmas feathered with simple hairs. Scales 2, distinct, obscurely 2- or 3-lobed at the point. Caryopsis smooth.

S. officinarum, the best known species, or that yielding sugar in India, is cultivated in all parts of that country, and several varieties are known. It was introduced into the south of Europe and the Canaries, and thence into the West Indies. Another species introduced from China, was named *S. Sinense* by Dr. Roxburgh. It was extensively distributed throughout India, and still is so to some extent, as the canes are large, rich in juice, and hard enough to resist the attacks of the white ants. Within the last few years, the Otaheite sugar-cane has been introduced from the Mauritius into India, and rapidly spread through the country. It is no doubt the same species that was many years since introduced into the West Indies. It is probably the Canne de Haite of Tussac, or *S. violaceum*.

Some of the species of *Saccharum*, owing to the silx in their cuticle, are so durable that they are employed in India for thatching, such as *S. canaliculatum* and *S. cylindricum*. This is the case with *S. spontaneum*, which also makes good mats. The natives of Bengal make their pens of the hollow stems of *S. semidecumbens* and of *S. tuscum*. The latter, as well as the culms of *S. porcerum*, are also used for screens and light fences, and other economical purposes.

SACCOLABIUM, a genus of Plants belonging to the tribe Vandee and the natural order Orchidaceæ, now extensively cultivated in hot-houses especially dedicated to their cultivation. This is an Asiatic genus, found in the Indian Archipelago, the Malay Peninsula, and thence extending north along the Himalayan Mountains to 30° 4' N. lat., where *S. guttatum* is found on trees, as well as in more southern latitudes. The genus consists of caulescent epiphytes, with 2-rowed coriaceous leaves, which are often oblique at the apex. The flowers are axillary, and either racemose or solitary.

SA'CCOMYS. [MURIDÆ; RODENTIA.]

SACRED-BEANS. [NELUMBIACEÆ.]

SAGENA'RIA. [COAL-PLANTS.]

SAGENO'CRINUS. [ECHINODERMATA.]

SAGENO'PTERIS. [COAL-PLANTS.]

SAGERET'IA, a genus of Plants belonging to the natural order of Rhamnaceæ, formed, by M. A. Brongniart, of old species of *Zizyphus* and of *Rhamnus*, and named after M. Sageret, a French vegetable physiologist. The species are found in both South and North America, Java, China, and in India along the foot of the Himalayas. The only species which requires particular notice is *S. thecans*, which is remarkable as being employed as a substitute for tea, even in China, where the poor are described by Osbeck as making use of the leaves in the same manner as those of the true tea, and for which it makes a good substitute from its astringency and fragrance.

SAGI'NA, a genus of Plants, from 'sagino,' to cram or fatten, a name not very appropriate. This genus belongs to the natural order Alismaceæ, and is characterised by possessing an inferior calyx, with 4 spreading permanent sepals; 4 ovate obtuse petals, shorter than the calyx; 4 stamens; superior ovary, with 4 short styles; capsule splitting into 4 valves, and numerous minute seeds attached to a central placenta. They form small herbs, which are very generally diffused over the temperate regions of the globe.

The following species are British:—

S. procumbens, with the central stem very short; the leaves linear, curved; the apex of the peduncles reflexed, but, after flowering, ultimately erect.

S. apetalá, with the leaves linear-mucronate.

S. ciliata has the outer sepal pointed, exceeding and adpressed to the mature capsule; their lips patent.

S. maritima has the central stem elongated, forked; leaves fleshy, blunt; peduncles always erect.

S. saxatilis has the central stem short and barren; peduncles and calyx glabrous.

S. subulata has the leaves awned; peduncles and calyx glandular, hairy.

S. nodosa has the upper leaves fasciculated; petals much longer than the calyx. This species is called Knotted Spuney.

(Babington, *Manual of British Botany*.)

SAGITTA'RIA (from 'sagitta,' an arrow, a term indicating the shape of the leaves), a genus of Plants belonging to the natural order Alismaceæ. The genus is characterised by possessing barren and fertile flowers, with a 3-leaved calyx and 3 petals. The fertile flowers have numerous pistils collected into a head, and 1-seeded compressed and margined pericarps. The species of this genus are water-plants, and are found in the hotter and temperate parts of the globe, and are frequently remarkable for the beauty of their flowers. The

only species indigenous in this country is the *S. sagittifolia*, Common Arrowhead, which is known by its arrow-shaped leaves with lanceolate straight lobes. The rhizomata of many of the species contain amylaceous matter, and form a nutritious food, for which purpose they are said to be used by the Kalmuk Tartars.

SAGO. [FOOD.]

SAGOIN. [SAPAJOUS.]

SAGRA. [EUPODA.]

SAGUERUS. [SAGUS.]

SAGUINUS. [SAPAJOUS.]

SAGUS, or SAGUERUS, a genus of Plants belonging to the family of Palms. The leaves are pinnate; the flowers monœcious; the spadix branched, without any common spathe, but with numerous partial ones; the fruit hard, shining, its surface divided into numerous rhomboidal spaces. The species are natives of the islands of the Indian Archipelago, and yield sago.

S. levis, the True Sago-Palm, has the petioles and spathes unarmed. This palm furnishes most of the sago sent to Europe.

S. Rumphii has the petioles and spathes guarded by strong prickles. According to Martin, the sago yielded by this plant is used principally in India, and seldom exported. [FOOD.]

SAHLITE. [AUOITE.]

SAIGA. [ANTILOPEÆ.]

SAIL-FISH. [SQUALIDÆ.]

SAIMIRI. [SAPAJOUS.]

SAINFOIN. [ONOBRYCHIS.]

SAINT BONIFACE'S PENNIES, the separated portions of the stalk of the Lily Encrinite. [ENCINITES.]

SAINT CUTHBERT'S BEADS. [ENCINITES.]

SAINT IGNATIUS'S BEAN. [LOGANIACEÆ.]

SAISIN. [ANTILOPEÆ.]

SAJOU. [SAPAJOUS.]

SAKIS. The genus *Pithecia* of Desmarest and Illiger comprehends those American Monkeys which are generally known by the name of Sakis, or rather those Sakis which have for the most part long and bushy tails, and thus have obtained the name of Fox-Tailed Monkeys; for the term Saki, in its general application, designates any American monkey whose tail is not prehensile.

Pithecia has the facial angle 60 degrees; head round; muzzle short; ears moderate, rounded; canine teeth very strong. Tail shorter than the body, not prehensile, and covered with very long hairs. Feet pentadactyle; nails claw-like, short and bent. Habits nocturnal.

Dental Formula:—Incisors, $\frac{4}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{6-6}{6-6} = 36$.

P. Satanas is the Cuxio of Humboldt; *Cebus Satanas*, Hoffm.; *Brachyurus Israelita*, Spix.

Colour entirely dusky black, paler beneath, where the hair becomes very thin, and has a purplish tinge which is visible on the face and hands. Hair of the very bushy tail, which is nearly of the length of the body, long and soft. Total length, including the tail, about 2 feet 9 inches.

The hair of the head is thick, and falls over the forehead, and the beard is very much developed.

The female is rusty brown.

It inhabits the forests of Brazil—Para, on the banks of the Orinoco.

It is partial to the fruit of a kind of palm; and it is represented in the act of eating it, by Humboldt, from whose figure ours is taken.

Pithecia Satanas.

P. melanocephala. This is the *Simia melanocephala* and Cacajao of Humboldt and Bonpland; also called in America Caruiri, Moufoeo, Chacuto, Chuenzo, and Mono-Robon.

Head very round, naked, and of a dull black colour, its physiognomy reminding the spectator of an old negro; the hair of the head directed forwards; eyes large and sunk, and the eyebrows composed of strong bristles; nose flat, separation of the nostrils wide; no beard; ears bare and very large.

It inhabits the forests which border the Rio Negro and Rio Casiquiare.

All kinds of fruit are acceptable to the voracious Cacajao, which is a weak, very inactive, mild-tempered, and timid animal. It even shrank from some of the small *Sapajona*. It trembled violently at the sight of a crocodile or serpent. When about to seize anything, it stretches forth its arms in the manner indicated in the cut, and holds the object with difficulty, on account of the length and slenderness of the fingers. It lives in troops.

Pithécia melanocephala.

P. Chiropotes, the Capuchin of the Oronoco, is very like *P. Satanas*, except in colour, indeed so like, that an uncoloured figure of the one might well serve for that of the other. *P. Chiropotes* is brownish-red; the beard is blackish-brown, arises below the ears, and covers a part of the breast. The eyes are sunk and large. The tail, like that of *P. Satanas*, is bushy. The claws are bent, except on the thumbs.

SAL-AMMONIAC, a Hydrochlorate of Ammonia, occurring in volcanic regions, as Etna, Vesuvius, and the Sandwich Islands. The sal-ammoniac of commerce is manufactured from animal matter and coal-ash. [AMMONIA, in ARTS AND SC. DIV.] Sal-Ammoniac occurs in white crusts or efflorescences. It crystallises in regular octahedrons, and is soluble in three parts of water. When quick-lime is mixed with it, it gives off a strong smell of ammonia.

SALACIA, a genus of Plants belonging to the natural order *Hippocrateaceæ*, which has been so differently defined by different botanists, that it sometimes includes species found in Asia, Africa, and America. At other times, the American species are referred to the genus *Tonella*, and the African species to the genus *Calypso*, and those of India to the genus *Johnia*, the last named in compliment to Dr. John, a Danish missionary, who was one of the founders of the Botanic Garden at Tranquebar, and sent many new plants to Dr. Roxburgh. The whole are formed of species which have little beauty, but the fruit of both the species of *Johnia* is eatable.

SALAMANDER. [AMPHIBIA.]

SALAMANDRIDÆ. [AMPHIBIA.]

SALANX, a genus of Fishes belonging to the family *Esocidæ*.

SALARIAS, a genus of Indian Fishes belonging to the family *Gobioidæ*. [Gobiæ.]

SALEA. [DRACONINA.]

SALENIA. [ECHINODERMATA.]

SALICACEÆ, Willow-Worts, a natural order of Apetalous Exogenous Plants, possessing the following characters:—Flowers with pistils or stamens alone, growing on the same or different plants, and arranged in the form of an amentum; stamens separate, or united together with 2-celled anthers; a superior ovary, with 1 or 2 cells; numerous erect ovules; style single, with 2 stigmas, or absent; many-seeded, comose, 10-12-celled, coriaceous fruit; seeds comose, and either attached to the lower part of the axis of each valve, or to the base of the cell; albumen absent; embryo erect; radicle inferior. They are trees or shrubs, with simple alternate leaves, and deciduous or persistent stipules. Combined with *Corylaceæ* and *Betulaceæ*, they formed part

of the natural order *Amentaceæ* of Jussieu, but they have been separated by Richard. They are distinguished from *Corylaceæ* by the absence of a calyx, and frequently by the venation of their leaves: from *Betulaceæ* they are known by their hairy seeds and polyspermous 2-valved fruit. They are generally found inhabiting woods in the northern districts of Europe, Asia, and America. The most northern woody plant that is known, the *Salix arctica*, belongs to this order. There are only two genera in this order, *Salix* and *Populus*; but they are of great importance on account of their timber and various economical uses. [SALIX; POPULUS.]

Salix caprea.

a, branch with staminate flowers; b, ditto, with pistillate flowers; c, staminate bract, with abortive pistil; d, pistillate bract, with closed ripened pistil; e, ditto, with valves open; f, seed, with hair; g, section of fruit, showing seeds; h, section of seeds, showing coyledons.

SALICARIA, a genus of Birds belonging to the family *Sylviadæ*, and separated by Mr. Selby from the genera *Locustella* and *Sylvia*. "The rounded form of the tail," says Mr. Yarrell, "the outer feathers being much shorter than those in the middle, and the partiality of these birds to moist situations, particularly conspicuous in the Sedge and the Reed Warblers, appear to separate them from the *Sylvan Warblers*." There are four British species of this genus.

S. locustella, the Grasshopper Warbler, is so called from its very peculiar and almost incessant cricket-like note. It comes to this country from the south, and appears about the middle of April, and departs in September. It is a shy bird, keeping at the bottom of a hedge, and creeping along more like a mouse than a bird. It feeds on small snails, slugs, and insects.

S. phragmites, the Sedge-Warbler, Sedge-Bird, is found during the summer in thick patches of reeds or willows, in marshes, or on the low sides of rivers, or on islands. Like the last, it is a summer visitor, arriving in April and leaving in September. White of Selbourne first observed its power of imitating the notes of other birds, as well as of its occasionally singing at night. It measures 4½ inches, and is somewhat a less bird than the last.

S. luscinioides, Savi's Warbler, Willow Locustella. It is a rare bird in this country, but, like the group to which it belongs, it frequents moist and shaded situations, among reeds and bushes, near water.

S. arundinacea, the Reed-Warbler, the Night-Warbler, the Reed-Wren. It is always found in company with the Sedge-Warbler, but is not so numerous in this country as that bird. It arrives here in April and departs in September. It sings usually in the day, but sometimes at night. "The character of the beak, the entire absence of the buffy white stripe over the ear-coverts, and the uniform colour of the whole of the upper surface of the body of this bird, distinguish it from either the Grasshopper-Warbler or the Sedge-Warbler, with both of which however it has many habits in common." [SYLVIADÆ.]

(Yarrell, *History of British Birds*)

SALICINIEÆ. [SALICACEÆ.]

SALICORNARIA. [POLYZOA; CELLARIÆ.]

SALICORNIA (from 'sal,' salt, and 'corni,' a horn, in reference to the taste and form of the plant), a genus of Plants belonging to the natural order *Chenopodiaceæ*. It is characterised by a single turbinate fleshy obscurely-lobed perianth; 10-12-stamens; short style; bi-trifid stigmas; fruit a utricle with a single seed. The species are mostly weeds inhabiting moist salt districts on the coasts of the north of Europe, Africa, and America.

S. herbacea, Jointed Glasswort, is a common plant in the salt marshes

and on the banks of salt rivers in Great Britain. It is known by its herbaceous stem, compressed and notched articulations, somewhat thickened upwards, and cylindrical spikes slightly tapering at the extremities. This and many other species belonging to the genus, and to the other genera of the same natural family, yield a great quantity of soda, for the purpose of obtaining which they are collected on the coasts of the South of Europe and the North of Africa. This species is often eaten as a salad or pickle under the name of Samphire, but is a different plant from the true Samphire. [CRITHMUM.]

S. radicans has a creeping stem, and is considered by some botanists a variety of the last.

S. fruticosa, Shrubby-Jointed Glasswort, is a doubtful native of Great Britain, but grows largely in the south of Europe and in North America, and is used for the same purposes as the above.

SALIFEROUS SYSTEM. [RED-SANDSTONE.]

TALISBURIA, a genus of Plants belonging to the natural order *Taxacee*, named in honour of R. A. Salisbury, a modern botanist of distinction. The tree, which is the only one of the genus, has long been known by the Japanese name Ginkgo. The genus is characterised by having monœcious flowers. The male flowers disposed in a filiform naked catkin, without calyx or corolla; stamens numerous; the anthers composed of 2 cells, which are pendulous, and united only at the apex. Female flowers solitary and terminal; calyx 4-fid, or rather a cup-shaped disc, from the thickened apex of the peduncle, surrounds the base of the solitary ovule; fruit forming a drupe, which has its base supported by a fleshy cup, with a juicy white pulp; seed nut-like, with an osseous shell; kernel white; embryo axillary, dicotyledonous, radicle above.

S. adiantifolia, the Ginkgo, grows naturally in Japan, is much cultivated in China, and is found in many gardens in Europe. Fine old specimens may be seen at Kew and in the Apothecaries' Garden at Chelsea. In congenial climates it attains the size of the walnut. It is remarkable for the form of its leaves, which are wedge- or fan-shaped, deeply cut in the centre or bilobed, and finely striated with veins, having some resemblance to the leaves of some species of *Adiantum*, whence it is commonly called Maiden-Hair Tree in this country. The pulp of the fruit is austere-tasted, but the kernel is sweet, with some degree of bitterness when raw, but agreeable as a dessert when roasted like chestnuts. They are much eaten in China. Dr. Abel says he saw the fruit exposed in the markets in China, but could not find out to what purpose it was applied. [CONIFERÆ.]

SALIVA, SALIVARY GLANDS. The principal glands by which the saliva is secreted are six in number, three being situated on each side of the face, namely, the parotid, the submaxillary, and the sublingual glands. Of these the parotid is considerably the largest, and has been already described. [PAROTID GLAND.] The submaxillary gland, which is next in size, has its principal mass situated immediately behind and beneath the middle of the base of the lower jaw, below the mylohyoid muscle, round the posterior edge of which a portion of it is continued, and leads to the submaxillary or Whartonian duct. The latter passes forwards and inwards, and opens on the surface of the mucous membrane of the mouth, just by the side of the frænum of the tongue. The sublingual gland is the smallest of the chief salivary glands; it is situated close by the duct of the submaxillary, into which several of its ducts open; others have their orifices on the surface of the mucous membrane of the mouth, by the side of the frænum linguae, and further outwards. Besides these larger glands there are a vast number more which secrete saliva, and which are situated in the substance of the lips and cheeks immediately beneath their mucous membrane, on whose surface their ducts open. Indeed the whole interior of the lips and cheeks is lined by a congeries of small glands, which in structure closely resemble the salivary, and probably do not differ from them in function.

The saliva as it exists in the mouth is not only the produce of these glands, but also of the buccal surface of the mouth. When not mixed with air it is a transparent, rather viscid fluid, which is usually weakly alkaline, but during the mastication of food it is often slightly acid. It is composed of a great proportion of water, mixed with portions of the epithelium of the mucous membrane lining the mouth, and holding in solution about seven parts in one thousand of albumen, saline (a principle almost peculiar to itself), and other animal matters, together with the saline substances found in the blood, and a very minute quantity of sulpho-cyanide of potassium.

One of the purposes served by the saliva seems to be the softening of the food, with which it is intimately mixed in mastication. Glands for its formation exist in all classes of animals from the insects upwards (with the exception of fish), and even in many that are lower in the animal kingdom than the insects. The saliva appears also to exert a chemical influence on the starchy parts of food, converting them into sugar. This power is not possessed by the secretion from the glands alone, but resides in the common saliva of the mouth.

The quantity of saliva secreted when the mouth is at rest is only sufficient to keep its internal membrane moist and slippery. When however the jaws are actively moved, and especially during feeding, or even at the thought of a meal or of certain kinds of palatable food, the quantity is greatly increased. During the twenty-four hours it is probable that from sixty to ninety grains of saliva are secreted by one parotid gland (Mitscherlich), and the quantity produced by all the

salivary glands of an adult man together may therefore be estimated at from four to five hundred grains.

(Lehmann, *Physiological Chemistry*, translated by Dr. Day for Cavendish Society.)

SALIX (Latin, 'salix,' a willow), the name of a genus of Plants, which, in conjunction with *Populus*, constitutes the natural order *Salicaceæ*. In many respects this is one of the most important genera of plants: the rapidity of their growth, the toughness and lightness of their wood, and their uses in medicine and the arts, have caused them to be extensively cultivated. But although largely cultivated and well known in most parts of the world, the botanical arrangement of these plants presents considerable difficulties, and few genera have had more time and labour spent upon them than *Salix*; and up to the present time the most able botanists differ as to the real nature of many species or varieties.

The genus *Salix* is known by possessing dioecious flowers; catkins many-flowered, imbricated, composed of a single-flowered flexible bract. The barren flowers have a small lateral abrupt gland, sometimes double; filaments 1, 2, 3, 5, or more, longer than the bract, and in some partly combined; 2-lobed anthers, opening longitudinally. The fertile flowers with a nectariferous gland; ovate, 1-celled, many-seeded ovary; permanent terminal style, with two stigmas, which are notched and obtuse or cloven acute, and spreading; ovate capsula composed of two revolute concave valves and one cell; numerous minute oval seeds, tufted with soft, simple, upright hairs. The willows are chiefly natives of the colder parts of the temperate regions of the northern hemisphere. *S. herbacea* and *S. arctica* are found nearer the pole than any other woody plants. *S. Babylonica* is a native of China, Japan, Armenia, and the north of Africa. Of all the species enumerated, only 17 are extra-European.

The Willow was known to the Greeks and Romans; in fact little has been added to our knowledge of the properties and uses of these plants since their time. On account of the flexible nature of their shoots and the toughness of their woody fire, they have always been used as materials for making baskets, hoops, crates, &c., and for these purposes great quantities are cultivated in this and other countries. The bark is made use of in the north of Europe for the purpose of forming mats in the same manner as the bark of the common linden-tree. In Tartary the woody fibre is macerated and separated, and then spun into threads, from which cloth is woven. Willows are much used in the manufacture of charcoal; and it has been proved that Willow Charcoal is superior to that procured from the wood of most other trees for the preparation of gunpowder. The bark of all the willows contains the tanning principle, and, according to Sir H. Davy, some of the species, especially *S. Russelliana*, *S. alba*, and *S. purpurea*, contain as much as the oak itself. From the bark of some is obtained a vegetable principle called Salicin, which acts upon the system in the same manner as quinine, and is used for the same purposes.

In order that the species of this genus may be studied successfully, a number of points require consideration, and it is only lately that an approach has been made to accuracy in their investigation. The flowers of the *Salix* are subject to many anomalies which have been productive of not a little difficulty, and have sometimes led to the supposition that this genus was an exception to the ordinary laws of vegetable development. The principal anomalies that are found are—1, male and female flowers occurring in the same catkin; 2, stamens apparently changed into pistils; 3, stamens accompanied by an imperfect pistil; 4, entire union of the filaments of the stamens. In the study and description of the species, it is of importance that the tendency to these anomalies should not be overlooked. Another difficulty in the way of the study of this genus is the occurrence of hybrids.

There are at present described nearly 300 species of *Salix*; of all which we shall not here give a description, but arrange the more common species under the heads Sallows, Osiers, and Willows. These terms are often applied to any of the species, but some have more frequently one of the designations than the other.

SALLOWS.

These are trees or low shrubs belonging mostly to Borrer's group *Cinerea*, and are characterised by downy branches, and mostly obovate, gray, hoary, toothed, more or less wrinkled, and stipuled leaves, very veiny beneath. Ovaries sericeo-tomentose.

S. cinerea, Gray Sallow. Stem erect; lower leaves entire, upper serrated, obovate-lanceolate, glaucous, downy, and reticulated with veins beneath; stipules half-heart shaped, serrated; ovary silky, style short, stigmas mostly entire. It attains a height of 20 or 30 feet, and is abundant in England on banks of rivers and in moist woods.

S. aquatica, Water-Sallow. Stem and branches erect; leaves slightly serrated obovate-elliptical, minutely downy, and rather glaucous beneath; stipules rounded, toothed; ovary silky, stalked, stigmas nearly sessile. This is also a British species, and one which Koch has made a variety of *S. cinerea*. The Olive-Leaved Sallow (*S. oleifolia*) is also referred by Koch to *S. cinerea*.

S. aurita, Round-Eared Sallow. Branches trailing; leaves obovate, somewhat serrate, convex, obtuse with a small hooked point, hairy, and reticulated with veins on both sides; stipules roundish, convex, toothed; ovary silky, stalked, stigmas nearly sessile.

S. caprea, Goat-Willow. Stem erect; leaves roundish-ovate, pointed, serrated, waved, pale, and downy beneath; stipules somewhat crescent-shaped; catkins oval; ovary stalked, ovate, silky; stigmas nearly sessile, undivided; capsule swelling. It is a native of Britain, and is distinguished early in the spring by putting forth its handsome yellow blossoms before other trees have assumed their foliage. The bark is much used for tanning, and the wood is used for making implements of husbandry. It is also grown for hoop-making, and in medicine the bark is sometimes used as a substitute for cinchona.

OSIERA.

The species of *Salix* called mostly by this name belong to Borrer's group *Viminalis*, which are described as trees of a more or less considerable size with long pliant branches and lanceolate leaves; ovaries nearly sessile, hairy or silky; their styles elongated; their stigmas linear, mostly entire. Any willow however that has long pliant twiggy branches, and is grown on this account, is called an Osier.

S. viminalis, Common Osier. Leaves linear-lanceolate, obscurely crenate, white, and silky beneath; stipules very small, sub-lanceolate; branches straight and twiggy; ovary upon very short stalks, lanceolate; style elongate; stigmas long, linear, mostly entire. This is the species that is used for the various kinds of basket-work, bands, &c., and for this purpose is largely cultivated in this country.

There are two other species, *S. stipularis*, Auricled Osier, and *S. incana*, Hoary Osier, growing on the continent of Europe, which are used for the same purposes as the above.

WILLOWS.

Amongst these we shall include a few species useful in the arts and medicine, belonging to the various groups into which Koch and Borrer have distributed the species of *Salix*.

S. Russelliana, Russell or Bedford Willow. Leaves lanceolate, tapering at each end, serrated throughout, very glabrous; foot-stalks glandular or leafy; ovary tapering, stalked, longer than the bract; style as long as the stigmas. A native of Britain, growing in marshy woods, osier-grounds, &c. This tree was first brought into notice by the Duke of Bedford, and has on that account received its present name. The best history of it is to be found in the introduction to the Duke of Bedford's splendid work on Willows, the '*Salicetum Woburnense*.' It was a tree of this species that was a favourite with Dr. Johnson at Lichfield, and hence called Johnson's Willow. It was destroyed by a hurricane, having attained a height of 60 feet and a girth of 13 feet. The growth of this species is very rapid, and as it may be extensively used for poles, &c., it is a profitable tree for growing in plantations. Its bark is said to contain as much tannin as the oak. The medicinal properties attributed to the bark of *S. fragilis* belong properly to this species. It acts as an astringent and tonic.

S. alba, Common White Willow. Leaves elliptical-lanceolate, pointed, serrated, silky on both sides; lower serratures glandular; stamens hairy; ovary smooth, almost sessile; stigmas deeply cleft; scales notched. It is a native of most countries of Europe, and is more extensively planted as a timber-tree than any other species. It grows rapidly, attaining a height of 30 feet in 10 or 12 years. Hundreds of miles of road between Moscow and the Austrian frontier are planted with this tree. The bark is used in the north of Europe both for tanning and dyeing. The wood is very useful, and is employed for making the handles of all sorts of instruments, in turnery, millwork, cooper, weather-boarding, &c. Willow hats and bonnets are made from the shavings of this willow. The bark may be used in medicine instead of *S. Russelliana*, but it is not so valuable. It is frequently called the Huntingdon Willow, and under that name is recommended by Gilpin and others as an ornamental tree.

S. Babylonica, the Weeping Willow. Leaves lanceolate acuminate, finely serrated, glabrous, glaucous beneath; catkins protruded at the same time with the leaves; ovary ovate, sessile, glabrous. This, the most favourite species of the genus, is a native of Asia, on the banks of the Euphrates near Babylon, whence its name; also of China, of Egypt, and other parts of North Africa. It is said that this willow was introduced into England by the poet Pope, who, being with Lady Suffolk when she received a parcel from Spain bound with withes, which appeared alive, took one, and planted it in his garden, which grew up, and afterwards became so well known as Pope's Willow at Twickenham. It is however more probable that it was introduced by the botanist Tournefort into Europe. This tree is increasingly cultivated in this country and on the Continent. It is one of the greatest favourites in China, as might be inferred from its constant introduction into Chinese pictures. Growing on the banks of its native Euphrates, it was the willow on which the weeping daughters of Zion "hung their harps." (Psalms, cxxvii.)

S. pentandra, Sweet Bay-Leaved Willow, is one of the latest flowering willows, not expanding its flowers till the beginning of June, which are very fragrant.

S. purpurea, Purple Willow, is a small decumbent shrub; a native of Britain. Of all the willows it possesses the largest amount of bitter principle in its bark, and on this account has been recommended for medicinal use.

S. vitellina, the Yellow Willow. It is a native of Great Britain in hedges, osier-grounds, and other places.

Bahington, in his 'Manual of British Botany,' describes 33 species of *Salix*. Hooker and Arnott, in the 'British Flora,' describe 37 species. In addition to these two works the student should consult Koch, 'De Salicibus Europæis Commentatio,' and Loudon's 'Arboretum et Fruticetum Britannicum.'

SALLOWS. [SALIX.]

SALMON. [SALMONIDÆ.]

SALMONIDÆ, *Salmon Tribe*, a family of Fishes belonging to the *Malacopterygii Abdominales*. These fishes have the body covered with scales, the first dorsal fin has soft rays only, and the second dorsal is small and destitute of rays, and of a soft fleshy nature; they are furnished with an air-bladder, and have numerous cæca. The more typical species appear to be confined to the northern hemisphere.

The genus *Salmo*, as at present restricted, contains those species, such as the Salmon and Trout, in which the upper boundary of the mouth is formed chiefly by the superior maxillary bones, the intermaxillaries being small, confined to the fore-part, and situated between the maxillaries; usually these latter bones descend in front of the superior maxillaries, and form the upper boundary of the mouth. The maxillary bones, intermaxillaries, palatines, vomer, and even the tongue, are furnished with teeth; the branchiostegous rays are absent ten in number; the natatory bladder, or air-bladder, extends the whole length of the abdomen.

Numerous species of this genus are found in the seas of the northern hemisphere, one of the largest of which is the Common Salmon (*S. salar*, Linn.), a fish too well known both in flavour and appearance to require any particular description. This fish, Cuvier states, is found in all the arctic seas, whence it enters the rivers in the spring. Mr. Yarrell observes that fishes ascend the rivers in some situations much earlier than others, depending on the time of their being in a breeding condition. "Rivers issuing from large lakes afford early salmon, the waters having been purified by deposition in the lakes; on the other hand, rivers swollen by melting snows in the spring months are later in their season of producing fish, and yield their supply when the lake rivers are beginning to fail. 'The causes influencing this,' says Sir William Jardine, 'seem yet undecided; and where the time varies much in the neighbouring rivers of the same district, they are of less easy solution. The northern rivers, with little exception, are however the earliest, a fact well known in the London markets; and going still farther north, the range of the season and of spawning may be influenced by the latitude.'" Artedi says, in Sweden the salmon spawn in the middle of summer. From some further observations in Mr. Yarrell's excellent work, it appears that the temperature of the water has considerable influence.

The number of fishes procured for food increases as the summer advances. "During the early part of the season the salmon appear to ascend only as far as the river is influenced by the tide, advancing with the flood, and generally retiring with the ebb, if their progress be not stopped by the various means employed to catch them. It is observed that the female fishes ascend before the males; and the young fish of the year, called grilse till they have spawned once, ascend earlier than those of more adult age. As the season advances, the salmon ascend higher up the river, beyond the influence of the tide; they are observed to be getting full of roe, and more or less out of condition, according to their forward state as breeding fish. Their progress forwards is not easily stopped; they shoot up rapids with the velocity of arrows, and make wonderful efforts to surmount cascades and other impediments by leaping, frequently clearing an elevation of eight or ten feet, and, gaining the water above, pursue their course. If they fail in their attempt and fall back into the stream, it is only to remain a short time quiescent, and thus recruit their strength to enable them to make new efforts.

"The fish having at length gained the upper and shallow pools of the river, preparatory to the important operation of depositing the spawn in the gravelly beds, its colour will be found to have undergone considerable alteration during the residence in fresh water. The male becomes marked in the cheeks with orange-coloured stripes, which give it the appearance of the cheek of a *Labrus*; the lower jaw elongates, and a cartilaginous projection turns upwards from the point, which, when the jaws are closed, occupies a deep cavity between the intermaxillary bones of the upper jaw; the body partakes of the golden orange tinge, and the salmon in this state is called a red-fish. The females are dark in colour, and are as commonly called black-fish; and by these terms both are designated in those local and precautionary regulations intended for the protection and preservation of the breeding fish."

The process of spawning is thus described in Ellis's 'Memoir on the Natural History of the Salmon':—"A pair of fish are seen to make a furrow, by working up the gravel with their noses, rather against the stream, as a salmon cannot work with his head down stream, for the water, then going into his gills the wrong way, drowns him. When the furrow is made, the male and female retire to a little distance, one to the one side and the other to the other side of the furrow; they then throw themselves on their sides, again come together, and, rubbing against each other, both shed their spawn into the furrow at the same time. This process is not completed at once; it requires from eight to twelve days for them to lay all their spawn, and when they have done they betake themselves to the pools to recruit themselves.

Three pairs have been seen on the spawning-bed at the same time, and even closely watched while making the furrow and laying the spawn.

"The adult fish having spawned, being out of condition and unfit for food, are considered as unclean fish. They are usually called kelts; the male fish is also called a kipper, the female a baggit. With the floods of the end of winter and the commencement of spring they descend the river from pool to pool, and ultimately gain the sea, where they quickly recover their condition, to ascend again in autumn for the same purpose as before, but always remaining for a time in the brackish water of the tideway before making either decided change, obtaining, it has been said, a release from certain parasitic animals, either external or internal, by each seasonal change, those of the salt water being destroyed by contact with the fresh, and vice versa." It is moreover probable that the constitution of the fish is such as to require a gradual change; that the salmon is considerably affected in passing from the salt water into the fresh, is evident from the change of colour which accompanies the difference of the state of the element.

To Mr. John Shaw of Drumlanrig, Dumfriesshire, naturalists are indebted for numerous important and interesting experiments instituted by him to determine certain doubtful points connected with the natural history of the salmon, and more especially to determine the developments and growth of the salmon-fry. Mr. Shaw's first paper, entitled 'An Account of some Experiments and Observations on the Parr, and on the Ova of the Salmon, proving the Parr to be the Young of the Salmon,' will be found in the 'Edinburgh New Philosophical Journal' for July, 1836, vol. xxi. His second paper, in which he gives an account of 'Experiments on the Development and Growth of the Fry of the Salmon, from the Exclusion of the Ovum to the Age of Six Months,' is published in the same work, vol. xxiv., p. 165; and lastly in the 'Transactions of the Royal Society of Edinburgh,' vol. xiv., p. 547, the author gives a summary of the preceding papers, and adds the result of further investigations.

The author, who has lived the whole of his life, with the exception of a few seasons, on the banks of streams where salmon are in the habit of depositing their spawn, had long been of opinion that the fish commonly called the Parr, and supposed to be a distinct species from the salmon, was the natural produce of the salmon; and by a series of very conclusive experiments he has evidently demonstrated the fact, that Parr are young Salmon.

The salmon has been known to attain upwards of 80 lbs. weight, but a salmon of half that size is considered a fine fish: "the largest known, as far as I am aware," observes Mr. Yarrell, "came into the possession of Mr. Groves, the fishmonger of Bond-street, about the season 1821. This salmon, a female, weighed 83 lbs.; was a short fish for the weight, but of very unusual thickness and depth. When cut up, the flesh was fine in colour, and proved of excellent quality."

Salmon have been kept in fresh-water lakes and other pieces of water having no outlet to the sea; these fish however, though of tolerably good colour and flavour, did not obtain the size of those which visited the sea annually. They are caught by nets of various kinds.

The other British species of *Salmo* are:—

S. trutta, the Salmon-Trout, Sea-Trout, or Phinock.

S. fario, the Common Trout, Trout, or River-Trout.

S. ferox, the Great Lake-Trout.

S. leuvenensis, the Lochleven-Trout.

S. salvelinus, the Charr, Case-Charr, Alpine Salmon, Salvelian Charr.

The plan of hatching the ova of the species of trout in boxes before permitting them to live free in their native haunts, has been found very successful.

The following are the other principal genera of the *Salmonidæ*:—

Osmerus.—Of this genus the Common Smelt (*O. eperlanus*) affords a familiar example. The smelts differ from the species of *Salmo* in having two ranges of teeth in each palatine bone, but there are only a few in front of the vomer; they have eight branchiostegous rays; the ventral fin is on a line with the anterior dorsal. They are taken in the sea, and at the mouths of great rivers. Mr. Yarrell, in the supplement to his volumes on 'British Fishes,' describes a new species of the present genus, which he names the Hebridean Smelt (*O. Hebrideus*), a name suggested by the locality in which the specimen was found.

Mallotus, Cuvier.—This genus is founded on a single species, the *Salmo Grandlandicus* of Bloch, a small fish employed as a bait in the cod fisheries: its teeth are dense, like the pile on velvet, in both jaws, as well as the palate and tongue; the branchiostegous rays are eight in number; the body is elongated and covered with small scales; the anterior dorsal and ventrals are situated rather behind the middle of the body; the pectorals are large and rounded, and almost meet beneath.

Thymallus, Cuvier.—Of this genus the Grayling (*T. vulgaris*) is the type. This fish is common in some of our streams, but is a local species; it differs chiefly from the trouts or salmon in having the mouth less deeply cleft, the orifice square, the anterior dorsal very high, and the scales larger.

Coregonus, Cuvier.—Here the teeth are very small, and the species are often edentate; the scales are very large, and the first dorsal is not so long as it is high in front. Numerous species of this genus are found in Europe. The Gwyniad (*C. ferox*, Cuvier) and the Vendace

(*C. Willughii*, Jardine) afford British examples of the genus. "The Gwyniad of Wales," says Mr. Yarrell, "was formerly very numerous in Llyn Tegid (Fair Lake) at Bala, until the year 1803, when pike were put into the lake, which have very much reduced their numbers." It is very numerous in Ulswater and other large lakes in Cumberland.

The Vendace was originally described by Sir William Jardine, in the third volume of the 'Edinburgh Journal of Natural and Geographical Science.' This author considered the fish in question as very closely allied to the *Salmo albus* of Linæus, but the difficulty of determining this point has induced him to apply to it the name of our distinguished naturalist. It is only known to inhabit the locks in the neighbourhood of Lochmaben in Dumfriesshire. *C. Lacepedie*, the Powan; *C. Pollan*, the Pollan, are also British species.

Argentina, Linæus.—But one species (*A. sphyrena*, Linn.) of this genus is known, an inhabitant of the Mediterranean. This fish has the mouth horizontally depressed; the tongue is armed, as in the trouts and smelts, with strong curved teeth; in front of the vomer is a transverse range of little teeth; the branchiostegous rays are six in number; the air-bladder is very thick, and loaded with that silvery substance which is used in colouring artificial pearls.

Crumata, Cuvier.—These are *Salmonidæ* with the same general form and small mouth, as observed in the Graylings, but differ in the number of the branchiostegous rays.

Anastomus of Cuvier differs chiefly from the last in having the lower jaw turned up in front of the upper one, and gibbous, so that the little mouth appears like a vertical slit at the end of the muzzle. The species inhabit the rivers of South America.

The genus *Gasterosteus* of Bloch also has the opening of the mouth directed upwards, but the abdomen is compressed and prominent; the ventrals are very small and far back; the first dorsal fin is situated over the anal, which is long; in the upper jaw are conical teeth, and in the lower the teeth are sharp and denticulated.

The species of the next genus, *Serasalmo*, are remarkable for the short, high, and compressed form of the body, which is furnished with small scales; their teeth are sharp, of a triangular form, and denticulated; there is often an adpressed spine in front of the dorsal fin. They inhabit the rivers of South America. To these may be added the genera *Tetragonopterus* of Artedi, *Chalcus*, *Myletes*, *Hydrocyon*, *Citharinus*, *Saurus*, *Scopelus*, and *Aulopus* of Cuvier, and *Sternopteryx* of Herman.

SALPA. [SALPIDÆ.]

SALPIDÆ, or SALPA'CEA, a family of Animals belonging to the Tunicated division of the *Mollusca*. Lamarck places the genus *Salpa* in his third section of *Tunicata* ('Tuniciers Libres ou Ascidiens'), with the following definition: "Animals disunited, either isolated or assembled in groups, without internal communication, and not forming essentially a common mass." These form his second order of *Tunicata*, with the title above given, and consist of the genera *Salpa*, *Ascidia*, *Bipapillaria*, and *Mammaria*. *Pyrosoma* is arranged under his second section: "Animals floating with their common mass in the bosom of the waters," in his first order ('Tuniciers Réunis ou Botryllaires').

These animals float in the open sea, and are characterised by a transparent elastic external membrane which is elongated and open at both extremities. The muscular fibres of the mantle, or membrane, lining the cartilaginous tissue, are arranged in flattened bands. The mouth and stomach, liver, and heart, are aggregated together into a small mass near the anterior aperture of the tunic; the intestine extends towards the opposite aperture, and terminates freely in the common cavity of the mantle. A narrow pleated riband-shaped band extends across the internal cavity, which is the branchie. The heart communicates with a large vessel at each extremity, one of which is ramified upon the visceral mass, the other upon the branchie and muscular tissues.

Whilst in the water the tunic expands and contracts. At each expansion the sea-water enters by the posterior aperture, and is expelled during contraction by the anterior one, its exit from the former orifice being prevented by a valve. It is the reaction of this jet of water that causes the animal to move along. The currents which thus pass through the animal yield nutrient matter, oxygenate the chylaceous fluid, and carry away from the animal the excretory matters and the ova.

The *Salpæ* are divided into 'aggregate' and 'solitary,' but these are states of the same species. Each solitary *Salpa* has the power of producing from an 'internal stolon' a number of other *Salpæ*, or new individuals (Zooids). They are in fact buds, or germs, and afford an instance of the gemmiparous method of reproduction. Each of these zooids has an organisation resembling its parent, and some of them possess an ovary and ova, and others possess testes and spermatic filaments, but the ova are not fertilised by the spermatic filaments of its own set, but always by another. The result of the fertilisation of an ovum is the production of a solitary *Salpa*, which now produces again aggregated *Salpæ*. This is one of the instances brought forward by Steenstrup in illustration of his views of the alternation of generations. Here the first salp produces aggregated salps which are unlike itself, but the aggregated salps produce solitary salps unlike their parents, but resembling their grand-parents. It is the second generation to which Steenstrup has given the name 'Nurses.'

The following is Rang's arrangement of the *Salpida* :—

Simple *Salpida*.

Genera, *Salpa*, Cuv.; *Timoriensis*, Quoy et Gaim.; *Monophorus*, Quoy et Gaim.; *Phyllirhœ*, Péron et Lesau.

Aggregated *Salpida*.

Genus, *Pyrosoma*, Péron.

Salpa.—M. De Blainville divides the genus into the following sections and subdivisions :—

* Species as it were truncated, without any prolongation going beyond the apertures.

A. Recurved species; the two terminal orifices very much approximated; aggregation (?)

S. polymorpha, Quoy et Gaim.

Salpa polymorpha.

B. Straight species; the orifices distant and terminal; the cartilaginous envelope consisting of three pieces; aggregation linear, oblique, two and two.

S. vaginata. Length two inches. It is a native of the Straits of Sunda.

C. Straight species; the orifices distant; the envelope of a single piece; aggregation circular.

S. pinnata. The body is marked with two dorsal lines, one yellow, the other white, and on each side of the belly is a violet line. There is also a variety with interrupted lateral lines. It is found in the Mediterranean Sea.

** Body pointed at one or both extremities, arising from a prolongation reaching more or less beyond the apertures.

D. A prolongation at the anal extremity only; the aperture of the side very small; aggregation (?). (Genus, *Monophorus*, Quoy et Gaim.) *S. conica*, Quoy et Gaim. ('Voyage de l'Uranie.)

E. A prolongation nearly of the same size at each extremity; mode of aggregation linear, oblique, two and two, or three and three.

1. Prolongation to the left.

S. fusiformis.

Salpa fusiformis.

2. Prolongation to the right.

S. Zonaria. Sheath flesh-colour; zones yellow. A native of the ocean near Antigua.

Salpa Zonaria.

F. A prolongation at each extremity; the anterior much the longest and caudiform; aggregation (?). (Genus, *Timoriensis*, Quoy et Gaim.)

S. Aroloidea.

G. Two prolongations, in the form of horns, at the posterior extremity only; aggregation (?).

S. bicornis. Found in the Straits of Sunda.

H. Three prolongations at the posterior extremity; aggregation (?).

S. tricuspidata.

Pyrosoma.—Animals elongated, fusiform, terminating in a point on one side and obtuse on the other, furnished with two apertures, one external, not terminal, the other internal and terminal, united among themselves towards their base by means of their external envelope, so as to compose numerous and regular rings, which concur to form a long free cylinder, rough with points externally, hollow and manubriated internally, and open at one extremity only. (Rang.)

Cuvier states that this great cylinder swims in the sea, by means of

Salpa firoleidea.

Pyrosoma giganteum; a, a portion magnified.

the combined contractions and dilatations of all the individual animals which compose it. The branchial orifices are pierced near the points, and the anus opens into the interior cavity of the tube. Thus, says Cuvier, one may compare a *Pyrosoma* to a great number of stars of *Botrylli* (*BOTRYLLUS*) strung one after the other, but the whole of which would be moveable.

Mr. George Bennett, in his interesting 'Wanderings in New South Wales,' after some remarks on the luminosity of the ocean says, "On the 8th of June, being then in latitude 30° south, and longitude 27° 5' west, having fine weather and a fresh south easterly trade-wind, and the range of the thermometer being from 78° to 84°, late at night the mate of the watch came and called me to witness a very unusual appearance in the water, which he, on first seeing, considered to be breakers. On arriving upon the deck, this was found to be a very broad and extensive sheet of phosphorescence, extending in a direction from east to west as far as the eye could reach; the luminosity was confined to the range of animals in this shoal, for there was no similar light in any other direction. I immediately cast the towing-net over the stern of the ship as we approached nearer the luminous streak, to ascertain the cause of this extraordinary and so limited a phenomenon. The ship soon cleaved through the brilliant mass, from which, by the disturbance, strong flashes of light were emitted; and the shoal (judging from the time the vessel took in passing through the mass) may have been a mile in breadth; the passage of the vessel through them increased the light around to a far stronger degree, illuminating the ship. On taking in the towing-net it was found half-filled with *Pyrosoma* (*Atlanticum* ?), which shone with a beautiful pale-greenish light, and there were also a few small fish in the net at the same time; after the mass had been passed through, the light was still seen astern until it became invisible in the distance, and the whole of the ocean then became hidden in darkness as before this took place. The scene was as novel as it was beautiful and interesting, more so from having ascertained, by capturing the luminous animals, the cause of the phenomenon." On a second occasion Mr. Bennett took in the towing-net a number of *Pyrosoma Atlanticum*, whilst the sea was phosphorescent.

Preparations of these curious animals will be found in the Museum of the Royal College of Surgeons of England. [TUNICATA; MOLLUSCA.]

SALSIFY. [TRAGOPOGON.]

SALSOLA, a genus of Plants belonging to the natural order *Chenopodiaceæ*, so named from 'salsus,' salt, in consequence of many of the species yielding kelp and barilla. The species are chiefly found on the sea-shore in temperate parts of the world, and also in hot parts of the world where the soil is saline, or there is salt water in the vicinity. The genus is characterised by having perfect flowers; the perianth 5-lobed, persistent, enveloping the fruit with its base, and crowning it with its enlarged scarious limb; stamens 5; styles 2; embryo spiral; herbs or small shrubs, smooth or pubescent; leaves alternate or opposite, roundish, seldom flat; flowers axillary and sessile.

S. Kali, Saltwort, so named from yielding barilla or kali, that is,

alkali, is found on the coasts of Europe, and of many parts of the world, and is one of the species which is burnt for the purpose of yielding kelp and barilla.

S. sativa is a species found on the southern coast of Spain, where some pains are taken to extend both it and the following species by cultivation, for the purpose of yielding barilla when burnt. The crop is cut in September, and laid in small heaps to dry. These heaps are collected and burned, forty or fifty of them, in a hole in the ground.

S. soda is found on the southern coast of Europe, and in the north of Africa.

Merat and Delens conceive that the species which yields the soda of Alicant is a new species, and not yet described, which they propose calling *S. Beril*. Other species are described by Forskål as yielding soda on the coasts of the Red Sea.

S. nudiflora Dr. Roxburgh describes as a native of salt barren lands near the sea in India, where it is gathered for fuel only; but as the taste is strongly saline, it would no doubt yield good fossil alkali; and he gave it as his opinion that this plant, with two Indian species of *Salicornia*, might be made to yield barilla sufficient to make soap and glass for the whole world.

S. Indica is another Indian species, growing in similar localities. The green leaves are eaten by the natives.

SALT. [SODIUM.]

SALTPETRE. [POTASSIUM.]

SALTWORT. [GLAUX; SALSOLA.]

SALVADORA. [SALVADORACEÆ.]

SALVADORACEÆ, a natural order of Monopetalous Exogenous Plants, comprising only one genus, *Salvadora*. It is characterised by possessing a superior ovary, regular flowers, single carpel, single style with a simple stigma, and a 1-celled fruit with a single seed. The position of the genus *Salvadora* has always been doubtful: by one author it has been referred to *Chenopodiaceæ*, although it has a monopetalous corolla; by others it is referred to *Myrsinaceæ*, from which it differs in the position of its stamens and the structure of the ovary and seeds. It is most nearly allied to *Plumbaginaceæ* and *Plantaginaceæ*; with the former it agrees in habit, and with the latter in the number of the parts of the flower, its membranous corolla, and simple style. They are Indian and North African plants, with eatable fruit.

S. Perica, the Mustard-Tree of Scripture, has a succulent fruit with an aromatic smell, and tastes like garden cress. The bark of the root is extremely acrid; bruised and applied to the skin, it soon raises blisters, for which the natives of India often use it. The leaves of *S. Indica* are purgative, and the fruit is said to be eatable.

SALVIA (perhaps from 'salvus,' healthy), a genus of Plants belonging to the natural order *Lamiaceæ*, or *Labiata*. It belongs to the Monopetalous division of Exogenous Plants, and is known by its 2-lipped tubular or campanulate calyx; bilabiate corolla, with the upper lip usually arched; 2 stamens with halved anthers, having a flat dilated connective, which is placed vertically with the anther on the upper end. The species of this genus are well known both as ornamental shrubs and on account of their uses in domestic economy. The best known, and that which is used most frequently in this country, is the *Salvia officinalis*, the Garden Sage. It is a native of various parts of the South of Europe. It is a low straggling shrub, with erect branches, hoary with down, leafy at the base; entire, stalked, oblong, narrowed at the base or rounded leaves; nearly simple racemes; many-flowered distinct whorls; campanulate coloured membranous calyx; corolla two or three times as long as the calyx, with a large projecting tube ringed inside; the lips erect, the upper lip straight, the lateral lobes of the lower one reflexed. This plant is much used in cookery, and is supposed to assist the stomach in digesting fat and luscious foods. Sage-tea is also commended as a stomachic and slight stimulant.

S. pomifera, Apple-Bearing Sage. Leaves crenate, hoary, articulated with veins, lanceolate; heart-shaped at the base; calyx 3-lobed, bluntish. It is a native of rough open hills in Crete and various parts of the Levant. It is remarkable for being liable to the attacks of an insect of the *Cynips* genus, which produces upon their branches little protuberances similar to galls upon the oak, but much larger. These morbid growths contain an acid aromatic juice, and on this account are valued by the inhabitants of Crete as an article of diet.

S. sclarea, Common Clary. Leaves oblong, heart-shaped, rugged, villous, doubly crenate; bractæ coloured, concave, longer than the calyx. This plant is a native of Italy, Syria, and Bithynia, and is one of the longest known of the exotic herbs found in British gardens. It is sometimes used for making wine, which has a taste resembling that of Frontignac, and is remarkable for its narcotic qualities.

S. splendens, *S. Indica*, *S. formosa*, and *S. fulgens*, are all handsome ornamental flowers, and as such are much cultivated.

S. pratensis, Meadow Clary, and *S. verbenacca*, Wild English Clary, are natives of Great Britain.

SALVINIA'CEÆ. [MARSIACEÆ.]

SAMADE'RA, a genus of Plants belonging to the natural order *Samarubaceæ*, which was named by Gärtner, though the origin of the name is unknown. The genus, though containing but few species, includes *Vitmannia* of Vahl and *Niota* of Lamarck. The genus is characterised by having bisexual flowers; calyx 4-5-partite; petals 4-5, much longer than the calyx; stamens 8-10; ovaries 5-seeded, on

a short stalk-like gynophore; styles as many. Fruit of one or more carpels, usually drupaceous. The genus is composed of trees or shrubs, with simple alternate and reticulately-veined leaves. Peduncles are axillary or terminal, pendulous when in fruit, and divided at the apex into a 5-12-flowered umbel. *S. tetrapetala* is a shrub, 10 feet in height, a native of Madagascar. *S. lucida* (*Niota lucida*) is another shrub, figured by Dr. Wallich ('Pl. As. Rar.,' t. 168), from Amherst, on the coast of Martaban. *S. Indica* (*S. pentapetala* of authors) is a large tree, a native of Southern India, especially on the Malabar coast; the fruit and bark are intensely bitter, like that of the other plants of the Quassia family. Niepa Bark, an Indian febrifuge, is obtained from this species.

SAMARSKITE. [URANIUM.]

SAMBU'CUS (from *σαμβύκη*, a musical instrument), a genus of Plants belonging to the natural order *Caprifoliaceæ*. It is known by possessing a 5-cleft calyx; rotate urceolate 5-cleft corolla; 5 stamens; 3 sessile stigmas; a roundish pulpy 1-celled berry hardly crowned by the remains of the calyx, with 3 or 4 seeds. The species are low deciduous trees inhabiting Europe and North America. The best known of the species is the Common or Black Elder (*S. nigra*). It is a small tree or large bush; the stem is irregularly, but always oppositely, branched; the young branches are clothed with a smooth gray bark, and filled with a light spongy pith; the leaflets are deep green and smooth, usually with an odd one; the inflorescence is a cyme composed of numerous cream-coloured flowers, with a sweetish but faint and heavy smell; fruit a globular purplish-black berry, with reddish stalks. This plant is a native of Europe, the north of Africa, and the colder parts of Asia. It is very common in most parts of Great Britain, and is generally found near human habitations. Considerable medicinal value has at all times been popularly attributed to this plant, and it is only recently that it has fallen into comparative disuse amongst medical practitioners. In the rural districts of England a wine is made from the berries, which is in great repute, and when drunk hot is an agreeable stimulant. The flowers are employed for making a distilled water, which is frequently used as a refrigerant, and on account of its agreeable odour is introduced into many articles of confectionery. The pith, on account of its solidity and great lightness, is used for making small figures and balls for electrical experiments. The undeveloped buds, when pickled, form a good substitute for capers.

S. Ebulus, the Dwarf Elder or Danewort, is distinguished by its cymes with three principal branches, lanceolate leaves, foliaceous stipules, and herbaceous stem. It is not an uncommon plant in England and Scotland in waysides and waste places. It has a very fetid smell, and the roots are violently purgative.

S. Canadensis, the Canadian Elder. Cymes with 5 principal branches; leaflets 4 pairs and an odd one, oblong, oval, acuminate more or less, pubescent beneath. The flowers are nearly scentless. It is a native of North America throughout Canada to the Carolinas.

S. racemosa, the Red-Berried Elder. Leaflets 5, membranous, oblong, acuminate, serrated, unequal at the base; petioles glabrous; flowers of a whitish-green colour. It is a native of the south of Europe and Siberia. It is a showy plant, and has a splendid appearance when covered with its fine large scarlet fruit. Many other species of this genus are worth cultivation, on account of their flowers, fruit, and foliage. Amongst these, *S. laciniata*, the Parsley-Leaved Elder, and *S. pubens*, the Downy Elder, may be mentioned.

SAMOLUS, a genus of Plants belonging to the natural order *Primulaceæ*. It has a 5-parted calyx, its tube adhering to the lower half of the germen; the corolla is salver-shaped, with a short tube and a 5-parted limb with interposed converging scales; the stamens, 5 in number, are inserted near to the base of the tube of the corolla; the capsules half covered by the persistent calyx, many-seeded, and opening with reflexed teeth.

S. valerandi, the Brook-Weed, or Water-Pimpernel, has obovate or roundish-blunt leaves; the upper leaves blunt with a point; the racemes many-flowered, ultimately elongated; the capsules subglobose. It is found in damp watery places in Great Britain.

(Lindley, *Vegetable Kingdom*; Buruett, *Outlines of Botany*; Babington, *Manual of British Botany*.)

SAMP'HIRE. [CRITHMUM.]

SAMY'DA, a genus of Plants belonging to the natural order *Samydaceæ*. The genus having all the characters of the family to which it belongs, is distinguished by possessing 10-12 stamens, all of which bear anthers, while the stigma is globose. The species consist of small trees or shrubs, found in the hot parts of America, such as the West Indies, Mexico, and Brazil, with a few doubtful species in the East Indies. The branches are sometimes thorny; the leaves alternate, entire, or serrate, with pellucid dots and twin stipules; flower-stalks axillary, single-flowered, solitary or fasciated with white but sometimes purple flowers.

SAMYDA'CEÆ, *Samyde*, a natural order of Apetalous Plants, of uncertain station, and placed by De Candolle amongst Polypetalous Exogens. They have 3, 5, or 7 sepals more or less cohering at the base; stamens perigynous, two, three, or four times as numerous as the sepals, with monadelphous filaments; superior 1-celled ovary; indefinite ovules attached to parietal placenta; capsules with 3-5 valves; numerous seeds fixed to the valves; fleshy albumen and a radicle pointing away from the hilum. The leaves are alternate with

the stipules, marked with round and linear pellucid dots. The apetalous flowers and fruit of this order approximate it to *Bixaceæ*, and its perigynous stamens and alternate stipulate leaves ally it to *Rosaceæ*. It is an entirely tropical order, composed of small trees or shrubs. The bark and leaves are slightly astringent. One of the species (*Cascarilla ulmifolia*) is used in Brazil as a remedy against the bite of snakes, for which purpose the leaves are applied to the wound, and an infusion of them is taken internally. Several other species of *Cascarilla* are used in native medicine.

Samyda serrulata.

a, branch with stipulate leaves and flowers; b, flower opened, showing the monadelphous stamens and the pistil; c, anther with its double cell; d, transverse section of ovary, showing seeds attached to five parietal placentae.

SAND. A mass of any comminuted minerals is in popular language called Sand; but the most abundant ingredient in the extensive sands of the deserts, sea-shores, river-banks, and soil, is granular quartz or flint.

Little attention has been paid by geologists to this abundant covering of the earth's surface. Most of the sands which we observe are the ruins of disintegrated rocks—red, white, gray, black, according to the rocks from which they were derived. On examining these rocks themselves, we find them composed of grains of such sand, not crystallised grains, but worn and rounded on their surfaces like small pebbles. The parts of these solid rocks then have once existed as mere loose sand, and we seem to return in a circle to the point of departure. The origin of sand is however seen in volcanic dust and ashes—in the disintegration of granitic, porphyritic, and other pyrogenous rocks; the aggregation of them is easily understood by examining Millstone-Grit, New Red-Sandstone, or the Grès de Fontainebleau; and the disintegration of sandstones is too common a phenomenon in English gothic buildings.

Soil often contains sand, though the subjacent strata be wholly calcareous or finely argillaceous. This is a phenomenon of the same order as the accumulation of detritus (boulders, gravel, clay, &c.) in situations far from the native place of such materials. It proves that the surface has been traversed by currents of water; and there can be little doubt in the mind of an observing agriculturist, that these washings of the earth's surface, by mixing materials of different qualities, have been in many cases the cause of the fertility of soils.

Some sands impregnated with oxide of iron (and thus often blackened or rendered ochraceous), and others which are nearly white, are very sterile; others of a gray or green brown, or redder hue, are often fertile. The latter almost always contain argillaceous ingredients (often a proportion of felspar), and probably it is in a great degree to the presence of potash in the felspar or the clay that their superiority is owing. [MANURE, in ARTS AND SC. DIV.]

SAND-BOX-TREE. [HURA.]

SAND-EEL. [AMMODYTES.]

SAND-GROUSE. [TETRAONIDÆ.]

SAND-LANCE. [AMMODYTES.]

SAND-MARTIN. [HIRUNDINIDÆ.]

SAND-PIPER. [CHARADRIADÆ.]

SAND-PRIDE. [PETROMYZIDÆ.]

SAND-SMILT. [MUCILINÆ.]

SAND-STAR. [OPHURA.]

SAND-TUBES. [FULGURITES.]

SANDAL-WOOD. [SANTALUM.]

SANDAL-WOOD, RED. [PTEROCARPUS.]

SANDARAC. [TRUJA.]

SANDERLING. [CALIDRIS.]

SANDORICUM, a genus of Plants belonging to the natural order *Meliaceæ*, which is named from a change in one of its eastern names, Suntoor or Sundoor. The genus contains only a single species, found in the hot parts of Asia, and is characterised by having the calyx 5-toothed; petals 5; stamens 10, joined into a tube, which is 10-toothed, and bears the anthers inside; stigmas 5-bifid. The drupe contains 5 ovate compressed nuts, which are 2-valved at the base, and 1-seeded.

S. Indicum, the only species, is an elegant tree of considerable size which is found in the Molucca and Philippine Islands, as well as in the southern parts of India. The leaves are alternate and trifoliate; leaflets entire; panicles axillary, with the flowers crowded on the short partial peduncles. The fruit is acid, and sufficiently agreeable to be mixed with syrups to make cooling drinks. Its root is bitter, and used in medicine in bowel complaints. It is sometimes called False Mangosteen, from some resemblance to its fruit, and also Indian Sandal-Wood.

SANDSTONE, OLD RED. [OLD RED-SANDSTONE.]

SANDSTONE, RED. [RED-SANDSTONE.]

SANGUINOLARIA. [PYLORIDIA.]

SANGUISORBA, the name of a genus of Plants, the type of the sub-order *Sanguisorbeæ*, in the natural order *Rosaceæ*. Of this genus (called Burnet) there are 9 known species. Most of them possess astringent properties. The Common Burnet (*S. officinalis*) is a native of Great Britain, and was at one time cultivated in chalky districts to a very considerable extent, but it has lately been superseded by sainfoin and other artificial grasses. It has a stem one or two feet high, branching upward; leaves pinnate; leaflets ovate, somewhat cordate at the base. Heads of flowers much crowded, dark purple; limb of the perianth in 4 ovate segments, its tube enveloping the germen, and having at its base 4 ciliated scales or bracteas; achene 1, rarely 2.

SANGUISORBACEÆ, *Sanguisorbeæ*, a natural order of Plants in Lindley's 'Vegetable Kingdom.' It constitutes an apetalous sub-order in the order *Rosaceæ* of most other botanists. [ROSACEÆ.]

SANGUISUGA. [ANNELIDA.]

SANICULA, a genus of Plants belonging to the natural order *Umbelliferae* and the tribe *Saniculeæ*. The calyx has 5 leaf-like teeth; the petals erect, obovate, with a long inflexed connivent point. Fruit sub-globose, covered with hooked spines; no ridges; vittæ numerous.

S. Europæa, the Wood-Sanich, is a native of Great Britain, in woods and thickets. The lower leaves are palmate, 3-5-lobed; lobes bifid, unequally serrate. The fertile flowers are sessile; barren flowers slightly stalked.

(Babington, *Manual of British Botany*.)

SANSEVIERA, a genus of Plants belonging to the natural order *Liliaceæ*, found on the coasts of Western Africa, of Ceylon and other eastern islands, as well as of India, remarkable for the strength and fineness of the fibres of their leaves. The genus is characterised by having a corol-like funnel-shaped perianth, which has a long rather straight tube, a sexifid limb, of which the divisions are either spreading or revolute. Stamens 6, inserted into the throat; filaments filiform; ovary 3-celled; ovules solitary; style filiform; stigmas obtuse, obscurely 3-lobed. Berry 3-celled, 3-seeded, or, from becoming abortive, 1-celled and single-seeded. The plants have a thick creeping root-stock, with radical equitant leaves, which are fleshy and often spotted; the stem-leaves are scale-like, and the flowers in racemes or thyrsi. They are easily cultivated and propagated in sandy loam in bark stoves.

S. Zeylanica, a species found in Ceylon, has smooth oblong-acute, flat, and linear-lanceolate, channeled, glaucous leaves, which are shorter than the scape; the style as long as the stamens, the bracts equalling the peduncle in length. This, like some of the other species, is remarkable for the tenacity and fineness of the fibres of its leaves.

S. Roxburghiana is a species, according to Mr. Haworth, which was confounded with the former by Dr. Roxburgh, and which the latter has figured in his 'Coromandel Plants.' It has linear ensiform leaves, which are channelled, keeled, subulate at the apex, green, and longer than the scape; style as long as the stamens; the bracts minute. Dr. Roxburgh describes this plant, and says it is called Moorva in Sanscrit, and in Bengalee Moorba, that in English it may be called Bow-String Hemp, and that it grows very commonly under bushes in the jungles in almost every soil in the southern parts of India. It flowers from January to May. In a good soil, and where the plants are regularly watered, the leaves become three or four feet long, and contain a number of fine remarkably strong white fibres, which run their whole length. The natives make their best bow-strings of these fibres, which are separated by the leaves being placed upon a flat strong table, when one end is pressed down with the foot, and the rest scraped with a piece of hard wood held in both hands. Forty pounds of leaves thus scraped yield about one pound of clean dry fibres.

The fibres may be applied to a great variety of uses. Dr. Roxburgh was inclined to think that the fine line called China grass is made of these fibres. As the plant grows readily from the slips which issue in great abundance from the roots, and as they require little or no care, Dr. Roxburgh recommended their cultivation in sandy soils. It has

lately been proposed in Calcutta to try the fibre on a large scale for rope-making.

S. lanuginosa is a third species, found on the sands of Malabar, while *S. Guineensis* is a species found along a great extent of the west coast of Africa, and which, from affording fibres which, like those of the Indian species, are fine and strong, has been called African Bow-String Hemp. This has been proposed as a substitute for and considered even superior to New Zealand flax. *S. Guineensis* is distinguished by having uniform lanceolate leaves, the style twice as long as the stamens; the bracts only a third of the length of the tube of the corolla; the flowers sessile.

SANTALACEÆ, a natural order of Plants belonging to the class of Exogens and sub-class *Incomplete*. They are trees, shrubs, or herbaceous plants, with round or irregularly-angled branches; alternate or nearly-opposite undivided leaves, sometimes minute, and resembling stipules. The flowers are small, in spikes, racemes, umbels, or solitary. The calyx superior, 4- or 5-cleft. Stamens 4 or 5, opposite the segments of the calyx. Ovary 1-celled, with from 1 to 4 ovules. Fruit 1-seeded, hard, dry, and drupaceous. Alhumen fleshy. This order is closely allied to *Loranthaceæ* and *Aristolochiaceæ*. One of its most remarkable characters is that its unilocular ovary contains always more ovules than one, which are pendulous and attached to the apex of a central receptacle. In the form of weeds the genera of *Santalaceæ* are found in Europe and North America; in Australia, the East Indies, and the South Sea Islands, they exist as large shrubs or small trees.

Osyris belongs to this order, although it differs in having dioecious flowers and a trifid calyx. This is however a different plant from the *Osyris* of Pliny, which possessed in former times a reputation for curing every disease. The modern genus possesses no sensible properties as a medicine, and is principally employed for the manufacture of hesoms, for which its long slender branches well fit it. The Ogehee Lime, which is used on the Mississippi instead of olives, is the fruit of *Nyssa candicans*. The *Nyssa* form trees of great beauty, and their wood is white, soft, compact, and light. The most valuable genus in this order is its type, the *Santalum*, of which the species *S. album* forms the true sandal-wood of commerce.

White Sandal-Wood (*Santalum album*).

a, branch with leaves, flowers, and fruit; b, flower with the calyx open, showing the perigynous stamens and their appendages, the inferior ovary, simple style, and lobed stigma; c, transverse section of fruit, with one seed; d, longitudinal section of fruit, with solitary pendulous seed.

SANTALUM, a genus of Plants which gives its name to the natural order *Santalaceæ*, to which it belongs. It has hermaphrodite flowers, the perianth united at the base with the ovary, the limb superior, tubular, and ventricose, quadri-lobed, deciduous; glands four, compressed, inserted into the throat, alternating with the lobes of the limb. Stamens 4, inserted into the throat opposite to the lobes of the limb; filaments awl-shaped, loaded with a pencil of hairs behind; anthers 2-celled; ovary half inferior, 1-celled; ovules 2, antropous pendulous from the apex of a free central placenta; style filiform, simple; stigma obscurely 2-3-lobed; drupe berried, 1-seeded; margined at the apex. Seed inverse. Embryo straight at the apex of a fleshy alhumen. Radicle above.

S. album, or the White Sandal-Wood, is a native of the mountainous parts of the coast of Malabar, and also of Timor and the islands of the Indian Archipelago, as it is probable that the same species extends to great distances. It forms a tree of moderate or rather of small size, but much branched, and in general appearance has been often compared to the myrtle, and in inflorescence to the privet. The leaves are opposite, with short petioles, oblong, entire, smooth, glaucous underneath; length from one and a half to three inches. The inflorescence is in axillary and terminal thyrsi. Flowers numerous, small, straw-coloured when they first expand, but change to a deep ferruginous purple; they are inodorous, as are all the exterior parts of the growing plant even when bruised. The tree when felled is about nine inches or a foot in diameter; it is then harked, cut into billets, and said to be hurried in a dry place for about a couple of months. The deeper the colour and the nearer the root, the more fragrant it is. As seen in commerce it is in compact pieces of a white colour and agreeable odour, but with little taste. It is usually described as being the young and outer wood, and that the inner parts, as they become older, become coloured towards the centre, and that this is the source of the yellow, while the white sandal-wood consists of the outer and younger wood of the same tree.

This is the general opinion respecting the origin of yellow sandal-wood, but Garcias thought it in his time to be the produce of a different tree. M. Gaudichaud is of the same opinion; and has moreover figured the plant in plate 45 of the botanical part of the 'Voyage de l'Uranie.' This he saw in the Sandwich Islands, and has named it *S. freycinetianum*; stating it to produce the sandal-wood which is so much valued by the Chinese, which they also obtain from the Feejee and Marquesa Islands, Moluccas, &c. They manufacture various articles with the yellow sandal-wood, which is the most fragrant. They also burn it both in their temples and private houses as an incense, and especially in the form of long slender candles, which are formed by covering the ends of sticks with the sawdust of sandal-wood mixed with rice paste.

S. myrtifolium is another species, or a strongly marked variety of *S. album*, found by Dr. Roxburgh in the mountains of the Rajamundry Circar, and which was figured by him in plate 2 of his 'Coromandel Plants;' it is distinguished by its opposite lanceolate leaves. The wood is of little value, according to Dr. Roxburgh, but Dr. Wallich says it is 'certe odoratissimum.'

About 200 tons are annually imported into Calcutta from the Malabar coast, and about twice as much into Canton from the islands of the Indian Archipelago.

SAP, in vegetable physiology, is the fluid which plants imbibed from the soil in which they are placed, and is the great source from which they are nourished, and their various peculiar secretions produced. One of the most important conditions of the growth of plants is, that they may be placed in circumstances to absorb from the soil those constituents of which their sap is composed. The constituents of sap may be divided into those which are essential, or necessary for the growth of all plants, and those which are special, or necessary only for the growth of particular plants or families of plants. The elementary bodies which form the essential constituents of sap are carbon, oxygen, hydrogen, and nitrogen. These bodies are capable of uniting with each other and forming a great number of secondary combinations, and are seldom, if ever, absorbed in a pure state by plants. The forms in which they enter the plant and constitute its essential ingredients are those of water, carbonic acid, and ammonia. Water is one of the most universally necessary constituents of organic beings, and exercises a double function in relation to their nutrition. In the first place it enters largely into their composition, and in the second place it is the medium by which the various compounds are carried into the system of both plants and animals.

Many water-plants are almost entirely composed of water, and there are none that do not contain this substance, in large quantities, as is seen in the diminution of their weight by drying. Plants however throw off larger quantities of water than they retain, and this is necessary to the supply of the organic and inorganic elements of which they are composed, and which are found present in the sap. In a series of experiments performed by Mr. Laws, in which he carefully weighed the quantity of water supplied to certain plants, and afterwards the quantity of organic and inorganic matters they possessed, he found that for every 200 grains of water absorbed and exhaled, one grain of organic matter was appropriated by the plant, and for every 2000 grains of water consumed, one grain of inorganic matter was appropriated. Water is supplied to plants both in the form of rain and vapour, but Schleiden has pointed out in opposition to the commonly received views on this subject, that by far the largest quantity of water supplied to plants is due to the latter source.

"The complete independence of vegetation of the atmospheric precipitation of rain in a liquid form is seen in the vegetation of the Oases, and of the cloudless coasts of Chili and Peru (see Darwin and Loudon), and in a small way in the experiments of Ward. The sand of the Sahara produces no vegetation, not because no rain falls upon it, but because it has not the power of condensing aqueous vapour. Of the water which falls as rain, very little is used directly by the plant; the greatest part runs off or is evaporated into the atmosphere whilst another part sinks into the earth and feeds the

springs. There are but few observations upon the quantity of water needed by plants, but the facts supplied by Hales and Schübler show that rain, after making allowances for that which flows away and is evaporated, does not supply more than a tenth part of what is necessary. It is unaccountable and inexcusable that not a single botanist, since the time of Hales, should have taken up and carried on his experiments. If we take the previous calculations of the quantity of water required by plants in England, which is deduced from Hales's experiments, and which agree with those of Schübler on *Poa annua*, we shall obtain the following approximative results:—According to Schübler, there falls in England upon the acre of 40,000 square feet, at the utmost 1,600,000 lbs. of water during 120 days of summer. According to the researches of Dalton, Müller, Berghaus, and Dausse, at least a third part of this water flows away into the rivers, but it is probably more than this, as the great rapidity of the flow of the water in steep, hilly, and mountainous regions is not sufficiently taken into consideration. A considerable but not accurately to be estimated quantity of water evaporates immediately after the fall of rain, as the vaporous state of the atmosphere indicates. From this it would appear that at the most there is left disposable for plants and future evaporation 800,000 lbs. of water on the acre. Now this quantity of water, according to the preceding experiments, would not cover more than two-thirds of the demand of an acre of cabbages, half of the demand of an acre of sunflowers, or of the Jerusalem Artichoke (*Helianthus tuberosus*), the fourth of a fruit garden, the fifth of a hop garden, and about the seventh or eighth of a meadow. It must be recollected that here only the water is taken into calculation which is given out from the plants and weeds growing in a meadow, but that which is afforded by the evaporation of the soil itself cannot amount to less than 2,000,000 lbs. for an acre. Thus much is very evident from these calculations, that the quantity of rain that falls upon the earth is no more a measure of the quantity needed or consumed by the plant, than is the quantity of humus, an index to the fertility of the soil. We may learn from this that the quantity of rain which falls in a given region is not a measure of its fruitfulness, but the quantity of moisture, the absolute and relative quantity of vapour, which yearly, and especially during those months which are most important for vegetation, is contained in the atmosphere." (Schleiden, 'Principles of Scientific Botany.')

Carbonic acid gas supplies plants with the carbon of their tissues. At one time it was supposed that the carbon of plants was supplied directly from the soil, by the agency of a substance called Humus. There are many facts in nature which show that this is impossible, for there are districts of the earth's surface which are constantly yielding carbon in the vegetable and animal products which they supply, and to which no humus is added to keep up the loss of carbon. This is the case with the produce of Switzerland, which for centuries has been sent into Europe, and yet no system of manuring is carried on in the agriculture of the Alps. Many districts of England and France are now covered with a fertile vegetation which a few centuries ago were barren sands. Such facts prove that the supply of carbonic acid is from the air and not from the soil. The sources of carbonic acid gas on the surface of the earth are very numerous and constantly operative, and yet this gas does not accumulate in the atmosphere. The only conclusion that can be come to with regard to its disappearance is, that it has been taken up by plants. It has also been proved by direct experiment that plants will not live without a supply of carbonic acid gas, and that they flourish where this gas is present.

The following are the sources of this gas:—

1. The respiration of man and animals. In one year it is calculated that a single human being throws 225 lbs. of carbon into the atmosphere. If this is multiplied by 1,000,000,000, it will give the enormous amount of carbon thrown into the atmosphere every year by man alone, which must at least be doubled for the rest of the animal creation. [RESPIRATION.]

2. Combustion is a vast source of carbonic acid gas. Man needs heat to maintain his own temperature, to cook his food, and to manufacture and move about with. The quantities of carbonic acid thus thrown into the atmosphere must be even greater than that produced by respiration, and at the present day must constitute a very prominent source of supply of food to the vegetable kingdom.

3. All sugar in decomposing ferments, and a large natural supply of carbonic acid is probably thus afforded, but in the manufacture of alcohol by man, the quantity of carbonic acid thus formed must be very considerable. In all vegetable and animal decay carbonic acid is formed, and thus animals and plants are converted into an inorganic substance before their elements are again used in the nutrition of organic beings.

4. Another source of carbonic acid is the interior of the earth. In all volcanic districts the springs come up charged with carbonic acid gas, and this gas is found constantly present in lake, river, and spring water. It is also found that the gases which are discharged from active volcanoes consist principally of carbonic acid gas. This accounts for the destructive effects of the vapours of a volcano, where persons are exposed to their direct action. This purely mineral source of carbonic acid is interesting, as proving that a constant supply of carbon is kept up, not only for sustaining, but for allowing an increase in the vegetable and animal kingdoms from the mineral kingdom alone.

Unless this source was known, it would be difficult to explain from whence the original supplies of carbon came, as we have every reason to believe that plants and animals have been created as individuals or pairs. To take the human race alone there must be 500,000,000 times as much carbon existing in it at the present moment as existed in the bodies of our first parents. Whence the source of this supply, if not from the mineral kingdom?

The sources of the supply of ammonia are the same as those of carbonic acid. The excretions of animals, the combustion of wood and coal, the decomposition of nitrogenous matters, the gases of volcanoes, are all sources of this gas.

The constituents of the sap which are not necessary for the growth of all plants are principally the metallic oxides, which it is well known enter very largely into the composition of some plants. The most common of these are the oxides of potassium, sodium, calcium, and magnesium. These occur in combination with various acids, but the acid is not found to exercise so much influence on the plant as the base. Although any of these oxides when presented in solution would be absorbed by plants, it would be only those adapted to the peculiar habit of the plant that would be appropriated. Thus plants which grow naturally on the sea-shore, and require soda for their growth, will take up potassa when presented to them in combination with soda, but they would reject the potassa by excretion and retain the soda. [ROOT.] The sap therefore which is found in plants varies in composition both from the nature of the soil and the nature of the plant.

From the soil the sap is conveyed by the roots into the plant, and is not long before it undergoes certain changes in its composition, but the nature of these changes, and the period at which they take place, are not well known. It is however a fact that the nearer a tree is tapped to its root, the more fluid is the sap which exudes. The channels through which the sap passes in its upward course are also a subject of difficulty. Various observers have contended for each of the different tissues being the sole conveyor of this fluid, but it is most probable that, with the exception of the spiral vessels, which seem appropriated to the conveyance of air, all the tissues of a plant are engaged in conveying sap. There are some parts which seem to convey more than others, and the younger tissues are always more filled with fluid than the older. Thus, when the trunk of a tree is cut through in spring, sap will be seen to exude from all parts of the cut surface, but in greatest quantities from the alburnum or sapwood, the most recently formed portion of the timber.

By whatever channels the sap pursues its upward course, we find that it undergoes great changes between the period of its absorption from the soil and its ultimate disposition in the secretions of the plant. The most important of these changes is the loss of a large portion of that water which it possessed when first absorbed. This water is got rid of by the process of exhalation, which takes place under the influence of external heat and light. In this way it has been ascertained that a common sunflower, three feet in height, will lose one pound four ounces of water every day; and a common cabbage one pound three ounces. Hales contrived to measure the force with which plants exhaled during the summer, and computed that in some plants it was five times as great as that which impels the blood in the crural artery of a horse. The part of the plant in which this process goes on most rapidly is the leaf, which, from its extensive surface and delicate structure, is well adapted for the performance of the function. For this purpose however the leaf is endowed with especial organs called stomates. The stomates are small openings in the cuticle of the leaf, the number of which varies exceedingly in different leaves, and the process of exhalation bears a direct proportion to their number. Exhalation goes on principally during the day, under the influence of the light of the sun, and almost completely ceases when the sun's rays are withdrawn. It is on this account that plants lose so rapidly their freshness on exposure to the light of the sun, when they have been plucked, or otherwise deprived of the means of obtaining a fresh supply of water. When the sap has arrived at the leaf and lost a certain quantity of water, it has been supposed that the peculiar secretions of the plant are there formed and sent down into the plant. This has been called the 'descent of the sap.' It is somewhat difficult to imagine how these secretions can pass back through so delicate an organ as the petiole, and pass down through bark or stem, even into the roots of the plant. The arguments which have been used for adopting this view are the facts that the peculiar secretions of the plant are not produced till the leaves are developed; that in ringing a tree the largest quantities of secretion is found in the upper and not the lower part of the wound, and that when the leaves are injured no secretions are found. It is answered that all the secretions of plants are formed in the interior of the cells where they are formed, and that their formation depends on the leaves, not because formed in the leaves, but because the leaves by their function of exhalation produce a supply of nutritive materials, which is carried to every part of the plant, and thus there could be no secretions without the leaves. Again, when a plant is ringed or cut, the amount of effusion of sap or juices will depend on physical circumstances, and a greater supply of secreted matter is found in the upper part of a ring, because there is most liquid matter to be effused from the trunk and branches of the tree above, and because of its dependent position.

The cause of the progression of the sap in plants has been a fruitful

source of speculation. Malpighi supposed that it depended on the contraction and dilatation of the air inclosed in the air-vessels. Borelli attributed it to the condensation and rarefaction of the air and fluids of the plant. Du Hamel, who was also supported by Linnaeus, accounted for it by the agency of heat. Hales demonstrated the insufficiency of this principle, but did not adopt one less objectionable. Capillary attraction has long been a favourite theory in explaining these motions, but it is liable to the same objections that all purely physical theories are, with regard to the movements of the fluids in plants and animals. Those hotanists who have referred these movements to a vital agency have not been more happy. Brugmanns, Coulon, Saussure, and others adopted the theory of vegetable irritability. The vessels in which the sap was contained were supposed to be susceptible of the action of stimuli, and when the sap, which acted as a stimulus, was applied to them, the vessels contracted and the sap was propelled. Knight referred the propulsion of sap to contraction and dilatation not of the vessels, but of the medullary plates or rays. It appears really to depend on the physical relations existing between the substance of the cell-wall and the fluids which it has to absorb. [ABSORPTION; ENDOSMOSIS.]

The movements observed in the sap are of two kinds, general and special. The general consist in the strong upward movements that take place in the spring, and which are called the 'ascent of the sap,' and in the diffusion of the secreted matters in a fluid state throughout the whole plant, the appearance of which, in dependent parts of the plant, have led to the notion of a 'descent of the sap.' The special movements are those which occur in the cells of plants, and which have been called cyclosis and rotation. [CYCLOSIS; TISSUES OF PLANTS; SECRETIONS OF PLANTS.]

SAPAJOUS, the name generally given to a group of South American Monkeys, including in its larger sense the Ordinary Sapajous [ATELES; LAOOTHRIX], and the other Sapajous (*Cebus*, Geoff.). These last, which are termed Sajous, have the head round, the thumbs distinct, but scarcely opposeable on the fore hands, and the tail entirely covered with hair, although still prehensile.

The whole of the Sapajous are very active, climb admirably, and are altogether well formed for an arboreal life. The fore-hands suffer by comparison with those of the Old World monkeys, and exhibit a less perfect organisation. The thumb is longer, but is more on a line with the other fingers. The palms both of the fore and hinder extremities are endowed with great sensibility. Small in size and playful in disposition, the Sapajous lead a gregarious merry life, feeding chiefly on fruits and insects. The facial angle is about 60°.

The species are very numerous, and Cuvier truly says, that they are nearly as difficult to characterise as those of the American Howlers. [MYCETES.]

One of the most common species is the Weeper (*Cebus Apella*); but why it should have obtained this dolorous title is not very clear, for when confined it is good tempered, playful, and hardy. The fur is rather rich, inclining to olive, with a golden tinge on the lighter parts; and the face is bordered with a paler circle, varying considerably in shading and breadth, being nearly wanting in some individuals. This species has been known to breed in confinement.

Humboldt describes another species, *C. albifrons*, the Ouavapavi des Cataractes, about the same size as the last, with a grayish-blue face, excepting the pure white orbits and forehead. The colour of the rest of the body is grayish-olive; but the hue is lightest on the back and belly.

It was found living in troops in the forests near the cataracts of the Orinoco. Mild and active, they are often kept by the Indians as playthings, and are very entertaining. Thus Humboldt saw one domesticated worthy at Maypures that caught a pig every morning, and rode him about while he was feeding in the savanna the whole day. Another in the house of a missionary bestrode a cat, which had been brought up with it, and patiently submitted to the rider.

C. fatuellus, the Sajou Cornu of the French, Horned Sapajou of the English, *Simia fatuellus* of Linnaeus, is a variety of the form marked by the extraordinary direction of the hair on the forehead. Colour, in some deep brownish or purplish black; in others, reddish-brown. The skin on the naked parts dark purple. The hair of the forehead stands up like a crescent, or a waterman's cap with the front elevated. When viewed in front it exhibits the appearance of two horns. The tips of these erect hairs and of those on the cheeks are paler. It is a native of French Guyana.

Cebus monachus, the Sai à Grosse Tête of the French, Large-Headed Sapajou of the English, has no frontal tuft like the last. On the contrary the head is covered with short whitish hairs of a shorn appearance. The breast and belly, sides of the cheeks, and all the front yellowish-white. Fore-arms, hinder extremities, and tail black. Irregular patches of black and brown cover the rest of the body.

Fifteen or sixteen species are recorded of this the most numerous group of the American monkeys. They may be considered as representing in that continent the *Guenons* of the Old World, which are also very numerous. [GUENONS.]

The genus *Saguinus* is allied to *Cebus*, and is thus defined by M. Lesson:—Same character as in the Sapajous, excepting that the ears are very large and deformed, and that the tail is covered with short hairs. Body slender. Facial angle, 60 degrees.

Horned Sapajou (*Cebus fatuellus*).

Large-Headed Sapajou (*Cebus monachus*).

Dental Formula:—Incisors, $\frac{4}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{6-6}{6-6} = 36$.

M. Lesson arranges the following species under the genus:—*S. sciureus*, *S. personatus*, *S. lugens*, *S. amictus*, *S. torquatus*, *S. Moloch*, *S. melanocheir*, and *S. infulatus*.

S. sciureus is the *Simia sciurea*, Linu.; *Callithrix sciureus*, Geoff.; Sagoi Saïmiri, and Saïmiré, of the French; Saïmiré of the natives of the Orinoco; and Titi of Humboldt.

Size about that of a squirrel, hardly more than 10 inches in length without the tail, which measures 13 or 14 inches. Body greenish-yellow above, becoming grayish on the thigh and arms; body beneath, nearly white. Feet, legs, and fore-arms reddish-chestnut. Muzzle dark; the rest of the face and ears flesh-coloured. Tail black at the tip. In both extremities the nails of the thumbs are broad; those of the fingers are more claw-like. It inhabits Brazil and Guyana.

This pretty species is often kept by the natives in confinement. One in the Paris Menagerie is described by F. Cuvier as very playful and good-humoured. The tail, when the animal was at rest, was wound round the body or limbs, a position in which it was kept when the little creature slept, which it did in a sitting posture, with the head bent down between the fore legs; but the tail was never used as a support. This is not an uncommon species.

Saimiri (*Saguinus sciureus*).

Cuvier will not allow the Saguins and Saimiris to be classed together, and indeed he separates the Saimiri above described and figured from the Saguins, making the Sakis intervene between the forms. He says that in the Saimiri the tail is depressed, and ceases to be prehensile, and that the head is very flat. He also observes that there is a membranous space in the interorbital partition in the skeleton.

Of the Saguins (*Callithrix*, Geoff.), he says that they have the tail slender, and that their teeth do not project, remarking that they had for a long time been associated with the Saimiris, but that the head of the Saguins is higher, and that their canines are shorter. Such, he observes, are the Saguin à Masque (*Callithrix personata*, Geoff.), and the Saguin en Deuil or La Veuve (*La Viduita*, *Simia lugens*, Humb.).

The first of these, *Callithrix personata* (*Saguinus personatus*) is grayish-yellow, with the head and the four hands black, and a reddish tail. It is a native of Brazil, where it is found between 18° and 21° S. lat., on the banks of rivers.

The second, *Callithrix lugens* (*Saguinus lugens*), has the body of a shining black, with a purplish lustre on some parts: the hair soft and shining. The face has the appearance of a bluish-white square mask, which is surrounded by a narrow margin of a purer tinge, while two stripes of the same colour run from the eyes to the temples. The throat is marked with a band of white, of which colour are the anterior hands on the outside, so that they there resemble a pair of white gloves, to which the natives compare them.

This species, which is the Macava Cabou of the natives, appears to be extremely rare. Humboldt saw only one specimen, and that in the forests bordering the rivers Cassiquiare and Guaviare. It was said to live in pairs; and this opinion was confirmed by the fear and dislike shown by the captive when placed near even some of the most diminutive species of the genus. It was very shy, and was active only when alone. When in the vicinity of persons, though they were occupied in general business, it would remain immovably attentive to all that passed, refusing food even, notwithstanding a long fast. When alone its behaviour was very different. If a bird was introduced, the monkey was instantly roused at the sight of it, darted upon it like a cat, and swallowed it instantly, its whole habit at such moments being that of a carnivorous animal.

SAPAN-WOOD. [*CASALPINIA*.]

SAPHIRINE, a Mineral occurring granular disseminated in *Anthophyllite*. The colour is pale-blue or greenish; streak white. Fracture uneven, conchoidal. Hardness 7·0 to 8·0. Lustre vitreous. Translucent. Specific gravity 3·42. It is found at Akudlek in Greenland. Its analysis by Stromeyer, gives—

Silica	14·50
Alumina	73·11
Magnesia	16·85
Lime	0·38
Oxide of Iron	3·92
Oxide of Manganese	0·53
Water	0·40

SAPINDACEÆ, *Soap-Worts*, a natural order of Plants belonging to the calycose group of Polypetalous Exogens. It consists of trees or shrubs, rarely herbaceous plants, with erect or climbing stems, with alternate often compound leaves, rarely simple, with or without stipules, and often marked with lines or pellucid dots. Their inflorescence is racemose or paniculate, with small white or rose-coloured rarely yellow flowers, which are seldom barren or hermaphrodite. The calyx consists of 4-5 sepals, slightly cohering at the base. The petals are the same in number as the sepals, one being occasionally

abortive. They are in general furnished with a petal-like scale, but are sometimes naked. They have a fleshy glandular disc occasionally occupying the base of the calyx. The stamens are definite, about twice the number of the sepals. The filaments are free or slightly connate, the anthers 2-celled. The ovary 3-celled, rarely 2-4 celled, the cells containing 1-2-3 ovules. Style undivided, or more or less deeply 2- or 3-cleft. The seeds have usually an aril, are without albumen, and have a curved or spirally twisted embryo. They are inhabitants of most parts of the tropics, more especially of South America and India. They are not found in Europe or the United States of America. One genus is found in Australia, *Dodonea*.

This order is closely allied to *Aceraceæ*, from which they only differ in their alternate leaves and petals. The number of their stamens 8, with 5 unequal sepals, point out a relation with *Polygalaceæ*. Their climbing habit and tendency to produce tendrils give them a remote relation to *Vitaceæ*. In this order, although the leaves, branches, and other organs act in a deleterious manner, yet their fruit and seeds are eatable and wholesome. The Litchi and Longan, favourite fruits in China, are produced by the genus *Euphoria*. These fruits are sweet, with a sub-acid flavour, and when dried are sometimes brought to this country. They are considered a great luxury in China, and are sent at a great expense from the provinces of Fokien and Quantong, where they grow, to Peking, for the consumption of the emperor. Several other genera bear fruits which are very delicious, and are eaten in Japan and Brazil. *Sapindus* is remarkable for bearing a pulpy fruit, the outer part of which has been used, on account of its detergent properties, as a soap. [*SAPINDUS*.] Some of the species of this genus also produce eatable fruits. *Paulinia* is another genus which has poisonous properties residing in the leaves and other parts of the plant, whilst the fruits are eatable. The whole of the order partakes more or less of these properties.

*Euphoria longana*.

a, branch with racemose flowers and alternate leaves; b, flower, showing the disc, stamens, petals, &c.; c, transverse section of ovary; d, longitudinal section of flower and fruit, showing divided stigma, erect ovules, disc, petals, and calyx.

SAPINDUS (contracted from *Sapo Indicus*, or Indian Soap), a genus of Plants belonging to the natural order *Sapindaceæ*, which has been so called in consequence of the berries of many of the species being employed for the same purposes as soap. The genus is tropical, containing between 20 and 30 species, which are found in the tropical parts both of the Old and New World. It is characterised by having the calyx 4-5-partite; petals as many as the sepals, a little longer, naked or hairy, or with a scale above the claw; torus or disc occupying the bottom of the calyx; stamens 8 to 10, inserted between the margin of the disc and ovary; ovary 3-, rarely 2-celled; ovule 1, erect at the base of each cell; style with a 3-, rarely 2-lobed stigma; fruit fleshy, 1-2-, rarely 3-lobed, each lobe 1-2-, rarely 3-seeded, with the seeds furnished with an aril.

The species consist of trees having leaves without stipules, with the inflorescence in racemes or terminal panicles. Flowers small, white, or greenish-white. Berries all red and saponaceous, on which account they have been employed for washing woollens and cloths of various kinds in different countries. For instance, in the West Indies and the continent of America, *S. saponaria* yields the so-called soap-berries, and in Java, *S. Rarak*; so in India several species, as *S. acuminatus*, *S. laurifolius*, *S. emarginatus*, and *S. delavayi*, yield berries which are called Reetha, and in their dried state may be bought

in every bazaar, as they are everywhere employed as a substitute for soap. The fleshy part of these berries is viscid, and in drying assumes a shining semi-transparent appearance; when rubbed with water they form a lather like soap. The bark and root have similar properties, and have been employed for the same purpose, as well as medicinally, in the countries where they are indigenous. The berries, which are about the size of cherries, inclose black shining nuts, which used formerly to be much imported and employed as buttons for waistcoats, after having been tipped with gold, silver, or other metal. The kernel of these nuts contains an edible oil, which is sometimes employed for burning. The fruits of *S. Senegalensis* and of *S. esculentus* are eaten, and the wood of some species, as of *S. rubiginosus*, is close-grained and hard, and forms valuable timber.

SAPIUM, a genus of Plants belonging to the natural order *Euphorbiaceae*. The flowers are monocious, the calyx bifid and 3-toothed, the style trifid, and the capsule 3-coccous.

S. aucuparium is a tree 30 feet high, with oblong lanceolate acute serrate leaves, with an intermixture of larger and rounder teeth, coriaceous, shining, and about 6 inches long; the spikes are terminal, lax, thick, green, and about 6 inches long; the male above, the female below; the calyx of both of a dark purple. It is a native of the woods of Carthage.

S. Indicum has alternate stalked leaves somewhat pendulous, broad, lanceolate, serrate, smooth, and of a deep shining green, from 2 to 4 inches long, and broad in proportion; the stipules small and deciduous; the calyx is 3-parted, the divisions somewhat cordate and expanding; the filaments longer than the calyx, the anthers ovate; the female flowers at the base of the catkins often solitary; the capsule or nut is globular, of the size of a nutmeg, 3-celled, 6-valved, thick, and exceedingly hard; the seed is solitary, affixed by the apex, oval, and smooth. The juice of this species, like the former, is highly poisonous.

(Lindley, *Flora Medica*; Burnett, *Outlines of Botany*.)

SAPODILLA. [SAPOTACEÆ.]

SAPOLINE. [BORON.]

SAPONARIA (from the Latin 'sapo,' soap, so called because the bruised leaves are said to produce a lather like soap when agitated in water), a genus of Plants belonging to the natural order *Caryophyllaceae*. It has a 5-toothed calyx naked at the base, 5 clawed petals, 10 stamens, and 2 styles; the capsules are 1-celled, opening at the top with 4 valves; the seeds are globular or reniform.

S. officinalis, Soap-Wort, has fasciculate corymbose flowers, a cylindrical slightly-downy calyx, retuse crowned petals, elliptic lanceolate-ribbed leaves, and an erect stem. It is a native of many parts of Europe by the road-side, and in Britain in meadows by river-sides and under hedges. The flowers are either single or double, of a rose or pink colour, seldom white. The double variety of this plant is esteemed as an ornament to the flower-border, but is found inconvenient, unless planted in pots, from the spreading nature of the roots, which extend under-ground like those of couch.

S. vaccaria has panicle flowers, pyramidal smooth fine-angled calyxes; membranaceous acute bractees; ovate lanceolate sessile leaves. It is a native among corn in many parts of Europe, particularly Germany, Switzerland, and the Levant. It derives its specific name from the idea that it increases the lacteal secretion in cows.

All the species of this genus are very ornamental. *S. ocyroides* is one of the most elegant plants we have in our gardens, and is well adapted for rock-work.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Burnett, *Outlines of Botany*.)

SAPONITE, a Mineral consisting of silica, magnesia, alumina, iron, and potash. It is found at Lizard's Point, Cornwall. When first extracted it may be kneaded like dough. It becomes brittle on drying, and is of a white, yellow, blue, or red colour.

SAPOTACEÆ, or **SAPOTÉÆ**, *Sapotads*, a natural order of Plants belonging to the polycarpous group of Monopetalous Exogens. It consists of trees and shrubs, which abound with a milky juice; the branches are round; the leaves alternate, simple, entire, coriaceous, destitute of stipules, their under sides being covered by a silky or downy pubescence. The flowers are axillary, regular, and united; the calyx is 4-8-cleft, imbricate in aestivation; the corolla is hypogynous, regular, and cleft; the lobes are equal in number to the sepals and alternate with them; the stamens are definite and distinct, some are barren and some fertile, the former being alternate with the sepals, the latter opposite; the ovary is superior, with several cells, in each of which is one erect ovule; style simple; stigma undivided; seeds nut-like, sometimes cohering into a several-celled putamen; embryo large, erect, and inclosed in fleshy albumen.

This family of plants is most nearly allied to that of *Ebenaceæ*, with which it agrees in habit, its monopetalous regular hypogynous corolla, the absence of a hypogynous disc, its several-celled ovary, and definite ovules and stamens. It differs however in the possession of milky juice, soft wood, hermaphrodite flowers, undivided stigma, and 1-seeded ovary with erect ovules. The plants of this family are chiefly natives of India, Africa, and America. Some of the species produce fruits which are much prized as articles of diet. Amongst these is the Sapodilla Plum, or Naseberry, which is the produce of *Achras sapota*. The Star-Apple (*Chrysophyllum*), Marmalade (*Achras mammosa*), the

Medlar of Surinam, and other eatable fruits, are derived from plants belonging to this order. Most of the species yield large quantities of a milky juice, which, unlike the secretions of most laetescens families of plants, may be used for alimentary purposes. The fruit and seeds abound in oil, which is solid like butter, and has a mild pleasant flavour. [BASSIA.] The bark of some species of *Achras* is astringent and tonic, and has been recommended as a substitute for quinine. [ACHRAS.]

Sapodilla Plant (*Achras sapota*).

a, branch with axillary flowers; b, flower, showing the imbricate calyx; c, pistil, with style and simple stigma; d, fruit (sapidilla plum); e, seed; f, embryo.

SAPPARE, a corruption of Sapphire. [KYANITE.]

SAPPHIRE. [ADAMANTINE SPAR; CORUNDUM.]

SAPWOOD. [ALBURNUM.]

SAPY'GIDÆ, a family of Hymenopterous Insects of the section *Fossoreæ*, the species of which are chiefly distinguished by the feet in both sexes being slender, and little or not at all spiny; the antennæ are at least as long as the head and thorax together, and generally increase in thickness towards the extremity.

In the genus *Sapyga* the eyes are deeply emarginate; the antennæ are subclavate, slightly curved outwards at the apex in the males, straight in the females, and inserted in a cavity at the base of the clypeus, with an elevated ridge between them; the superior wings have one marginal cell, which passes beyond the third submarginal, and is acuminate; and four submarginal cells, the second the smallest and receiving the first recurrent nervure, the third receiving the second, and the fourth apical.

The species of this genus are usually of moderate size. The females are said to form holes in the mortar of walls, or in putrescent wood, in which they deposit their eggs with food to supply the larvæ. Latreille supposes them to be parasitic upon some of the wild bees; and Mr. Shuckard observes that he has caught the *S. punctata* (a species found in this country) entering the cells of *Osmia bicornis*. The species just mentioned is from $4\frac{1}{2}$ to $5\frac{1}{2}$ lines in length, and of a black colour, excepting the abdomen, which is red, and has a transverse white spot on each side of the fourth, fifth, and sixth segments—such is the colouring of the female; the male has the body black, with a white spot on each side of the second, third, fourth, and fifth segments.

A second species of this genus, the *S. clavicornis*, is also found in England. Both sexes are black, and have interrupted yellow bands on the abdomen.

The genus *Thynnus*, according to Latreille, also belongs to the present family, and the species are readily distinguished by the antennæ being filiform and the eyes entire, that is, not emarginate, as in *Sapyga*.

Polochrum.—This genus, like *Thynnus*, has the antennæ filiform, but the eyes are emarginate, as in *Sapyga*; the mandibles are tridentate.

SARCINA, a genus of Plants belonging to the family of *Alga*. This microscopic *Alga* was first detected by Professor Goodair of Edinburgh in 1842, in the matter vomited by a patient under his care. It was subsequently observed by Mr. Busk and Mr. Edwin Quekett, and many other observers. It consists of masses of cells which are arranged in a square form. Each of the cells is nucleated, and vary in number from 4 to 64 on each frond.

The species most commonly found is that discovered by Goodair,

and which he called *S. ventriculi*. This species has been referred by Robin, in his 'Histoire Naturelle des Végétaux Parasites,' to a genus which he calls *Merismopodia*.

Although this plant is found most frequently in matters vomited from the stomach of human beings, it is not at all confined to this spot. It has been found in the urine several times, although it may be doubted as to whether it could have been originated in this fluid before it was excreted. A case is recorded by Virchow, in which it was found in human lungs which were in a state of carcinomatous disease. It has also been observed in the stomachs of the lower animals.

In the cases where this plant has been detected in vomited matters, they have always been in a state of fermentation, and the fluid in most instances presents an acid reaction. The *Sarcina* becomes paler by the action of acids and alkalis, but they are not destroyed by these re-agents. They become slightly brown on the addition of iodine.

It does not appear that the presence of *Sarcina* is the cause of disordered states of the system, but they may rather be regarded as the results of disease. *Sarcina* have been detected under circumstances which render it probable that they are not uncommon tenants of the human stomach, and that they may exist in considerable numbers without inconvenience. The treatment of diseases with which they are found associated should therefore be rather directed to the removal of the diseased condition than to the destruction of the *Sarcina*. [ENTOMBYTA.]

(Robin, *Histoire Naturelle des Végétaux Parasites qui croissent sur l'Homme et sur les Animaux Vivants*; Beale, *The Microscope, and its Application to Chemical Medicine*.)

SARCINULA. [MADREPHTYLICÆ.]

SARCOIDEA, a group of *Polypori*, of which the type is the old Linnæan genus *Alcyonium*. [ALCYONIDÆ.]

SARCOLITE. [ANALCIME.]

SARCO'PHILUS (F. Cuvier), a genus of *Marsupialia*, founded on *Dasyurus ursinus*, Auct., *Didelphys ursina*, Harris.

F. Cuvier states that *Sarcophilus* approaches nearer to the *Thylacini* than to the *Dasyuri*, but that it is very different from either. These differences are well pointed out in the last part of his 'Histoire Naturelle des Mammifères,' where a very good figure of the animal is given, and of which the subjoined cuts are copies. [MARSUPIATA.]

Head of *Sarcophilus ursinus*. (F. Cuvier.)

Sarcophilus ursinus. (F. Cuvier.)

SARCORAMPHUS. [CONDOR; VULTURIDÆ.]

SARCOSTEMMA (from *sarx*, flesh, and *stemma*, a crown, in reference to the leaflets of the inner corolla being fleshy), a genus of Plants belonging to the natural order *Asclepiadaceæ*. It has a rotate corolla, a coronet of double stamens; the outer one cup-shaped or annular crenated, the inner one 5-leaved, higher than the outer one, with fleshy segments; the stigma is nearly blunt; the follicles slender and smooth, and the seeds comose. The species of the genus are natives of Australia and the East Indies, as well as of South America.

S. glaucum, Glauco-Leaved *Sarcosteinma*, is a lactescent smooth twining herbaceous plant. The leaves are lanceolate, short-stalked, slightly revolute, membranous, being with the midrib prominent on the under side, which is glaucous; the umbels are many-flowered between the petioles, on very long peduncles; the segments of the calyx lanceolate, ciliated, and acuminate; the corolla white, with a large fleshy annular wavy coronet; the segments of the corolla fringed and spreading.

S. Brownii is a twining glabrous plant, with lanceolate acuminate glabrous leaves, and interpetiolar umbels; the pedicels, calyxes, and corolla downy; the segments of the corolla ovate, bluish, concave, and glabrous inside; the outer corona an entire narrow ring; the leaflets of the inner corona ovate, bluish, and glabrous a little higher than the gynostegium; the lower leaves are large and ovate-oblong, the upper ones becoming gradually narrower with revolute edges, painted with white on the nerves, and greenish-blue on the veins; the calyx is small; the pollen-masses oblong, a little curved, hairy, hanging by short pedicels rising from blackish glands. These plants thrive best in a mixture of peat, sand, and vegetable mould; cuttings of them root readily in sand, if placed in heat without any hand-glass over them. They should have little or no water when in a dormant state, particularly the tuberous-rooted kind.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*.)

SARDONYX. [AGATE; QUARTZ.]

SARGASSUM. [FUCACEÆ.]

SARGUS. [SPANIDÆ.]

SARIGUE. [MARSUPIATA.]

SAROTHAMNUS, a genus of Plants belonging to the natural order *Leguminosæ*. It has a 2-lipped calyx, the upper lip with 2, the lower with 3 teeth; the style is long, curved, thickened upwards, and channelled within; the stigma terminal, capitate, and small; the pod is flat.

S. scoparius, the Common Broom. The only British species is a well-known plant, with a stem 2 or 3 feet high, angular, and glabrous. The leaves are ternate or simple; the leaflets obovate. The flowers are axillary, solitary, or in pairs, shortly stalked, large, and of a bright yellow. The pods are dark brown, hairy at the edges, and have numerous seeds. It is found on dry hills and heaths.

(Babington, *Manual of British Botany*.)

SARRACENIACEÆ, *Sarraceniads*, the Water-Pitcher order, a natural order of Plants, placed by Lindley in the Albuminous group of Polypetalous Exogæus. It consists of herbaceous perennial plants inhabiting bogs, with fibrous roots and radical leaves, with a hollow urn-shaped or pitcher-shaped petiole, at the point of which is articulated the lamina, or blade of the leaf, which covers the petiole like a lid. The flowers are solitary or on scapes, and the petals and sepals are herbaceous; the calyx is composed of 5 persistent sepals, often having a 3-leaved involucre without, imbricate in aestivation; corolla of 5 petals, unguiculate and concave; the stamens are hypogynous and indefinite, filaments short; anthers 2-celled, bursting longitudinally; ovary superior, 5-celled, with a central many-seeded placenta; style single; stigma much dilated, peltate, with 5 angles. Fruit a globose capsule, with 5 lobes, 5 cells, and 5 valves. Seeds very numerous; albumen abundant. The affinities of this order are not very obvious. It is usually placed near *Papaveraceæ*, on account of its dilated stigma, indefinite stamens, and embryo in the midst of a copious albumen. Lindley considers it to be related to *Dioncæa* [DIONCÆA], wherever that genus may be ultimately placed. In the remarkable structure of the leaves this order agrees with *Nepenthaceæ* and *Cephalotaceæ*.

Sarracenia purpurea.

a, entire plant with leaves and flowers; 1, the dilated stigma; b, ovary with columnar style; c, transverse section of fruit, showing seeds attached to parietal placenta; d, seed; e, section of seed, showing the minute embryo and abundant albumen.

There are but 2 genera belonging to this order, of which there are about 6 species, all of them inhabitants of the bogs and swamps of

North America. Of their properties we know but little; they are chiefly interesting on account of their pitcher-like leaves, which are capable of holding water, and are thus said to furnish drink to wild animals in their native forests during periods of drought. The pitchers frequently contain the dead bodies of flies and other insects, which become putrid and produce an unpleasant smell around the plant, but are said to afford to the plant a source of nutrition.

SARSAPARILLA. [SMILAX.]

SASSAFRAS, a genus of Plants belonging to the natural order *Lauraceæ*. This is one of the genera into which the old genus *Laurus* of Linnaeus has been divided by Nees von Esenbeck and other botanists. It is known by its dioecious flowers, 6-parted membranous calyx, with equal segments permanent at the base. The barren flowers have 9 stamens in 3 rows, the 3 inner with double-stalked glands at the base; the anthers linear, 4-celled, with their faces turned inwards. The fertile flowers have sterile stamens, which are fewer than or as many as in the barren flowers. The fruit is succulent, placed on the thick fleshy apex of the peduncle, and seated in the torn unchanged calyx. The leaves are deciduous. Flowers yellow. The species of this genus most known is the *S. officinale*, the Sassafras Laurel, on account of its medicinal virtues. It is an inhabitant of the woods of North America, from Canada to Florida. It is mostly a small tree or bush, but sometimes attains the height of 40 or 50 feet. Its flowers are arranged in naked downy racemes, which open before the leaves appear, and are furnished with subulate deciduous bracts. The leaves are membranous, bright green, smooth above, finely downy beneath, very variable in form, and tapering in a wedge-like manner into the petiole. The fruit is of a bright blue colour, as large as a small cherry, and seated upon red clavate peduncles. In America the Sassafras is divided into two varieties, the red and white. Its great use is for medicinal purposes. It is however employed in America for making bedsteads and other articles of furniture, which are not liable to the attacks of insects, and give out a very agreeable odour.

S. Parthenoxylon is a lofty timber-tree growing in the forests of Sumatra. The bark is rough and brown. Leaves alternate, rather long, petioled, ovate, acute, often acuminate and varying in breadth, about 3 inches long, entire, with somewhat revolute edges, smooth, glaucous beneath; nerves lateral and irregularly alternate. The fruit has a strong balsamic smell, and yields an oil, considered useful in rheumatic affections. An infusion of the root is used in medicine.

SASSOLIN. [BORON.]

SATIN-BIRD. [CORVIDÆ.]

SATURNIA, a genus of Insects belonging to the order *Lepidoptera* and the family *Bombycidae*. The antennæ are fringed in the male; the head is small; the wings are very broad and entire; the palpi and trunk are wanting.

S. Pavonia minor, the Emperor Moth, is one of the handsomest of the British species of Moths. It is about 3 inches wide. The colour is grayish-brown, faintly tinged with purple; the hinder margin of all the wings has a band of pale brown and purple, the hinder band being much waved. The centre of each wing has a large spot or ocellus, which is placed on a light ground; it consists of a black pupil, with a yellow or gray iris, and partly surrounded by a light blue crescent. The larva is of a green colour, having a black band on each segment adorned with pink tubercles, bearing a whorl of six hairs diverging like a star. It constructs a curious cocoon, the extremity not being close, but terminated by a converging circle of very stiff hairs, which enables the insect to make its escape from within, but completely prevents all ingress.

To the genus *Saturnia* some of the largest of the *Lepidoptera* belong. *S. Atlas*, the Giant Atlas Moth, has wings measuring 7 or 8 inches across. This species also, with *S. Cecropia* and *S. Luna*, have their wings produced into a tail. The cocoons of *S. Cynthia* and *S. Mylitta* are used in India for the production of silk. Latreille states that these are the wild species of silk-worm of China. *S. Cynthia* is the Arrindi Silk-Worm of India. (Roxburgh, 'Linn. Trans.', vol. vii.) *S. Prometheus*, a North American species, forms its cocoon within the leaf of a sassafras-tree, having previously fastened the stalk of the leaf to the stem by a strong silken web, whereby it is prevented from falling with the other leaves. (Westwood.)

SAUCE-ALONE. [ERYSIMUM.]

SAURIA (σαῦρος, or σαῦρα, a lizard), the term by which the great family of Lizards is generally designated. The animal forms more strictly included under it are those comprised under the genera *Lacerta* (after deducting the Crocodilians and the Salamanders) and *Draco* of Linnaeus.

To these, Cuvier observes, the family *Anguis* might even be joined, because their osteology, especially that of the head, resembles the osseous structure of many of the Lizards.

In the large acception of the term Saurians, the Pterodactyles, Enaliosaurians, and Crocodiles are included.

The general relations of this order will be found under the article **REPTILES**. We shall here refer to their general structure and organisation, and to their classification.

If we take the living forms collected under the above-mentioned genera of Linnaeus, after eliminating from the genus *Lacerta* the groups above excepted, we shall find that all the animals have a similar

structure of the skull, of the shoulder-blade, and of the os hyoides, or that they exhibit but slight variations in the composition and proportion of the parts, whilst they differ considerably from the Crocodiles and Tortoises, and still more from the Salamanders, as Cuvier, with his usual acuteness, has observed.

With regard to the structure of the os hyoides, Cuvier remarks, that it becomes important in proportion as we approach the Fishes; and he observes that in man it is composed of five parts: namely, a body in the form of a flattened transversal arch; two anterior and very long horns, which proceed to attach themselves to the temporal bone below the meatus auditorius, and of which the upper part is there soldered at a very early period, and takes the name of the styloid process of the temporal bone; whilst the lower part, for a long time simply ligamentous, has below, at the point of junction with the body, an osseous grain (cornu minus); and, finally, two posterior bony cornua (cornua majora) supporting the larynx by means of a ligament which attaches to them the thyroid cartilage.

The numerous variations which this bone of the tongue presents in the class *Mammalia*, depend on the form of its body, on the more or less prompt soldering which takes place with the posterior cornua, and on the form and the proportion of the pieces of the anterior cornua. Very often in the Ruminants, the Solipedes, and the Cetaceans, the body takes, in becoming soldered to the posterior cornua, the shape of a crescent; and it often happens also, especially in the two first families, that it produces anteriorly a more or less long apophysis; but the anterior horns are always suspended to the cranium, and nearly without exception to a small apophysis of the os petrosus and to the neighbouring part of the tympanic cavity.

This suspension does not take place in those birds in which the anterior horns run round the back of the cranium [*PICIDÆ*; *TROCHILIDÆ*], and are only there attached by muscles and cellular substance.

The body of the tongue-bone is most frequently of a rhomboidal form. To its posterior part is articulated or soldered a slender unequal bone on which the larynx reposes, and which singly represents the two posterior cornua; and to its anterior part another bone, sometimes double, which penetrates into the tongue, and which Cuvier names the lingual bone. The anterior horns consist generally of only two pieces.

With regard to the diversities of this bone in the different families, he remarks that in the Saurians it continues with little change to the *Ophisauri*, the *Orvets* (*Anguis*), and the *Amphisbanae*. In the two former the anterior horn is nearly reduced to a membranous state; but the posterior one is well ossified. In the *Amphisbanae* the second articulation of the anterior horn is reduced to a simple vestige. There is none in the third horn. The os hyoides in the true serpents is reduced to two long cartilaginous filaments, which only sustain forwards, as the sole vestige of the body, a species of membrane, hardly discernible in those which are not very large.

The teeth in the true Saurians are not placed in sockets, nor are those which are to replace the teeth which are lost or shed produced in the cavities of the old teeth; but the gelatinous germs of the teeth adhere to the internal surface of the dental bone without having any bony partitions between them, and sometimes without being guarded on the internal side by a lamina of that bone: in the latter case their bases are only separated from the cavity of the mouth by the gum. The base is not divided into roots; but when the tooth grows the same phenomenon is manifested as is seen in fishes. The gelatinous nucleus becomes ossified; it unites itself intimately on one side to the bone of the jaw, whilst it contracts on the other an intimate adherence with the tooth which it has exuded; the tooth then appears like a prominence, an apophysis of the jaw, only it is covered with enamel, whilst its base is naked and purely osseous, and around this base are to be seen striæ and little pores by which the vessels have penetrated or still penetrate into its internal cavity, and which also mark the spot where the rupture will take place when this tooth must yield up its place. The new teeth spring not in the cavity of the old ones, as in the crocodile, but near the internal surface of their base, or in certain species in the thickness of the bone above or below the base according to the jaw.

Professor Owen, in his valuable chapter on the 'Teeth of Saurians' ('Odontography,' pt. ii., p. 234, et seq.), commences his inquiry with the *Ophisaurians*, observing that there are several genera of reptiles, which, like the true snakes, are externally devoid of locomotive extremities, or have them indicated only by minute rudiments, but are covered by small uniform scales, and resemble the Saurians much more than the Ophidians in their anatomical structure, especially in the fixed condition of the jaws, which cannot be divaricated laterally, or rotated backwards and forwards upon a moveable tympanic pedicle. These Snake-Lizards, he observes, have always intermaxillary as well as maxillary teeth.

In the *Amphisbæniæ*, Professor Owen remarks that there are both pleurodont and acrodon species, as in the true Saurians; but the pleurodons are the most numerous, and have their teeth applied against the internal surface of an external alveolar wall. In *Trogonophis* however the teeth are blended by their whole base with the alveolar ridge, are so closely approximated that they cohere, and are unequal, conical, subcompressed, and obtuse. The intermaxilla r

teeth are in unequal number, the middle azygos tooth being longer than the rest.

In *Chirotes* Professor Owen found the teeth slightly curved, simple, and nearly equal, with the exception of the azygos intermaxillary tooth, which is longer than the rest. They are small at first, but increase as they are placed backwards. [CHIROTES.]

The typical Blind-Worms, or Anguans, have, according to the Professor, only maxillary teeth; the palatine teeth being absent. In *Anguis fragilis* [BLIND-WORM] the first five of the upper teeth on each side are small, with cutting edges, and are placed on the intermaxillaries; the next eight are much larger, pointed, and recurved, and are separated by intervals. In general form therefore, Mr. Owen observes, the teeth of the true *Anguis* adhere to the Ophidian type; but in the *Ophiomorus*, or Miliary Blind-Worm, and in the *Acontias*, they are eouical, obtuse, and straight. In the sub-genera *Lerista*, *Ablepharus*, *Hysteroscopus*, *Dibamus*, *Typhlinus*, and the rest of the family of Blind-Worms, the teeth are likewise simple and conical.

The Scincoidians, or Smooth-Scaled Lizards, have small mouths and slender sharp teeth, fitted apparently, observes Professor Owen, for insect food. [SCINCIDÆ.]

The teeth in *Tropidophorus* are described as straight, cylindrical, simple, slightly compressed at the summit, and confined to the jaws. In the true Skinks (*Scincus*, Dnm. et Bih.), of which the *Scincus officinalis* is the type, the palate also is furnished, four or five small obtuse teeth being situated on each pterygoid bone. The maxillary teeth of *Scincus* are conical, obtuse, and sometimes slightly incurved.

In the Chameleons, the same author states that the teeth are conical, compressed, trenchant, with the summit simple, or terminating in three points, arranged in the same longitudinal line; and that, in most species, the teeth gradually increase in size, and become wider apart as they are situated farther back upon the jaws. Professor Owen further observes that the teeth are so completely confluent with the alveolar plate, as to appear, externally, when in place, to be mere processes of that border of the jaw; but, he remarks, their true nature is evident when viewed from the inner side of the jaw. The number of teeth vary in the species. [CHAMELEONS.]

In the Agamians, or Agamid Lizards, forming the genus *Uromastyx*, the dentition, which at first sight seems to consist of a merely notched or dentated margin of the jaw, resembles that of the Chameleons. These notches, or processes, are however true teeth, originally developed as independent parts, and afterwards becoming confluent, by their base and a great part of the outer side, with the alveolar parapet of bone.

The canines of the Dragons [DRACONINA] are proportionally longer than those of *Stellio*, but otherwise the dentition is the same.

There is a resemblance between the mutable *Agama* (*Trapelus*) and the *Stelliones*, inasmuch as the former have two conical teeth longer than the rest, beginning the series in the lower jaw and superior maxillary bones; but the *Agama* have four small conical intermaxillary teeth, without corresponding teeth below. Seventeen triangular teeth were found to succeed the canines in the lower jaw, and fifteen in the upper jaw, in *Trapelus ater*. *Agama orbicularis* resembles the *Trapelus* in its dentition, with the exception that the molar teeth behind the canines are more conical.

In the Geckotians [GECKOTIDÆ] the teeth are more pointed, more slender, more equable, and more numerous than in the preceding group. The Professor remarks that the summit of the tooth is always simple, and that the base is obliquely soldered to the internal surface of an outer alveolar parapet. The number of the teeth varies very much in the different sub-genera; but none of the *Geckotidæ* have teeth on the roof of the mouth.

The Iguanians [IGUANIDÆ] are characterised, like the preceding groups, by a short contractile tongue, slightly notched at its extremity, but, as he remarks, they are distinguished for the most part by having teeth on the pterygoid bone, and also by the complicated form of the crown of the maxillary teeth in the typical genera, the species of which subsist chiefly on vegetable substances. In most of the family the teeth are set in a common shallow oblique alveolar groove, and are soldered to excavations on the inner surface of the outer wall of the groove.

The following genera are enumerated by MM. Duméril and Bibron as showing the pleurodont type of dentition, and as being also furnished with pterygoid teeth, namely:—*Polychrus*, *Urostrophus*, *Anolis*, *Corythophanes*, *Basilius*, *Aploponotus*, *Amblyrhynchus*, *Iguana*, *Melopoceros*, *Cyclurus*, *Brachyophus*, *Leiosaurus*, *Hypsibates*, *Proctotretes*, *Ecpymotes*, *Senocercus*, and *Oplurus*. But the following pleurodents, *Hyperanodon*, *Tropidolepis*, *Phrynosoma*, and *Callisaurus*, have no pterygoid teeth.

In the genera *Iatiurus*, *Calotes*, *Lophyrus*, *Otocryptis*, and *Chlamydosaurus* among the Aerodonts, the maxillary teeth may, Professor Owen observes, be divided into anterior, lanary, and posterior teeth; and he states that no Iguanlian lizard has teeth on the palatine bones.

"The most strictly vegetable-feeding reptiles," says the Professor, "are the true *Iguana* and the *Amblyrhynchi*; yet the size of the teeth, their mode of implantation, and the limited motions of the jaws permit only an imperfect comminution of the food by these instruments; and their summits are rather chipped off than ground down by use. The appearance of abrasion is greatest in the posterior

teeth; especially in the *Iguana cornuta*, in which the crowns of the teeth are thicker than in the *Iguana tuberculata*, and make a nearer approach to the very remarkable form of tooth that characterises the gigantic *Iguanodon*." [IGUANODON.]

Professor Owen describes the fang of the tooth of *Hylæosaurus* as sub-cylindrical, sub-elongate, and smooth; the crown as expanded, compressed, slightly incurved, and with the narrow sides straight and converging at a slightly acute angle to the apex. In all the teeth which the Professor had seen, these sloping sides showed the effects of attrition, the enamel being worn away and the dentine exposed. The tooth is described as consisting of a body of dentine covered by a thick coating of clear structureless enamel, and surrounding a small central column of true bone, consisting of the ossified remains of the pulp, which presents the usual characters of the texture of the bone in the higher reptiles. The dentine differs, like that of existing Lacertians, from the dentine of the *Iguanodon* in the entire absence of the numerous medullary canals which form so striking a characteristic of the latter reptile. The main calciferous tubes are described as characterised by the slight degree of their primary inflections, and as continued in an unusually direct course from the pulp-cavity to the outer surface of the dentine at nearly right angles with that surface, but slightly inclined towards the expanded summit of the tooth. They are stated to be chiefly remarkable for the large relative size of their secondary branches, which diverge from the trunks in irregular and broken curves, the concavity being always turned to the pulp-cavity. In most parts of the tooth the Professor found the numbers of these branches obscuring even the thinnest sections. The ossified pulp exhibited the parallel concentric layers of the ossified matter surrounding slender medullary canals, interspersed with irregular, elliptical, radiated cells. [HYLÆOSAURUS.]

Professor Owen observes that one gigantic extinct species of Saurian Reptile [MOSASAURUS] has been found to agree with many of the existing species in the Lacertian, Iguanlian, Anolian, and Sciuroid families, in having the pterygoid bones armed with teeth; but, he remarks, the maxillary teeth combine the pleodont with the aerodont characters; and the skeleton indicates a special adaptation for swimming and marine life.

The teeth of *Geosaurus*, which appears not to be happily named, inasmuch as the large eyes defended by broad sclerotic plates indicate, as Professor Owen observes, that the sea was its dwelling-place, resemble those of the large Varanians in their compressed subrecurved crown, with a trenchant anterior and posterior edge, which likewise presents a fine and close dentition. A very fine fragment, we believe, the best known, is in the British Museum. Sömmering's conjecture that *Geosaurus* might be a young *Mosasaur* is no longer held good, and Cuvier's observations on the difference of their teeth are acknowledged to be just. Professor Owen remarks that the form of the vertebrae of *Geosaurus* indicates its near affinity to the crocodilian group, and that the Argenton fossil crocodile presents the same subcompressed teeth with dentated margins as *Geosaurus*.

The Varanians form a family of scaled Saurians, including the Monitors of the Old World: some of the species come nearest in size to the crocodiles. This family, Professor Owen remarks, manifests its affinity to that group in the absence of pterygoid teeth, and in the number of successive tooth-germs which may be observed at the same time behind the fixed and functional teeth. Independently of these characters, the Varanians must excite our interest from exhibiting in some species a form of tooth which most nearly resembles that which characterises *Megalosaurus* and other very remarkable extinct terrestrial species of gigantic squamate Saurians.

In a small extinct species of Lizard from the gault and chalk formations, and for which Professor Owen proposes the name of *Raphiosaurus*, the teeth are awl-shaped, about three lines in length above the alveolar border, close-set, and equal-sized. Their rounded base was ankylosed to the alveolar groove, and their outer side attached to a well-developed external alveolar wall.

For the varieties in the form of the teeth presented by the existing Varanians we must refer to the work itself, observing only that Professor Owen points out the *Holoderm*, *Varanus Niloticus*, *V. arenarius*, *V. Timoriensis*, *V. Bengalensis*, *V. bivittatus*, *V. variegatus*, and *V. crocodilinus* as the principal species which exhibit such varieties.

Professor Owen commences the family of the Thecodonts, extinct Saurians which exhibit a mode of fixation of the teeth different from the Aerodonts and Pleurodents, with the genus *Thecodontosaurus*, observing that these Thecodonts, which in other parts of their organisation adhere to the squamate or Lacertine division of the order, have their teeth implanted in sockets, either loosely, or confluent with the bony walls of the cavity; and to this group the most ancient Saurians belong.

The *Thecodontosaurus* discovered by Dr. Riley and Mr. Stutchbury in the Dolomite Conglomerate at Redland near Bristol, is, as well as their *Palæosaurus*, also there found by them, allied in the form of the teeth to the typical Varanian Monitors, but they differ in having the teeth imbedded in distinct sockets: to this condition however the *Varani* make an approach in the shallow cavities containing the base of the teeth along the bottom of the alveolar groove.

One of the two teeth of *Palæosaurus* found by Dr. Riley and Mr. Stutchbury is compressed and pointed, with opposite trenchant and

serrated margins; but its breadth is much greater than its length; this they ascribe to a species which they name *P. platyodon*; the other they refer to a species designated by them *P. cylindrodon*.

The genus *Cladeiodon* (Owen) derives great interest from having been found in the same quarries of New Red-Sandstone (Keuper?) at Warwick and Leamington as contained the remains of *Labyrinthodon*. "In their compressed form," says Professor Owen, "anterior and posterior serrated edges, sharp points, and microscopic structure, these teeth agree with those of the Saurian reptiles of the Bristol conglomerate. In their breadth, as compared with their length and thickness, they are intermediate between the *Thecodontosaurus* and the *Palæosaurus platyodon*; they are also larger and more recurved, and thus more nearly approach the form characteristic of the teeth of the *Megalosaurus*. From these teeth however they differ in their greater degree of compression, and in a slight contraction of the base of the crown. I propose therefore to indicate the genus, of which, as yet, only the teeth are known, by the name of *Cladeiodon*, and for the species from the Warwickshire sandstone the name of *C. Lloydii*, in testimony of the friendly aid of Dr. Lloyd of Leamington, to whose exertions I owe the materials for the description of the teeth of the present genus, and the still more remarkable ones of the British species of *Labyrinthodon*, with which the teeth of the *Cladeiodon* are associated."

Professor Owen retains the name of *Protosaurus* for the small species of Saurian found in the pyritic schists of Thuringia, which, he observes, like the dolomitic breccia near Bristol, rank as the oldest member of the new red-sandstone. He adds in a note, that besides the Thecodont type of dentition the *Protosaurus* differs from all recent Saurians, and resembles the Pterodactyle in the great relative size of the cervical vertebrae and the ossified tendons of the muscles of that region of the spine; it differs from all reptiles, except the extinct *Rachæosaurus*, in the bifurcate superior spines of the caudal vertebrae.

In the extinct Saurian from the Oolitic Formation at Neuffen in Würtemberg (*Thaumatosauros oolithicus*, Meyer), Professor Owen found the teeth conical, slightly curved, straighter on the inner side of the crown, and implanted by a long and strong root, rather obliquely, in a deep socket. The base and basal portion of the crown presented a nearly circular transverse section, and the wide pulp-cavity in this part of the tooth exhibited an elliptical transverse contour; the tooth becomes slightly compressed towards the apex. Its implanted base is stated to be the broadest part of the tooth; the breadth of the crown to its height is as one to three; the crown is described as invested with a thin layer of enamel, the basal half of which is marked by longitudinal striae; these striae seemed to consist of folds of the enamel, which do not extend into the dentine. The successional teeth are noticed as penetrating into the interior of the fixed teeth in the progress of their development.

The teeth of *Ichthyodon*, a gigantic reptile from the Jura Limestone of the Canton of Aargau, are described as somewhat resembling those of the *Thaumatosauros*, but the external longitudinal striae of the crown of the tooth as being sharper and more elevated, and the enamel between the striae as roughened by irregular linear risings; whilst the teeth of the *Pœcilepleuron*, an extinct reptile, also of gigantic dimensions, from the Oolitic Beds at Caen, has, according to the single tooth referred to that species, a more compressed crown than the teeth of *Thaumatosauros*; the striae are also described as wider apart, and the two diametral ones as developed into ridges which extend to the apex of the tooth.

In noticing the teeth of the Enaliosaurians, Professor Owen observes that those of the *Ichthyosauri* [*ICHTHYOSAURUS*] have a simple, more or less acutely conical form, with a long and usually expanded or ventricose base or implanted fang, and that they are confined to the intermaxillary, maxillary, and premandibular bones, in which they are arranged in a pretty close and uninterrupted series, and are nearly of equal size. They consist, he informs us, of a body of unvascular dentine, invested at the base by a thick layer of cement, and at the crown by a layer of enamel, which is itself covered by a very thin coat of cement; the pulp-cavity is more or less occupied, in fully-formed teeth, by a coarse bone. He observes that the external surface of the tooth is marked by longitudinal impressions and ridges, but the teeth vary both as to outward sculpture and general form in the different species.

"The chief peculiarity," he says, "of the dental system of the *Ichthyosauri* is the mode of implantation of the teeth. Instead of being anchylosed to the bottom and side of a continuous shallow groove, as in most Lacertians, or implanted in distinct sockets, as in the *Thecodon*, *Megalosaur*, or *Pterodactyle*, they are lodged loosely in a long and deep continuous furrow, and retained by slight ridges, extending between the teeth, along the sides and bottom of the furrow, and by the gum and the organised membranes continued into the groove and upon the base of the teeth. The germs of the new teeth are developed at the inner side of the base of the old ones."

The chief distinction offered by the dental system between the *Ichthyosauri* and *Plesiosaurs* is pointed out by Professor Owen as existing in the loose implantation of the teeth of the latter in separate alveoli. In this deviation from those of the *Ichthyosaur*, the *Plesiosaur*, observes the Professor, approximates to the crocodilian type,

and this affinity, he adds, is likewise manifested in the unequal size of the teeth, and the development of some of the anterior ones into large tusks. They are described as being composed, like those of the *Ichthyosaur*, of a body of hard and simple dentine, covered at the crown by a coat of enamel, and at the base by a coat of cement; but the latter is relatively thinner than in *Ichthyosaur*, and is not indented into the substance of the dentine.

Professor Owen proposes the subgeneric name of *Plesiosaurus* for a gigantic extinct reptile whose remains have been found in the Kimmeridge Clay. The teeth are described as differing from those of *Plesiosaurus* in their greater relative thickness as compared with their length, and in the subtriangular shape of their crown. The outer side is slightly convex, sometimes nearly flat; it is separated from the two other facets by two sharp ridges; these are more convex, and the angle dividing them is often so rounded off, that they form a demi-cone, and the shape of the tooth thus approximates very closely to that of *Mosasaurus*, with which it is equal in size, but from which it is readily distinguished even when the crown only is preserved, by the ridges which traverse the inner or convex sides; the outer flattened surface alone being smooth. The long fang of the perfect tooth at once removes it from the *Acerodons*, and allies it with the *Thecodonts*, among which it approaches nearest, in the superficial markings of the crown, to *Plesiosaurus*. The vertebrae of the neck are so modified that the peculiarly elongated proportion of this part of the spine, which characterises the typical *Plesiosauri*, is exchanged for one that much more nearly approaches the opposite condition of the cervical region in the *Ichthyosauri*; thus presenting an abrogation of the main characteristic of the *Plesiosauri* combined with the more crocodilian proportions of the teeth of this *Plesiosaurus*, of which a fine specimen (*Plesiosaurus brachydeirus*, Owen) from Market-Raisin is preserved in Dr. Buckland's collection at Oxford, consisting of considerable portions of the upper and lower jaws.

We now have to examine the other parts of the skeleton of the Saurians. That of the Enaliosaurians is noticed in the articles *ICHTHYOSAURUS* and *PLESIOSAURUS*; that of the Crocodilians, under the article *CROCODYLIDÆ*. Among these animals there is a wonderful adaptation of the structure to their modes of progression and habits of life. In the extinct Pterodactyle, we have, more especially in the anterior extremities, a modification in the development of the bones, to enable the animal to move through the air with a true flight. [*PTERODACTYLE*.] In the great mass of the terrestrial Saurians, the bones of the extremities are elongated, to facilitate progression on the earth, on trees, or even, as in the case of the Geckos, on smooth walls and ceilings. When we come to the aquatic groups, we have in the Crocodilians a more compact form of the bones of the hand and foot, but still adapted to occasional progression on land, till at last, in the Enaliosaurians, the short, compact, and compressed bones of the extremities become mere paddles to row the body through the water, like those of the tortoises among the reptiles, and of the seals and whales (in the latter as far as the anterior extremities are concerned) among the mammiferous animals.

Cuvier remarks that the study of the vertebrae of the living Saurians is highly necessary, in order to a recognition of the numerous fossil bones belonging to this family, and he thus proceeds to describe those of the former:—The atlas of the Monitor is a ring composed of three pieces—two upper ones, united to each other at the dorsal part, notched in front and behind for the nerves, and one lower piece. The anterior surface of the axis (dentata), or rather of that portion of it which is analogous to the odontoid, penetrates in the ring of the atlas and fills nearly half its width, leaving always in front a concavity for the condyle of the head. Below, on the junction of the atlas, of the odontoid, and of the body of the axis, is a triangular piece which gives off a pointed hook directed backwards. The axis is compressed; its annular part takes, above, the form of a longitudinal pointed crest; its anterior articular facets have their plane turned outwards; the posterior ones have them downwards; the body terminates in a transverse convexity of a kidney shape; on each of its lateral surfaces is a small and but slightly projecting crest, which has, towards its anterior third, a small point; below, there is a crest, under the posterior part, which is enlarged backwards. The sutures which distinguish the annular part of the body are soon effaced; but for a long period a small epiphysis may be seen at the posterior point of each of the two crests. The five succeeding vertebrae resemble the axis, excepting that they are without an odontoid; but their anterior surface has a concavity proportioned to the convexity of the preceding vertebrae, their dorsal or spinous crest or process is elevated and shorter, and their transverse processes enlarge slightly, and present a convex facet for the support of the cervical rib. The lower crest exists; and this is what distinguishes the cervical from the dorsal vertebrae, the body of which last is even below, with the exception of the three first, which have each a tubercle becoming gradually less and less. At the point of these crests is an epiphysis, which in the other sub-genera forms the crest by itself. The dorsal vertebrae after the twelfth have always a squared spinous process, an anterior concave and a posterior surface, both of a kidney-shape, horizontal articular apophyses, the posterior looking downwards, the anterior upwards; and on each side under the anterior apophysis, by way of a transverse apophysis, a vertical oval-shaped tubercle for supporting the rib. The number of

these vertebræ is 22, there being no lumbar vertebræ; for there are ribs from the neck to the pelvis amounting to 27 pairs, including the 5 cervical, but the first and the last of these ribs are very small. The first pair of ribs is attached to the third cervical vertebra. The first five pairs are not united by means of cartilages to the sternum, and on this circumstance Cuvier relies to distinguish the cervical vertebræ, which, adding the atlas and dentata (these last having no ribs), makes their number 7, as in the Crocodiles and Mammals generally. The first three dorsal ribs only are attached to the sternum; the 17 succeeding ones are false ribs. Cuvier remarks that the total absence of lumbar vertebræ appears to him a general rule in the family of Saurians.

There are two sacral vertebræ in the Monitor. The first has, in lieu of a small tubercle, a large apophysis, convex externally, and presenting to the ossa ilii an articular surface notched behind, and of a horse-shoe shape. The second has also a large apophysis, but simply widened and flattened horizontally. The caudal vertebræ after the eighth are very numerous (70, 80, and more); they may be easily recognised by their spinous and transverse apophyses or processes, which are long and narrow, and their articular apophyses or processes, which are nearly vertical, the anterior looking inwards, the posterior outwards; and also by having on their lower surface, towards the hinder part, two small tubercles for supporting the chevron bone, which occupies the place of a lower spinous process. These two small tubercles are placed more forward in the Monitors than in the other sub-genera; for in the latter they touch the posterior articulation, so that the chevron bone appears to be attached to the vertebræ. All the caudal vertebræ of the Monitor have, like the preceding, the anterior surface concave and the posterior convex, and they go on diminishing in proportion as they approach the extremity of the tail, their prominences finishing by being reduced almost to nothing.

The cervical vertebræ, determined by the anterior false ribs, are eight in number, that is to say, there are six pairs of these false ribs, and this number is found in many other sub-genera, particularly in the *Iguana*, the Basilisks, the Lizards, the Geckos, the Anolides, the *Agama*, and the Stelliones. The last two, and sometimes the last three ribs, though they do not reach to the sternum, yet are placed under the shoulder, and concur in the formation of the thorax, so that the vertebræ which support them may be placed among the dorsal, which would reduce to five the number of vertebræ really belonging to the neck. In the ordinary Lizards, the Skinks, and slightly in the Anolides and the Geckos, the cervical ribs attached to the fourth, fifth, and sixth vertebræ are singularly compressed and widened at their free extremity. The differences which characterise the vertebræ of the different sub-genera, independently of what Cuvier had already remarked as to the position of the tubercles of the caudal vertebræ for the chevron bones, especially consist, he informs us, in the respective length and stoutness of their bodies, and the respective length and width of their apophyses. The *Iguana* has the spinous processes of its dorsal vertebræ less lofty, and, cut, as it were, more obliquely. The bodies of its caudal vertebræ are more elongated, so that with a less number they form a greater length. Their spinous processes decrease more rapidly. The Basilisks have very nearly the characters of the *Iguana*, but their dorsal spinous processes are high and narrow, as well as those of a part of their tail. The *Agama* have also the dorsal spinous processes high, straight, and narrow; but the Stellions have them low. In the Lizards they are tolerably high, but directed somewhat obliquely backwards.

The ribs of the Saurians are slender, round, and the anterior ones only have the costal head slightly enlarged and compressed. Cuvier had never seen any of them with a division at their upper extremity into a head and tubercle. The anterior ribs of the Monitors are a little more widened in the upper parts than those of other Saurians. Instead of those simply ventral ribs which are seen in the Crocodile, many sub-genera, especially in the *Polychri*, Anolides, and Chameleons, after the ribs which are united to the sternum, have others which unite mutually with their corresponding rib, and thus surround the abdomen with entire circles.

The sternum of the Saurians, taken together with their shoulder, forms, says Cuvier, a kind of cuirass for the heart and large blood-vessels. It is more complicated than in the Crocodiles, and formed upon a plan very different from that of the Tortoises. It consists essentially of a long narrow depressed bone, which gives off anteriorly two branches directed to each side, more or less recurrent, according to the species, and between which its point passes sometimes to advance more forward under the neck. This bone penetrates with its posterior part into a cartilaginous plate of a rhomboidal shape, which has two sides forward and two backward, and which often shows traces of a longitudinal division into two portions. Its interior sides are continued with the edges of the anterior part of the bone, but in diverging to the right and left. They are sometimes ossified, particularly their edge, which has a groove, in order to give support, like a mortise, to the sternal edge of the clavicular bone. The posterior sides of the rhomboidal cartilage serve for the insertion of the false ribs. So far there is no great difference in this part of the organisation from that of the Crocodile, except in the anterior branches of the elongated bone, which give it the form of a T, of an arrow, or of a

cross, according to the species; but a more considerable difference is apparent in the development of the coracoid bone, and in the constant presence of a clavicle more or less large. The coracoid bone, as in the Crocodiles, the Tortoises, and all the animals which have a true arm, concurs in the formation of the glenoid cavity, and in the true Saurians affords nearly half of it. Widening more than the bony plate of the shoulder-blade, it proceeds to articulate itself to the sternal rhomboid by a wide edge, which takes the form of the blade of an axe; but its peculiarity consists in the giving off one or two apophyses, by means of which it supports a great cartilaginous arch which passes on the slender and advanced bone of the sternum, and lies across that of the coracoid bone of the other side.

The scapula, or shoulder-blade, produces the other part of the glenoid facet; it goes on, as ordinarily, enlarging on the side of the thorax and towards the back; and at about a third or the middle of its length stops short, but is continued in a single portion, which is generally cartilaginous, or which, when it is ossified, which frequently happens, becomes so in a different manner, and with another texture, like the cartilage adhering to the coracoid bone. In the case of ossification, the scapula is always divided into two bones.

The clavicle rests on one side against the slender bone of the sternum, or against its lateral branch, and often also it reaches to the opposite clavicle; on the other side it proceeds to rest against the anterior edge of the scapula, either against the osseous portion or that which remains longer cartilaginous, and which often presents a tubercle or small crest for its reception. Sometimes the bony scapula gives off an apophysis which goes to sustain the body of the clavicle, but this is all that it presents as a slight resemblance to an acromion: the tubercle of the cartilaginous part resembles that process much more.

The pelvis of the Saurians (Cuvier takes the Monitor as the example) is composed of three bones, which concur, as in the viviparous quadrupeds, to compose the cotyloid fossa. Its upper part is formed by the ossa ilii; its neck is wide and short; its spinal part, instead of being directed forwards, as in the viviparous quadrupeds, or of being rounded as in the Crocodile, runs obliquely backwards in the form of a narrow band, and has only a small point in front. The pubis and the ischium are each united to its opposite in the median inferior line; but the pubis is not joined to the ischium, and the two oval holes are only separated by a ligament. Their neck is wide, short, and flat. That of the pubis is pierced with a rather large hole, and its anterior border produces a point which is recurved downwards and outwards. Cuvier adds that the pelvis in the different sub-genera is especially distinguished by the symphysis of the pubis, which is formed by a rather wide truncature in the Monitors, and even slightly in the *Sauvages*; but only by a narrow point in the majority of others. The Chameleon differs from all the others in its narrow ossa ilii, which proceed perpendicularly in widening slightly to attach themselves to the spine. These ossa ilii are still further distinguished by a triangular cartilage, analogous to that of the shoulder-blade. The symphysis of its pubis is formed by a truncature, and there is no lateral point.

The cylindrical bones of the Saurians exhibit the following characters:—The humerus agrees very much in form with that of birds. Its upper head is compressed, to answer to the hollow fossa which the shoulder-blade and coracoid bone together present to it. Its lower pulley is formed of two projecting rotatory portions, entirely rounded, the external of which is the least developed. The internal condyle also projects more than the external, the deltoid crest produces an angle more projecting forwards, and its posterior tuberosity is less hooked. In these two last respects it more resembles that of the Crocodile; but it has in general all its articular surfaces much better defined. But the humerus of a lizard may always be distinguished from that of a bird, because the former is not hollow, nor pierced with holes for the admission of air into its interior. The ulna of the Saurians is compressed and trenchant on its radial edge. Its sigmoid facet is oval, and its olecranon projects but little; its carpal head is also oval and uniformly convex. The radius is delicate; its upper head is oval and concave; its lower, which is slightly convex, presents to the first bone of the carpus a rounded tubercle and a fossa of a crescent-shape. The femur in its upper part resembles that of the Crocodile much more than that of birds, and this has reference to the direction of the foot in reptiles. Its upper head is compressed and curved in front, and has its trochanter on the tibial side placed nearer to the head of the bone than in the Crocodile, much more projecting, and of a compressed form. The lower head of the femur, on the contrary, much resembles that of birds, especially in the small hollow on the peroneal side for the head of the fibula. The patella is very small, often hardly visible. The leg is always composed of two bones, of which the tibia is the largest. Its upper head is triangular, as ordinarily; its lower is transversely oblong and flat. The fibula of the Monitors is flattened and widened below, where it unites to the tarsus by a narrow line. In the *Iguanas* and the greater part of the other genera it is nearly of a size throughout, slender, with its upper head compressed, and its lower demi-oval and slightly oblique.

The bones of the fore and hind feet in the Saurians consist of a carpus composed of nine bones, like that of the Tortoises, and Cuvier remarks that its composition may equally be compared to the *Simiada*. In the first row are a radial bone, a cubital bone (rather large), and a

pisiform bone fitted against the lower part of the ulna. In the lower row are five small bones, disposed in a curve and answering to the five metatarsal bones, and a ninth, placed between the two large bones of the first row, and the first, second, third, and fourth of the second row. The metacarpals of the thumb and little finger are rather shorter than those of the other three fingers. The number of phalanges amounts to two for the thumb, three for the fore finger, four for the middle finger, five for the ring finger, and three for the little finger. The tarsus, like that of the orcodile, has only four bones. In the first row are two: 1, a tibial bone, which extends also partially under the fibula, and presents a facet to it; it is irregularly rectangular, wider than it is long, thick on its internal border, and presenting in its profile some relationship to the astragalus of a Ruminant; 2, a fibular bone, smaller and soon uniting itself into a single piece with the preceding, on the same plane with which it is. In the second row are also two; one larger, triangular on its anterior surface, and stouter backwards, where it articulates with the two of the first row, and supports the metatarsals of the fourth and fifth toes; the second, smaller, placed between the preceding and the metatarsals of the third and second toes. This last also slightly touches upon the astragalus, which only supports the metatarsal of the great toe. The first four metatarsals are slender and nearly straight; they go on elongating to the fourth; the fifth is short, widened, and recurved on its upper head towards the great bone of the second row, to which it is articulated by the side. The great toe has two phalanges; the second toe, three; the third, four; the fourth, five. It is this, which is the longest, that gives to the foot that elongated and unequal form which characterises it in the lizards. The fifth, which is nearly as short as the great toe, has, like the third, four phalanges. Cuvier remarks that in the ordinary position of the hind feet of the Saurians, that is, with the toes directed backwards, the tibia and great toe are at the external border of the foot, and the little toe is at the internal border. The unequal phalanges of all the feet are trencant, arched, and pointed. This description, observes Cuvier, allowing for some differences in proportion, answers for all the sub-genera which have well-developed feet, with the exception of the Chameleons alone and some peculiarities relative to the toes in certain Geckos; and even in the Chameleon it is in the proportion of the bones of the carpus and tarsus, rather than in their number and arrangement, that the difference appears. The mode in which the bones of the feet are grouped in the chameleon is in an inverse manner, that is, the great and little toes of all the feet together and directed inwards, and the three others also together and directed outwards. [CHAMELEONS.]

The other parts of the organisation of the Saurians will be found in detail, where necessary, under REPTILES and the different articles relating to families and genera. We shall here only observe that their heart, like that of the Tortoises, is composed of two auricles and one ventricle, which is sometimes divided by imperfect partitions. Their ribs are moveable, and can be raised or depressed for the purposes of respiration. Their lung extends more or less towards the hind part of the body, and often penetrates into the abdomen, whose transverse muscles glide under the ribs and even towards the neck to embrace it. Their generation, with few exceptions (*Zootoca*, for instance), is oviparous, and the eggs have a more or less hard shell. In some (Chameleon, for instance) it is a mere tough calcareous skin, and this is its general condition. The coitus is complete, and effected sometimes by means of two intromittent organs and sometimes by means of one only. The young come into existence in the same form which they retain through life. The toes are armed with nails, with very few exceptions, and the skin is either covered with scales more or less serrated, or at least with small scaly grains. All have a tail more or less long, nearly always thick at the base. The greatest number have four feet, some two only, and a few mere rudiments not apparent externally.

The following is a synopsis of the families of the *Sauria*, adopted by Dr. J. E. Gray in his 'Catalogue of the Specimens of Lizards in the British Museum.' The genera and species of the *Lacertinidae* are given, the other large families are described under their proper names:—

Order I. LIZARDS. *Sauria*.

Mouth not dilatable, jaws toothed, the lower jaw-bones being united by a bony suture in front. Eye generally with distinct eyelids; drum of the ear generally distinct. Limbs four, distinct, rarely in such a rudimentary state as to be hidden under the skin. Toes clawed. Body elongate, rounded, covered with imbricated or granular scales; ribs distinct, mobile, and with a distinct sternum. Tail elongate, tapering, rarely prehensile, generally covered with whorls of scales. Egg with hard skin. The young not undergoing any metamorphosis.

Sub-Order I. *Leptoglossae*.

Tongue flat, elongate, and bifid.

Tribe I. *Cyclosauria*.

Scales of the belly square, in cross hands, of the back and tail rhombic and imbricate, or circular and subgranular. Tongue elongate, flattened, free, nicked, or with two elongate cylindrical horny tips. Eyes diurnal, with two valvular lids. Feet for walking; toes unequal, compressed.

a. Head with small many-sided shields. Tongue sheathed at the base.

1. *Monitoridae*.—Head-shields flattish, scales small. Inhabit the Old World and Australia. [MONITORIDÆ.]

2. *Heloderma*.—Head-shields and scales of body convex, tubercular. Teeth with a groove behind. Inhabit the New World.

b. Head with large regular shields. Tongue mostly free at the base.

* Sides flattish, covered with small often granular scales.

3. *Teiidae*.—Supra-orbital plate horny. Teeth solid, rooted. Scales small, granular, often with large plates. Inhabit the New World. [TEIIDÆ.]

4. *Lacertinidae*.—Head pyramidal, covered with regular many-sided shields; supra-orbital plate rigid. Throat scaly, often with a cross fold in front, and a collar of larger scales behind. Tongue elongate, flat, free at the base, exsertile, long-forked. Teeth hollow, rooted. Scales granular or rhombic, keeled. Sides flat, covered with small granular scales. The species inhabit the Old or Eastern World and Australasia.

Synopsis of the Genera.

I. Nostril erect, in the lower hinder angle of the nasal shield, just above the labial shield, with one or two shields behind it. Eyelid distinct.

A. Toes simple, compressed, not keeled nor fringed. Collar distinct.

a. Scales granular or 6-sided, elongate. Posterior nasal shield single. Collar distinct.

Zootoca.—Lower eyelid scaly, opaque.

Z. vivipara, the Scaly Lizard, Common Lizard, and Nimble Lizard. It is the *Lacerta vivipara* of Jacquin; *Lacerta agilis*, Pennant; *Zootoca muralis*, Gray. It has the ventral shields 8-rowed, the temple covered with many-sided shields, with a large central shield; its colour olive; back with a white-edged blackish streak on each side, and a central black streak; belly orange (in summer), black-spotted.

This little lizard is a common inhabitant of heaths and hanks in most of the districts of England, extending even to Scotland. It is also one of the few reptiles found in Ireland. Its range is very limited on the Continent, and is not found in Italy or France. Its movements are graceful and rapid, it comes out of its hiding place during the warm parts of the day, from the early spring till autumn. It lives upon insects, which it seizes with its mouth. In this species the eggs are retained in the oviduct until the young are ready to be hatched, and they are thus produced alive. The young when brought forth are fully-formed, and capable of running about and taking their own food. The usual length of this lizard when full grown is from 5½ to 6½ inches.

Z. muralis, the Tiliquesta, is a native of the south of Europe.

Z. oxycephala, the Long-Headed Lizard, is a species brought by Mr. Webb from either Spain or Madeira.

Z. taurica, a native of the Crimea, Morea, Corfu, and Sicily.

Z. taniotata, the Striped Lizard, a native of South Africa.

Z. derbiana, a native of Australia.

Z. galloti, Madeira.

b. Scales granular or 6-sided, elongate. Posterior nasal shields 2, small, one above the other. Collar distinct.

Lacerta.—Lower eyelid opaque. Chin-fold distinct. Abdominal shields narrowed behind.

L. agilis, the Sand-Lizard. It is the *L. stirpium* of Milne-Edwards and others. The upper hinder nasal small, rather in front of the larger lower one; scales of the temple small, unequal, irregularly many-sided, often with a larger central one; throat-fold indistinct, brown, spotted or eyed with black; sides green, brown-eyed, beneath white. This species is a native of Great Britain, and is especially abundant in the neighbourhood of Poole in Dorsetshire. Its general abode is on sandy heaths, where, from the rapidity of its movements, it is often mistaken for some form of snake. On account of the rapid locomotion it is not often caught. It does not bear confinement, but pines away and dies. When caught it often bites, but no ill-consequences are the result. The female lays her eggs to the number of 12 or 14 in hollows in the sand, which she excavates for the purpose. They are subsequently hatched by the heat of the sun. The eggs appear to be laid a considerable time before they are hatched. In this respect this species differs very much from the common lizard, which always brings forth her young alive. This lizard is larger than the *Zootoca vivipara*, as those of average size measure about 7 inches in length.

L. viridis, the Green Lizard, has the scales of the temple inequilateral, many-sided, with a central larger one; back granular, oblong, with shelving sides; throat-fold distinct. This species is a native of Guernsey and Jersey, and also of the south of Europe. It is much more readily caught than the last species, and never attempts to bite. It may be readily tamed and taught to come to the hand for food. It will lie coiled in the two hands, and never attempt to escape.

L. ocellata and *L. laevis*, both natives of the south of Europe, are the only other species of the typical genus *Lacerta*.

Thetia.—Lower eyelid transparent. The only species is *T. perspicillata*, a native of Algiers.

Teira.—Lower eyelid opaque. Chin-fold distinct. Abdominal folds and shields square. *T. punctata*, a native of Madeira, is the only species.

Nucras.—Lower eyelid opaque. Chin-fold indistinct. Abdominal shield narrow behind. Preanal shields one before the other.

N. Lalandii, is a native of the Cape of Good Hope.

N. tesselata, is a native of South Africa.

N. erigua and *N. chalybea*, the Small Lizard and Steel-Black Lizard, are natives of the Caucasus.

c. Scales rhombic, keeled. Posterior nasal shields 2, small, one above the other.

Notopholis.—Collar and throat-fold distinct.

N. Fitzingeri is a native of Sardinia.

N. Capensis is a native of South Africa.

N. Moresticus inhabits the Morea.

N. nigropunctata, a native of the Island of Corfu.

Tropidosaurus.—Collar and throat-fold indistinct. *T. montana*, a native of Java, is the only species.

d. Scales rhombic, keeled. Posterior nasal shields single. Collar indistinct.

Algebra.—Ventral shields roundish, thin.

A. barbarica, the Zermouneah, is a native of Algiers.

A. Capensis and *A. Dumerilii* are natives of the South of Africa.

B. Toes keeled beneath, and sometimes fringed on the sides. Scales keeled. Posterior nasal single.

Acanthodactylus.—Toes fringed on the sides.

A. velox. A native of North Africa.

A. Bellii. Found in Algiers.

A. Capensis. South Africa.

A. Savignii. Algiers.

A. lineato-maculatus. Morocco.

A. Boskianus. North Africa.

A. inornatus. Tripoli.

Psammodromus.—Toes not fringed on the sides. Collar indistinct.

P. Hispanicus, the Garrigues, is a native of Spain.

P. cinereus inhabits the South of France.

II. Nostril horizontal on the ridge, between three swollen scales, one between the nostril and labial. Toes keeled beneath or fringed on the side.

a. Eyelid distinct.

Scapteira.—Toes depressed, fringed on the edge, not keeled beneath. Collar indistinct. *S. graminea*, a native of Nubia, is the only species.

Eremias.—Toes compressed, keeled beneath, not toothed on the edge. Collar distinct. Preanal shields small, in several series, in central series one behind the other.

E. arguta. The Arguta is a native of Tartary.

E. velox. The Crimea.

E. Knorri. South Africa.

E. Capensis; *E. Burchellii*; *E. dorsalis*; *E. Namaquensis*; *E. lugubris*, are also described by Dr. Smith as natives of South Africa.

E. guttulata. North Africa.

E. lineo-ocellata. South Africa.

E. pulchella. South Africa.

Mesalina.—Toes compressed, keeled beneath, not toothed on the edge. Collar distinct. Preanal shield single, semicircular, with 1 or 2 arched series of smaller ones round it.

M. Pardalis. North Africa.

M. rubro-punctata. North Africa.

Cabrita.—Toes rather compressed, keeled beneath, not fringed on the sides. Collar none.

C. Lechenaultii, a native of India, is the only species.

b. Eyelid rudimentary. Eye circular, exposed.

Ophiops.

O. elegans is found on the shores of the Mediterranean.

O. macrodactylus is a native of Asia Minor.

** Sides with a distinct longitudinal fold, covered with small granular scales.

5. *Zonuridae*.—Ears distinct. Limbs distinct, or rarely quite hidden. [ZONURIDÆ.]

6. *Chalcidae*.—Ears hidden under the skin. Limbs very short; femoral pores none. Lateral fold indistinct. [CHALCIDÆ.]

** Sides rounded, covered with scales like those on the back.

7. *Anadiadæ*.—Scales of the back and sides thin, imbedded, smooth, in alternating cross series; of the tail elongate, smooth, in longitudinal series. Ears distinct. Femoral pores distinct.

8. *Chirocolidae*.—Scales of the back imbricate, 6-sided, lancesolate, keeled, narrow, in cross series; of the tail in rings, alternating with each other. Ears hidden. Femoral pores distinct.

9. *Cercosauridae*.—Scales of the back, sides, and upper part of the tail keeled, in longitudinal series. Limbs 4: feet for walking.

10. *Chamaesauridae*.—Scales imbricate, all elongate, rhombic, keeled

in longitudinal series, the keels forming longitudinal ridges. Limbs simple, undivided. Temple scaly.

Tribe II. *Geissosauræ*.

Scales of the belly and (almost always) of the back and sides quincuncial, rounded, imbricate. Sides rounded. Tongue narrow, short, flat, end slightly nicked. Head with regular shields.

a. Eyes distinct, exposed, eyelid rudimentary. Head conical.

11. *Gymnophthalmidae*.—Head-shields normal. Nostrils lateral, in a nasal shield. Limbs 4 or 2. Body fusiform.

12. *Pygopidae*.—Head-shields normal. Nostrils over the upper edge of the first labial. Pupil round or oblong. Abdominal shields 6-sided, in 2 or 3 series. Tail with a central series of larger shields. Limbs 2, posterior. Australasia.

13. *Aprasiidae*.—Head-shields normal. Nostrils in a suture between the nasal and first labial (sometimes united?). Limbs none. Ventral and dorsal scales nearly similar. Australasia.

14. *Lialidae*.—Head-shields subimbricate, scale-like. Cheeks scaly. Nostrils in a small single nasal on ridge of the face.

b. Eyes distinct, eyelids distinct, connivent. Head conical.

15. *Scincidae*.—Rostral shield moderate, triangular. Nostrils in a plate between the frontal and labial shields. [SCINCIDÆ.]

16. *Ophiomoridae*.—Rostral moderate, triangular. Nostrils in a notch on edge of nasal and the supranasal shields.

17. *Sepsidae*.—Rostral rather large, square. Nostrils in a notch in the hinder edge or the rostral. [SEPSIDÆ.]

18. *Acontiidae*.—Rostral large, cnp-like. Nostrils in the rostral, with a narrow slit to its hinder edge.

c. Eyes hidden under the skin.

19. *Typhlinidae*.—Head conical. Rostral shield cup-like. Nostrils in the rostral shield, with a slit to its hinder edge.

20. *Typhlopsidae*.—Head short, depressed. Rostral shield elongated, extended up the forehead. Nostrils in an elongated nasal shield. [TYPHLOPSIDÆ.]

Sub-Order II. *Pachyglossæ*.

Tongue thick, convex, attached to the gullet at the base.

Tribe III. *Nyctisauræ*.

Scales of the belly small, rhombic, imbricated; of the back and sides granular. Tongue thick, short, convex, end slightly nicked. Eyes nocturnal; eyelids circular, not connivent, pupil linear, erect. Feet for walking; toes subequal, scaly beneath, and generally dilated.

21. *Geckotidae*.—The Old and New World. [GECKOTIDÆ.]

Tribe IV. *Strobilosauræ*.

Scales of the belly small, rhombic, imbricate; of the back and sides imbricate. Tongue thick, short, convex, end slightly nicked. Eyes diurnal, with valvular eyelids; pupil round. Feet for walking; toes unequal, compressed.

22. *Iguanidae*.—Teeth on the inner side of the jaw-bone. New World. [IGUANIDÆ.]

23. *Agamidae*.—Teeth on the edge of the jaw-bones. Old World and Australasia. [DRACONINÆ.]

Tribe V. *Dendrosauræ*.

Scales of the belly, sides, and back, granular. Tongue elongate, subcylindrical, worm-like, very exsertile. Eyes globular, very mobile, with a small, central, round opening. Toes equal, united into two opposing groups.

24. *Chamelonidae*.—Teeth on the edge of the jaw-bone. Old World. [CHAMELEONÆ.]

SAURICHTHYS, a genus of Fossil Fishes. [FISH.]

SAUROCEPHALUS, a genus of Fossil Fishes. [FISH.]

SAURODON, a genus of Fossil Fishes. [FISH.]

SAUROPHAGUS. [LANIADÆ.]

SAUROPHIS. [ZONURIDÆ.]

SAUROPSIS, a genus of Fossil Fishes. [FISH.]

SAUROTHERA. [CUCULIDÆ.]

SAURURACEÆ, *Lizards'-Tails*, a natural order of Plants belonging to the Achlamydoe group of Incomplete Exogens. It consists of only a few genera, which are aquatic or marshy herbs or herbaceous plants, with perennial root-stocks, knotted stems, and simple entire alternate leaves, with vaginal stipules. The flowers are naked, and seated upon a scale. The stamens are 6 in number, hypogynous; filament slender; anthers continuous with the filament, having 2 lobes bursting longitudinally; the ovaries are 4, containing one or more ovules; style short; stigma simple; the seeds are few, with an abundant albumen, in the midst of which lies a small embryo, which is inclosed in a persistent vitellus.

These plants are very near *Piperaceæ*, from which they mostly differ in the compound nature of their ovary. This order connects Dicotyledons with Monocotyledons. Its foliage, stipules, and seeds connect it with the former; but the floating habit of some of the species, and their general character, ally them with some of the families of the latter class. They are natives of North America, China, the north of India, and the Cape of Good Hope, where they are found growing in marshes and pools of water. Their properties are not

well known, but they seem to be the representatives of the peppers in colder climates; and on account of their less exposure to light, their secretions are not so strong, and their properties not so active, as their allies in the tropics.

a, branch, with leaves and spikes of flowers; b, a naked flower seated on its bract; c, transverse section of fruit; d, section of fruit, showing the seed, with large albumen and the embryo in its permanent sac; e, the seed.

SAURY. [Esos.]
SAUSSUREA, a genus of Composite Plants belonging to the sub-order *Cynarocephaleæ*. The florets are all hermaphrodite and tubular; the anthers with ciliated setæ at the base; the involucre is imbricated and unarmed, the receptacle scaly; the pappus in 2 rows, the outer one consisting of short rough bristles, the inner one feathery.

S. alpina has a stem from 3 to 12 inches high, erect, downy, and simple, terminating in a small corymb of heads with pinkish florets and purple anthers; the leaves are nearly glabrous above, cottony beneath, the lower ones ovate-lanceolate, the upper ones sessile-lanceolate, all distantly-toothed, the heads in a dense corymb, the involucre subcylindrical, with depressed hairy scales. This is the only British species. It is found in alpine situations.

(Babington, *Manual of British Botany*).
SAUSSURITE, a Mineral, also called *Axe-Stone*, *Jade*. It occurs massive. Cleavage parallel to the faces of a rhombic prism. Fracture splintery. Hardness 5·5. Extremely tough. Colour greenish and grayish-white. Streak white. Lustre pearly, inclining to vitreous on the faces of cleavage. Nearly opaque, but translucent on the edges. Specific gravity 3·2 to 3·4. Before the blow-pipe it fuses with difficulty into a white glass. It was discovered on the edge of the Lake of Geneva by Saussure in rounded masses. It has also been found in Styria, Corsica, and at Madras. Its analysis by Saussure gives:—

Silica	44
Alumina	30
Soda	6
Lime	4
Oxide of Iron	12·5

—96·5

SAUVAGEACEÆ, *Sauvageæ*, a natural order of Plants formed by Bartling, and consisting only of the genus *Sauvagesia*, of which there are six or seven species. Another genus, *Luxemburgia*, was referred to this order by Bartling, but this has been placed by De Candolle in *Frankeniaceæ*. Lindley, in his 'Natural System,' makes *Sauvagesia* a sub-order of *Violaceæ*, from which, he observes, it is principally distinguished "by the stamens being opposite the petals, by the anthers not having a membranous termination, by the presence of five hypogynous scales, and by their fruit having a septical dehiscence, so that the seeds adhere to the edges and not the centre of the valves, and by the strongly-ribbed and imbricated calyx." This last character gives them a relation to *Hypericaceæ*, but from this order they differ in their parietal placentæ and the presence of stipules. They are natives of the tropical parts of South America, growing in moist meadows and the vicinity of streams. The genus *Sauvagesia*, named after the celebrated physician Sauvages, is characterised by possessing 3 rows of petals; the outer petals 5, ovate or oblong, spreading, deciduous; the intermediate ones filiform, variable in number; the interior 5 opposite the outer, erect, converging into a tube much smaller; calyx deeply 5-parted, and a capsule inclosed in

the permanent floral organs, more or less deeply 3-valved and many-seeded. One of the species, *S. erecta*, Upright Sauvagesia, is held in great repute as a medicine in South America. It is very mucilaginous, and has a bitter taste. It is used in Brazil in diseases of the eye, and in Peru and the West Indies it is employed in slight inflammatory affections of the mucous membranes of the bladder and intestines.

- SAUEGARDE. [TEIDE.]
- SA'VACOU. [BOAT-BILL.]
- SAVI'GNIUM. [CIRRIPEDIA.]
- SAVIN. [JUNIPERUS.]
- SAW-FISH. [SQUALIDÆ.]
- SAWWORT. [SERRATULA.]
- SAXI'CAVA. [LITHOPHAGIDÆ.]

SAXICOLA, a genus of Insectorial Dentirostral Birds belonging to the family *Sylviadæ*. Three British species belong to this genus as now constituted, the Stonechat, the Wheatear, and the Whinchat. This genus has the following characters:—Beak straight, slender, the base rather broader than high, surrounded with a few stiff hairs; the superior ridge of the upper mandible prominent, the sides towards the point compressed; the point itself curved and indented. Nostrils basal, lateral, oval, half closed by a membrane. Wings: the first quill-feather about half as long as the second; the second shorter than the third or fourth, which are the longest in the wing. Feet: the tarsus rather long, three toes in front, one behind; the outer toe connected by a membrane to the middle toe; claw of the hind toe short, strong, and curved. (Yarrell.)

S. rubicola, the Stonechat. This is the Traquet Rubicole and Moteux Traquet of the French; Saltabastone, Zompa-cardi, and Saltinpalo of the Italians; Schwarzeckhler Steinschatzter of the Germans; Clochder y Cerrig of the Welsh; and Stonechatter, Stonesmith, Stonesmich, Stoneclink, and Moor-Titling of the English.

The old male in summer plumage has the head, throat, back, and small coverts of the wings perfect black; but each feather very finely bordered with ruddy brown; a great white spot on the sides of the neck, on the upper part of the wings, and on the rump. Breast deep ruddy, lower parts very bright ruddy; wings brown bordered with brighter brown; base of all the tail-feathers white, the rest of a blackish brown. Length 4 inches 4 or 5 lines.

Male after the Autumnal Moul. —Wider ruddy borders at the end of the feathers on the throat; those of the nape and the back fringed with large borders of that colour; breast bright ruddy, the rest of the lower part of the body clear Isabella colour; wider borders on the quills, and the end of the tail ruddyish.

Stonechat (*Saxicola rubicola*).

Lower figure, male; upper figure, female, in perfect plumage.

Female.—Upper parts blackish brown with borders of yellowish ruddy; wings and tail-feathers brown bordered with yellowish ruddy; throat black, with small whitish and ruddyish spots; the white space on the sides of the neck and of the upper part of the wing less extended; ruddy colour of the breast less vivid.

Young males before their second moult like the old female.

Young at their Departure from the Nest.—Feathers of the upper parts grayish brown; all terminated by a small whitish spot.

After the autumnal moult all the individuals have brown ash-colour on the head and the back; this colour occupying solely the fine points of the barbs, they by exposure and friction cause in the spring the black colour of the middle of the feathers to appear. (Temm.)

It is found in Russia, Germany, France, Provence, Italy, Smyrna, Japan, the Decan, the banks of the Ganges, the mountain-chain of Upper Hindustan, Senegal, and South Africa (Cape). England, Ireland, and Scotland.

Though several of this species remain through the winter months, the general body quit the British Islands in autumn, nor do they return till the spring is forward; seldom appearing on our heaths and commons, dappled with furze and bushes, before the end of March: but March is often bleak; and when the winds blow roughly, they quit these open spots for the shelter of the snug lanes and groves. Still however the open tracts are their favourite haunts, and, wind and weather permitting, there they are to be seen almost ever in motion, now on a stone, now on a bush, from which they dart to seize the passing insect and then return. Although their song, which is given on the wing, is short, it is pleasing; and they are in a degree mocking-birds, being no bad imitators of the song of others. Besides insects, worms are acceptable food to them; and for these they may be frequently seen foraging on the ground.

The nest, which is of considerable size in proportion to the bird, is framed in the beginning of April on the ground or some dwarf bush. Externally it is fabricated of moss and grass; and a few fine bents, hairs, and feathers form the lining. The eggs, which are laid from the middle of April to the third week in that month, are pale-blue with somewhat of a grayish tint, finely dotted with obscure reddish-brown at the large end.

When the young are hatched—that is, about the middle of May—the old Stonechats become very bold. They make a constant clamour, and put in practice many a ruse to deceive the schoolboy and draw him from their nest.

S. ananthe, the Wheatear (*Motacilla ananthe*, Linn.; *Vitiflora* of Belon and Brisson). It is the Moteux, Vitrec, and Cul-blanc, of the French; Codo-Bianco, Culo-Bianco, Fornarella, Petagnola, Culbiano, and Codetta d'Estate, of the Italians; Steinschwatz, Steinschnapperl, Graurückiger, Steinschmatzer, and Weisschwanz, of the Germans; Tapuit of the Netherlands; Stensquetta of the Swedes; Steendolp, Steensquette, and Steengylpe, of the Norwegians; Fallowfinch, Fallow-Chat, Fallow-Smith, Whitetail, Fallow-Smiter, Horsematch, Snorter, Stone Chacker, Chickell, and Chack-Bird, of the English; and Tinwyn y Cerrig of the Welsh.

The old male has the upper parts of the body ashy-gray; forehead, band above the eyes, and throat, white; black passing from the root of the bill below the eye and covering the orifice of the ears; wings black; rump and tail white for two-thirds of the length of the latter; the rest, towards the end, black, excepting the two middle feathers, which are entirely black; front of the neck and breast buff-colour; the rest of the lower parts pale buffy-white. Total length 6½ inches.

Female.—Upper parts ashy-brown; forehead rusty-gray; deep brown above the eye and covering the orifice of the ears; wings blackish-brown, bordered with bright brown; white at the origin of the tail, less extended; neck and breast rusty; the rest rusty-white.

Young of the Year.—At their departure from the nest, with the upper parts variegated with rusty and ash-colour, and spotted with brown; feathers of the rump white; throat and lower part of the body ruddy, dotted and finely striped with blackish-brown; wing-coverts bordered with rusty; quills and tail-feather bordered with ruddy.

The geographical distribution of this bird is very wide. Lapland, Denmark, Sweden and Norway, Iceland, and Faroe Islands.

In Europe it is abundant, particularly on the northern shores of the Mediterranean. It is found in Dalmatia and the Morea. Belon saw it flying above the bushes in Crete; Mr. Strickland noticed it at Smyrna in April; and Mr. Keith Abbott procured it at Trebizoud (40° 45' N. lat., 40° 25' E. long.)

In these islands, where it is generally diffused, the Wheatear arrives about the middle of March, and the great body have left us about the end of September, though some stragglers stay later, and have been seen as late as past the middle of November. The Hebrides, Orkneys, and Shetland are visited by them.

Insects generally, which are captured on the wing, *Coloptera* and their larvæ, and worms, form the food of the Wheatear, which generally sits on the watch upon an elevated clod or stone.

The nest is framed of dried roots and feathers, rabbit's-down, &c.; and the eggs, generally six in number, are pale-blue. The bird manifests sometimes great precaution in selecting a place for it not easily detected. Various curious positions are recorded by naturalists.

Mr. Salmon states that in Suffolk and Norfolk a deserted rabbit-burrow is usually selected for the nest, which is placed near the entrance. In such situations, he adds, the nest is sure to be discovered by the accumulation of a number of small pieces of the withered stalks of *Pteris aquilina* which the old birds amass outside the entrance. Mr. Yarrell found the nest in a fallow field under a large clod, to which his attention was drawn by a portion of its materials appearing outside the hole through which the bird passed to the hollow space within.

When the Wheatears begin to draw towards our southern counties previous to their departure, they soon fall victims to the eagerness with which they are sought as delicacies for the table. They are caught by the shepherds in traps. The numbers thus taken in the season, which commences on St. James's Day (25th July), when the traps are first opened, appear to be almost incredible. A shepherd has been known to capture 84 dozen in a day. Pennant declares that about Eastbourne about 1840 dozen were annually caught in his time. They are roasted wrapped up in vine-leaves, on account of the great tenderness of the flesh. The flavour is delicious, and it has been termed, not inaptly, the English Ortolan.

The flight of the Wheatear is smooth and rapid, but low. Its song, though heard with difficulty in the open air, is soft and sweet, often uttered while on the wing in the season of love, as the male hovers over the female, expanding the feathers of his tail.

The following quatrain appears under the figure of this species in the 'Portraits d'Oyseaux, Animaux, Serpens, etc., observez par P. Bélon du Mans':—

"L'oyseau petit, que l'on nomme Culblanc,
Cherche à se paître et à vivre de vermine
Qu'il trouve en herbe, ou que dans terre il mine:
Et a tel nemme, pour avoir le cul blanc."

Besides the Wheatear here noticed, Mr. Gould describes and figures the following as European:—The Black Wheatear (*S. cachinnans*, Temm.); the Pied Wheatear (*S. leucomela*, Temm.); the Russet Wheatear (*S. staphazina*, Temm.); and the Black-Eared Wheatear (*S. aurita* Temm.).

Wheatear (*Saxicola ananthe*). Lower figure, male.

S. rubetra, the Whinchat, Auct., *Motacilla rubetra*, Linn. This is the Grand Traquet, Traquet, Groulard, Tarler, Thyon, Semel (in Lorraine), of the French; Grosser Fliegenfänger, Gestettenschläger, and Braunkchlicher Steinschmätzer, of the Germans; Saltahastone con

la Gola Bianca and Stiaccino of the Italians; Furzechat and Blackberry Eater of the English; and Clochder yr Eithin of the Welsh.

The old male has the top of the head, sides of the neck, and upper parts of the body, blackish-brown; each feather with a wide border of rusty-yellow; above the eyes an elongated streak of white, reaching to the occiput; throat and longitudinal streak on each side of the neck pure white; front of the neck and breast fine bright rusty; a great spot on the wings and tail of pure white; extremity of tail, as well as the two middle quills, and all the shafts, blackish-brown. Length nearly five inches.

Female.—With yellowish-white wherever the male has pure white; the white space on the wing less, and all the feathers with a small brown spot; the rust of the breast is less pure, and the lower parts, as well as the upper part of the tail, are rusty white.

The young have white and grayish spots all over their plumage.

It is found in Norway, Sweden, temperate Russia, but not Siberia: all southern Europe to the Mediterranean shore: common in Smyrna in winter. (Strickland.) In the British Islands they are generally, but not numerous, diffused in the summer; have been seen in the Hebrides, but are not recorded as having visited Orkney or Shetland. They arrive here about the middle of April, but, as a general rule, depart in autumn.

The flight of the Whinchat is undulating, and it flits from hush to bush, perching on one of the topmost twigs. Furze commons are its favourite haunts. Worms, insects, small shell-molluscs, and slugs, form its principal food, but it also eats berries. The nest resembles that of the Stonechat, and is formed of dry grass stalks and a little moss, the lining being finer bents or stalks. It is usually placed on the ground.

The song is very pleasing, and resembles, according to Bechstein, that of the Goldfinch; and the bird will sing not only during the day, but in the evening, and sometimes at night.

Whinchats become, like the Wheatear, very fat in August, and, though smaller, are equally delicate for the table.

In the 'Portraits d'Oyseaux' the following quatrain is printed under the figure of this species:—

"Es summités des buissons hoche l'alle
Incessamment le Traquet ou Tarter;
Et le voyant sans cesse varier,
Comme un traquet de moulin on l'appelle."

Whinchat (*Saxicola rubetra*).

Upper figure, female; lower figure, male.

SAXIFRAGA (from 'saxum' and 'frango,' in allusion to their supposed medical virtues), a genus of Plants, the type of the natural order *Saxifragaceæ*. It is characterised by possessing a calyx, either free or partly united to the ovary, and divided into 5 segments; a corolla

NAT. HIST. DIV. VOL. IV.

consisting of 5 petals; 10 stamens, with awl-shaped filaments and roundish anthers; pistils having two styles with obtuse stigmas; a capsule with 2 beaks, 2-celled, many-seeded, opening between the beaks; the seeds upon a receptacle attached to the dissepiment.

Of the species 24 are British. They are mostly inhabitants of alpine and subalpine regions of the colder and temperate parts of the northern zone. They are most of them true rock plants, and send forth their roots between the crevices of the rocks on which they grow.

S. umbrosa, London-Pride, or None-so-Pretty. Calyx reflexed; leaves undivided, obovate, with sharp cartilaginous teeth, tapering gradually into a broad foot-stalk which varies in length; scape from 9 to 18 inches high, erect, panicle, red and hairy, with a few small scattered entire bracts; flowers numerous, with obtuse petals, white or flesh-coloured, beautifully spotted with yellow near the base, and dark red towards the extremity; capsule superior, purplish. This plant was found by Tournefort on the hills of Spain, and is a native of Great Britain and Ireland. It is one of the most popular of garden flowers, blossoming in April and June, and attaining perfection even amidst the smoke of London. In Ireland it is known by the name of St. Patrick's Cabbage.

S. Geum, Kidney-Leaved Saxifrage. Calyx reflexed; leaves undivided, roundish, kidney-shaped, sharply toothed, more or less hairy; foot-stalks linear, channelled; scape panicle, capsules superior. This species is found on mountains in the south of Ireland, and is considered by some botanists as only a variety of the former.

S. granulata, White or Granulated Meadow Saxifrage. Calyx spreading; radical leaves, kidney-shaped, on long footstalks, obtusely lobed; those of the upper part of the stem nearly sessile, acutely lobed; stem panicle, root consisting of numerous small clustered tubers. This plant is found in Great Britain, and, though not common, is abundant on gravelly soils. The roots of this species, forming as they do little granular masses, were at one time sold in the shops under the name of Saxifrage Seed.

SAXIFRAGA'CEÆ, *Saxifragæ*, a natural order of Plants belonging to the apocarpous group of Polypetalous Exogens. It consists of shrubs and herbaceous plants with single alternate leaves without stipules. The calyx consists of five sepals more or less united at the base; the petals are equal in number to the lobes of the calyx, and alternate with them. The stamens are perigynous, 5-10 in number; anthers 5-celled; they have an hypogynous or perigynous disco; the ovary is inferior, or nearly superior, consisting of two carpels, which cohere more or less by their face at the base, but diverge at the apex; 1- or 2-celled, with a parietal or central placenta. They have no styles, and the stigma is sessile on the tops of the lobes of the ovary. The seeds are numerous, very minute; the embryo is taper, lying in the axis of fleshy albumen. The genus *Parnassia* belonging to this order differs in having four parietal placentæ, which are opposite the lobes of the stigma. [*PARNASSIA*.] The genus *Heuchera* has irregular flowers and stipules.

Saxifraga granulata.

a, entire plant; b, calyx cohering to the carpels, with perigynous stamens c, longitudinal section of flower, showing the half superior ovary and ovules attached to central placenta, with the relation of the stamens to the petals.

This order is most nearly allied to *Rosaceæ*, but it differs in its many-seeded partially-united carpels, its albuminous seeds, and in its not possessing stipules. The habit of *Saxifragaceæ* allies them to *Caryophyllaceæ*, but they differ in the character of their placentæ, the situation of the embryo, and other points. This order also approaches

Crassulaceae, but *Saxifragaceae* are distinguished by possessing a less number of carpels, and by the absence of glands at the base of the carpels. They are for the most part mountain plants, chiefly remarkable for the delicacy and beauty of their flowers, which are usually white. They inhabit the mountainous districts of Europe and the northern parts of the world, and constitute the chief beauty of the vegetation in high alpine stations.

The whole order is represented by De Candolle as possessing astringent properties. The *Heuchera Americana* is remarkable for its powerful astringency, and is used in medicine under the name of the North American Alum-Root. [HEUCHERA.] *Chrysosplenium* is reputed to possess both sperient and diuretic properties; but these cannot be very powerful, as it is used in the Vosges as a salad, under the name of *Creason de Roché*. [CHRYSOPLENIMUM.]

SAXIFRAGE. [SAXIFRAGA.]

SAXIFRAGE, GOLDEN. [CHRYSOPLENIMUM.]

SCABBARD-FISH. [TENOIOIDES.]

SCABIO'SA (from 'scabies,' the Latin word for scab or itch, which disorder the common sort is said to cure), a genus of Plants belonging to the natural order *Dipsaceae*. The inner calyx consists of 5 bristles, the outer one is membranous and plaited; the receptacles scaly. The fruit nearly cylindrical, with 8 excavations; the corollas 4-5-cleft, with 4 stamens. The species are perennial or suffrutescent herbs with variable leaves.

S. succisa, the Devil's-Bit, has an abrupt root appearing as if it were bitten off at the end, the heads of the flower and fruit nearly globose; the outer calyx hairy, 4-cleft; the lobes ovate acute; the inner calyx consisting of 5 bristles. The corolla is 4-cleft; the lower leaves toothed, the upper ones entire; the stem and both sides of the leaves hairy or glabrous. The flowers are dark violet or purple, varying to flesh-colour and white. It is a native of Europe to the Caucasus, and is very plentiful in Great Britain. In cultivation the plant becomes much more branched than in a wild state. In days of superstition it was fabled that the devil, envying the good this plant might do mankind, bit away part of the root, and hence its common specific name. According to Bergen, the root is astringent, and an infusion of it is bitter, but not unpleasant. A strong decoction of it was formerly an empirical secret for gonorrhoea. Linnæus says the dried leaves are used to dye wool yellow or green. It is usually regarded as the *Πικυδρομον* of Dioscorides (4, 173), but Fraas thinks the plant of Dioscorides is the *S. Ambrosioides*.

S. Columbaria has the outer calyx membranous, plaited, and notched, the inner one of 5 nerveless bristles; the corolla 5-cleft, the radical leaves oblong, stalked, crenate, entire, or lyrate; the upper leaves pinnatifid, with linear segments. The flowers are purplish, the involucre narrow. It is a native of Europe, the Caucasus, and Siberia, and is very common on chalky soil in Great Britain. It is a very polymorphous plant.

S. grandiflora has a branched downy stem, with rather villous leaves, the radical ones oblong crenate, the cauline ones pinnatifid, with lanceolate linear spreading segments; the corollas simply radiant, of a cream-colour or white, with reddish tubes; the calyx consists of 5 reddish-brown bristles. It is a native of Barbary, Italy, and Sicily, in fields, and is worth cultivation.

(Don, *Dichlamydeous Plants*; Lindley, *Vegetable Kingdom*; Bakington, *Manual of British Botany*.)

SCABIOUS. [SCABIOSA.]

SCAD. [SCOMBERINÆ.]

SCALARIA, a genus of *Mollusca*, the species of which are called Wentletraps.

Lamarck arranges *Scalaria* between *Vermetus* and *Delphinula*.

Cuvier observes that the *Scalaria*, which he places between *Turritella* and *Cyclostoma*, have, like the *Turritella*, the spire elongated into a point; and, like the *Delphinula*, the mouth completely formed by the last whorl; this mouth is moreover surrounded by a bourrelet, which the animal repeats at intervals, so as to form a succession of step-like elevations.

M. De Blainville gives *Scalaria* its position between *Prote* and *Vermetus*.

M. Rang makes it come between *Pleurotomaria* and *Melanopsis*.

Mr. Swainson has arranged it as the first genus of his sub-family *Turbinæ*, the fourth of his family *Turbinæ*. [TURBININÆ.]

The animal is very spiral, furnished with a proboscis, two tentacles provided with a filament, and carrying the eyes upon an external convexity. Foot short and oval. Male organ very slender.

Shell subturritate, with the spiral whorls more or less close, furnished with elevated longitudinal ribs, which are interrupted and nearly trenchant; aperture round, rather small, the borders united and forming a delicate and recurved bourrelet.

Operculum horny, delicate, rather large, and pauci-spiral. (Rang.)

M. De Blainville divides the genus into the following sections:—

A. Species, the whorls of whose spire are contiguous. Ex. *S. communis*.

B. Species, the whorls of whose spire do not touch each other in any direction, or which are disjointed. Genus *Aciona*, Leach.

The first of these sections comprises the False Wentletraps of collectors, and the second those designated by them as True Wentletraps.

There are about 100 recent species of *Scalaria* known.

Species of this genus, which is marine, have been found at depths ranging from 7 to 80 fathoms in sandy mud. The True Wentletraps are found in the seas of warm climates; some of the false (*Scalaria communis*, for example) occur in the European seas and upon our own coasts. The animal exudes a purple fluid when molested. The species are found in Greenland, Norway, Great Britain, the Mediterranean, the West Indies, China, Australia, the Pacific, and the seas of Western America.

S. pretiosa (*Turbo scalaris*, Linn.; *Aciona scalaris*, Leach).—The shell conic, umbilicated, contorted into a loose spire, pale-yellow, with white ribs, the whorls disjointed and smooth, the last ventricose. It is found in the East Indian seas; China.

Precious Wentletrap (*Scalaria pretiosa*).

a, front, showing the mouth; b, back; c, view showing that the whorls are disconnected.

This elegant shell, so much sought after by collectors, was known among the French as the *Scalata*, *La Vraie Scalata*, and *Le Vritable Escalier*; among the Germans as the *Rechte Wendeltreppe*, among the Dutch as the *Oprechte Wendeltrap*; among the Belgians as the *Wendeltrap*, and to the English as the *Wentletrap*, *Wendeltrap*, and *Royal Staircase*. The specific name given to it by Lamarck was at one time well deserved on account of its rarity and the great price which a fine specimen would bring in the market, especially when it exceeded two inches in height: such a specimen has been sold in former days for 2400 livres, or 100 louis! But those times are gone by; the shell is no longer rare, and good specimens only fetch shillings where they once brought pounds. A very fine example however still commands a considerable sum. That in Mr. Bullock's museum, supposed to be the largest known, brought 27l. at his sale, and was, in 1815, estimated at double that value.

S. communis (*Turbo clathrus*, Linn., the Common Wentletrap) has the shell turrited, imperforate, white or pale fulvous; the ribs rather thick, smooth, and suboblique. There is a variety of this species with the shell rather longer, rosy-violaceous, and with purple-spotted ribs. Length of the common variety about 16 lines, of the rosy-violaceous variety 17½ lines. (Lam.)

Common Wentletrap (*Scalaria communis*).

a, front; b, back; c, operculum; d, shell and animal.

The number of fossil species of *Scalaria* is also about 100. They are found from the Coral Rag upwards.

SCALD-FISH. [PLEURONECTIDÆ.]

SCALE MOSSES. [JUNGERMANNIACEÆ.]

SCALOPS. [SORCIDEÆ.]

SCALPELLUM. [CIRRIPEDIA.]

SCAMMONY. [CONVOLVULUS.]

SCANDIX, a genus of Plants belonging to the natural order *Umbelliferae*. It is known by the margin of its calyx being obsolete or obscurely 5-toothed; petals obovate, emarginate, and mostly furnished with an inflexed point; fruit with a very long beak, separable into two parts, each with 5 blunt equal ribs, the furrows without vittæ; seed squarely convex, with a deep furrow in front. This genus is composed of annual herbs, with square rather striated stems, bi-pinnate leaves, the leaflets divided into linear lobes. The umbels have few rays. The involucra are wanting or composed of one leaf.

S. Pecten Veneris, the Common Shepherd's Needle, or Needle Chervil, is a native of Europe and the North of Africa, and is very plentiful in the cultivated fields of Britain. It is known by its involucres possessing jagged leaves, and its nearly smooth fruit with a bristly-edged beak. It possesses slightly acrid and aromatic qualities, and is supposed to be the *Σκάνδιξ* of Dioscorides, which was used as a potherb by the Greeks.

One of the species of this genus, *S. cerefolium*, the Garden Chervil, is now referred to the genus *Anthriscus*. [ANTHRISCUS.] It was formerly much cultivated in gardens. It is known by its twice-pinnate leaves, with channelled footstalks, stem slightly hairy at the joints, umbels sessile, either axillary or opposite the leaves; fruit somewhat furrowed, not ribbed, smooth. It is a native of the South of Europe.

SCANSO'RES, Mr. Vigors's name for an order of Birds comprising the families *Ramphastide*, *Psittacide*, *Picide*, *Certhiade*, and *Cuculide*. [RAMPHASTIDÆ; PSITTACIDÆ; PICIDÆ; CERCITIDÆ; CUCULIDÆ.]

SCAPHIDURI'NÆ. [STURNIDÆ.]

SCAPHITES. [CEPHALOPODA.]

SCAPHODUS, a genus of Fossil Fishes. [FISH.]

SCAPOLITE, a Mineral, also called *Chelmsfordite*, *Paranthine*, and *Wernerite*. It occurs crystallised and massive. Its primary form is a square prism. Cleavage parallel to the lateral faces and the diagonal planes of the primary form. Fracture uneven, conchoidal. Hardness, easily scratches fluor-spar and sometimes apatet. Colour white, gray, green, reddish, violet. Lustre vitreous; translucent, opaque. Specific gravity from 2.612 to 2.724. When strongly heated by the blow-pipe it swells up and fuses into a brilliant white enamel. *Scapolite* occurs in Sweden, Norway, Finland, and North America.

The analysis of the mineral from Pargas by Nordenskiöld, gives—

Silica	43.83
Alumina	35.43
Lime	18.96
Water	1.03

—99.25

Nuttallite, *Meionite*, *Dipyre*, *Gehlenite*, *Somervillite*, and *Mellilite* are varieties.

SCAPTEIRA, Fitzinger's name for a genus of *Pristidactyle* *Cælodont* Saurians (Lacertian or Autosaur Lizards) of Duméril and Bibrou.

SCARABÆIDÆ, a very extensive group of Coleopterous Insects, forming the chief part of the section *Lamellicornes*. The Scarabæides of Latreille were regarded by Linnæus as a genus, but this great naturalist being acquainted with 87 species only, whilst the various collections at the present time contain together about 3000, it is natural that entomologists should have sought for characters among the species of this immense group by which they might be divided into sections; hence we find in the works of Fabricius (Linnæus's pupil) the present group raised to the rank of a family, and subdivided into several genera. These genera are however but few in number compared with those instituted by modern entomologists, which amount to nearly 200.

The Scarabæides (or *Scarabæidæ*) are distinguished from the other section of *Lamellicorn* Beetles (the *Lucanidæ*) chiefly by the structure of their antennæ, which are proportionately shorter; the basal joint being of moderate size, that is, but little longer than those which follow it [COLEOPTERA, vol. ii., col. 64, fig. 9]; whereas, in the *Lucanidæ*, the basal joint is usually very long, and often nearly as long as all the other joints taken together [COLEOPTERA, fig. 13], the latter forming in their natural position an angle with the first joint. The club with which the antennæ terminates also generally differs considerably in form. In the *Scarabæidæ* it is most usually composed of three leaf-like joints, but sometimes the number is increased to seven, as in the Common Cockchafer (*Melolontha vulgaris*); and these joints, when the insect is at rest, are closely applied together, and form either an elongated or rounded knob, which is bent at an angle with the basal joints. In those species which have the club rounded the two outer joints are stouter than the others, and have the external surface convex and the internal concave. In the *Lucanidæ* the terminal joints are produced in front at an angle with the axis, but are less expanded, and generally more distinctly separated and shorter than in the *Scarabæidæ*. The more typical species of the *Lucanidæ* moreover are remarkable for the great development of the mandibles in the male sex. The Common Stag-Beetle (*Lucanus Cervus*) affords a familiar example of this family.

Latreille divides the *Scarabæidæ* into six sections, to which he applies the following names:—*Coprophagi*, *Arctocoli*, *Xilophili*, *Phyllophagi*, *Anthobi*, and *Melitophili*.

The *Coprophagi* have the antennæ generally composed of eight or nine joints, the three last of which form the club; the labrum and the mandibles are membranous and hidden, and the lobe with which the maxillæ are terminated is also of the same texture; it is broad and curved inwards. The terminal joint of the maxillary palpi is always the largest, and either approaches to an oval form, or is nearly cylindrical; but the terminal joint of the labial palpi is almost always more slender than the preceding joints, and often very small. Behind the last-mentioned palpi is a small membranous protuberance. The mentum is emarginate, and the claws of the tarsi are always simple.

To this group belong the Dung-Feeding *Scarabæi*, and these are for the most part of a black colour, or black and brown. Some few species however are adorned with brilliant metallic colours. They are usually of a short and broad form; in some the body is somewhat depressed, and approaches to a square form; the head is large, broad, and flattish, and has numerous notches in front; the fore legs are very broad and deeply notched on the outer side, and are moreover remarkable for the want of tarsi to the anterior pair of legs, and the absence of a scutellum. To this section belongs the Sacred Beetle of the Egyptians, the *Scarabæus sacer* of Linnæus. It is about one inch long, or rather more, and of a black colour. This species is not only found in Egypt, but is met with in the south of France, Spain, and Italy, and, as well as other species of the group to which it belongs, incloses its eggs in a ball of excrement, which it forms by rolling the substance by means of its hind legs. The size of the ball, when completed, is much larger than that of the insect, being sometimes as much as one inch and a half in diameter.

In other species of the *Coprophagi* the body is convex, and although short, slightly inclining to a cylindrical form. A great portion of these have the head armed with an erect horn in the male sex, and the fore part of the thorax truncated or slightly concave, elevated in the middle, and not unfrequently produced at the sides into short stout pointed horns, as in the genus *Copris*. In a closely-allied genus (*Phanoxys*), the species are usually adorned with brilliant colours. These insects have often a very long horn on the head, or this is sometimes replaced by two short horns; the thorax has a concavity in front, and usually has an angular protuberance on each side of the disc. These insects are usually of moderate size, and sometimes large, but there are two extensive groups of *Coprophagi* the species of which are small; they constitute the genera *Onthophagus* and *Aphodius*. In the former the body is short and subdepressed; the thorax is nearly as large as the elytra, and has a concavity in front, and a protuberance in the middle of the posterior boundary of this cavity; the head is usually armed with a small horn, which is directed backwards and upwards. In the *Aphodii* the body approaches to a cylindrical form and the head and thorax are destitute of horns.

Of the genera mentioned, we possess no British examples of the first, or *Scarabæus* proper (or *Atenuchus*, according to some authors). The species of this group are confined to the warmer parts of the Old World. The species of the genus *Copris*, *Onthophagus*, and *Amphodius*, are of universal distribution, if we except Australia, where we are not aware that the first of these genera occurs. The species of *Phanæus* are almost entirely confined to the warm parts of South America, the only exceptions occurring in North America.

The species of the second great section of the *Scarabæidæ* (the *Arenicoli*) are distinguished by their having the mandibles horny and usually projecting; the lobe of the maxillæ is straight; the terminal joint of the labial palpi is always distinct, and nearly as long as the pre-celling; the antennæ have ten or eleven joints; they are moreover distinguishable from other *Scarabæi* (the species of *Aphodius* excepted) by their elytra being extended over the apex of the abdomen. The three principal genera in this section are *Geotrupes*, *Bolboceras*, and *Trox*. The species of *Geotrupes* are usually of moderate size, of a black colour, often tinted with blue or green, and usually brilliant beneath. The body is convex, and the head and thorax are rarely furnished with protuberances. They are almost entirely confined to Europe, North Asia, and North America. They feed upon the excrement of cattle, under which they construct their burrows. Several species are found in England, and some are seen in great abundance flying about the roads towards the evening.

In *Bolboceras* the body is nearly hemispherical; the males are often provided with an erect horn on the head, and protuberances on the fore part of the thorax. The species are usually of moderate size, and appear to be found in all the temperate and warm parts of the globe. Only one species is found in this country.

The species of the genus *Trox* are also usually of moderate size, and are found in all parts of the globe. In these insects the body is convex, and remarkable for the roughness of the upper parts; they are always of a dull brown or grayish colour, and appear as if covered with a coating of dried earth. Their food (according to Latreille) consists of the roots of vegetables, but they will also eat decayed animal substances, and in this respect differ from other *Scarabæi* the habits of which we are acquainted with.

The *Xylophili* have the antennæ 10-jointed, the mandibles laterally exposed; the maxillæ are various. It embraces the larger forms of the genus *Scarabæus*, as the *S. Hercules*, which is the largest insect known. The genus *Dynastes* also belongs here. [DYNASTES.]

The *Phyllophagi* have the antennæ 8-10-jointed; mandibles hidden by the clypeus and maxillæ; club of antennæ sometimes 7-5-jointed. This division embraces the *Anoplognathidæ* and *Melolonthidæ*. [MELOLONTHIDÆ.]

The *Anthobii* have their labium produced, the mandibles corneous, the maxillary lobe membranous. The species live upon flowers or leaves. They embrace the genera *Glaphyrus*, *Anthicoma*, *Anthipna*, *Chasmatopterus*, *Chasme*, and *Dicheles*. None of them are found in Great Britain. They inhabit the southern parts of Europe, and the warm parts of both hemispheres.

The *Meliophili* are distinguished by their mandibles being membranous. They embrace three families, the *Trichiidæ*, the *Goliathidæ*, and the *Cetoniadæ*. The species of the first family are rare in England. The *Goliathidæ* embrace the gigantic beetles belonging to the genus *Goliathus*, and commonly called Goliath Beetles. The *Cetoniadæ* are perhaps the most important insects of the group. [CETONIADÆ.]

SCARBROITE, a Mineral—a Hydrated Silicate of Alumina. It occurs massive. Its fracture is conchoidal. Hardness about 2.0. It is easily scratched by the knife, and polished by the nail. Adheres to the tongue, and has a strong earthy smell when breathed upon. Colour white. Opaque. Dull. Streak shining. When put into water it does not become transparent, nor fall to pieces, but increases in weight. Specific gravity 1.48. It occurs in veins in the beds of sandstone covering the calcareous rock near Scarborough, between septa of oxide of iron. Its analysis by Vernon gives—

Silica	7.90
Alumina	42.75
Water	48.55
Oxide of Iron	0.80

—100.

SCARITIDÆ, a family of Coleopterous Insects belonging to the section *Geodephaga*, which section corresponds to the genera *Carabus* and *Cicindela* of Linneus. The *Scaritidæ* have the prothorax separated from the elytra by a narrow cylindrical neck; the mandibles are usually large, and armed with strong teeth on the inner side; the labrum is small; the mentum is furnished with a tooth; the antennæ are usually short, and have the basal joint long; the legs are short; the anterior tibiae are broad, and strongly notched on the outer side, and fitted for burrowing; and the anterior tarsi in the males are not dilated. The body is usually elongated, and straight at the sides; the head, thorax, and elytra, are nearly equal in width. The principal genera contained in this family are *Scarites*, *Parimachus*, *Campodontus*, *Acanthocles*, *Clivina*, and *Dischirius*.

In *Scarites* (Fabricius) the mandibles are strongly toothed on the inner side, the second and third joints of the antennæ are obconic, and the following joints are shorter, compressed, and subquadrate.

The species of this genus are very numerous, and are found in nearly all the temperate and warmer portions of the globe.

The species of the genus *Parimachus* differ chiefly from *Scarites* in being proportionately broader, and of a somewhat depressed form; in having the thorax produced on each side behind, and forming distinct angles; the mandibles are shorter and more arched, and the maxillæ have no terminal acute hook. The species of this genus are peculiar to North America, and are of a tolerably large size, averaging about one inch in length.

Dejean separates from *Scarites*, under the generic name *Oxygnathus*, the *S. elongatus* of Wiedemanu, which differs in having the mandibles more slender and elongated, and destitute of teeth on the inner side. The only known species is found in the East Indies; it is of a very narrow form.

Campodontus is another genus founded by Dejean upon a single species. In this insect the labial palpi are decidedly shorter than the external maxillary palpi; and, like them, are terminated by a spindle-formed joint; the basal joint of the antennæ is scarcely longer than either of the following joints. It inhabits Guyana.

The genus *Acanthocles* is established by Latreille upon a singular insect found at the Cape of Good Hope; it is of a short and broad form, and has the anterior tibiae still more strongly notched than in the species of *Scarites*; the tibiae of the middle and hinder pair of legs are stout, curved, and concave on the inner side, and very rough and covered with short spines on the outer side. The thorax is broader than long, and the elytra are almost equal in length and width, distinctly striated, and rounded at the apex. This insect is of a black colour (as are almost all the *Scaritidæ*), and about three-quarters of an inch in length.

The species of *Clivina* are of small size, averaging about a quarter of an inch in length, and nearly cylindrical form. The basal joint of the antennæ in these insects is scarcely longer than the others, the mandibles are comparatively short, and the terminal joint of the palpi is pointed. They are found nearly all over the world; they live under stones, and frequent damp situations.

In the genus *Dischirius* the species also have a wide geographical range, and are of small size; indeed the smallest of the present family: they are very nearly allied to *Clivina*, but are almost invariably adorned with metallic colours, usually brassy-green. The terminal joint of the labial palpi is proportionately stouter than in *Clivina*; the thorax usually approaches to a spherical form, and the tibiae are less strongly notched. Numerous species of this genus are found in England, the largest of which is less than a quarter of an inch in length. They are always found on the wet mud on the margins of ponds and such places.

SCARUS. [LABRIDÆ.]

SCATTER-TUFT. [ALGÆ.]

SCAUP-DUCK. [DUCKS.]

SCELIDOTHEIUM. [MEGATHERIIDÆ.]

SCELOTES. [SCINCIDÆ.]

SCEPA/CEÆ, a small natural order of Plants belonging to the rectemphyrose group of Incomplete Exogens. The plants of this order are trees having alternate coriaceous leaves, with membranous stipules, which form the scales of the bud. The flowers are dioecious; the males are arranged in catkins, the females in short axillary racemes. The calyx is inferior, 4-, 5-, 6-leaved, in one or two whorls; stamens 2-5, with 2-celled anthers; ovary with 2 cells, in each of which there are 2 ovules; no style; stigma with 2 short emarginate lobes or 4-fringed ones; seeds single or two, enveloped in a succulent aril; embryo green, in the axis of albumen. These plants are allied to *Cupulifera* and *Betulacea* in their amentaceous flowers, but their arillate albuminous seeds and dehlcent 2-celled pericarp distinguish them from these as well as any other orders to which they may seem to have relation. They are natives of the tropical parts of India. The wood of one of the species, *Lepidostachys Roxburghi*, or *Kokra*, is used in India for various economical purposes on account of its hardness.

SCHIELITE. [TUNGSTEN.]

SHELLY, a local name for *Gwyniad*, the *Coregonus fera*.

SCHIELTOPUSIK. [ZONURIDÆ.]

SCHERERITE, or SCHEERERITE, a Mineral occurring in acicular crystals and small translucent layers. Colour white or yellowish-white. Lustre pearly. Devoid of taste or smell; is very friable. It melts at 112° Fahrenheit, and distils at 194°. It is insoluble in water and alkaline solutions, and in alcohol unless it be heated, but it dissolves in ether and oil of turpentine. When exposed to fire it inflames, and is entirely dissipated, with a somewhat aromatic smell.

It occurs in beds of lignite at Uznach, near St. Gall in Switzerland and also at Bagh in the same country.

According to Macaire Prinsep it contains—

Hydrogen	24.0
Carbon	73.0
	—97.0

SCHEUCHZER. [AMPHIBIA.]

SCHEUCHZERIA, a genus of Plants belonging to the natural order *Alismacea* and the sub-order *Juncaginæ*. The perianth is composed of 6 leaves; it has 6 stamens with slender filaments. The ovaries

with 2 ovules. The stigma adnate to the ovary and downy. The capsules compressed and inflated, 1-2 seeded.

S. palustris is the only known species of this genus. It has a stem from 6 to 8 inches high, the leaves are distichous, few, alternate, semi-cylindrical, obtuse, and with a minute pore on the upper side at the apex. The raceme is terminal, and consists of about five greenish flowers. The capsules about three, and much inflated. It is found in England and Scotland in bogs.

(Babington, *Manual of British Botany*.)

SCHIEFER SPAR, Slate Spar, Foliated Carbonate of Lime, a Mineral occurring massive. Its structure is laminar, the laminae being thin and generally curved, wavy or undulating. It yields easily to the knife. Its colour is white, reddish, yellowish, or greenish. Streak white. Lustre pearly on the surface of the laminae, and vitreous on the edges. Translucent. Specific gravity 2.740. It is almost entirely soluble in acids with effervescence. It occurs in Cornwall, Scotland, and Ireland. It has the following composition:—

	Sursee.	R. Phillips.
Carbonate of Lime	95.33	98.118
Silica	1.66	00.050
Oxide of Iron	1.00	00.800
Water	2.00	Water and loss 1.032
	99.99	100.00

SCHILLER SPAR, a Mineral occurring crystallised. Its primary form an oblique rhombic prism. Cleavage parallel to the lateral planes and both the diagonals. Fracture uneven. Hardest, scratches calcareous spar, is scratched by quartz. Colour olive, blackish, grayish, yellowish-green. Lustre metallic. Nearly opaque; translucent on the edges. Specific gravity 2.692.

When exposed to a strong heat it becomes hard, and forms a mass resembling porcelain.

Found at Baste in the Harz, at Zöbletz in Saxony, in Piedmont, Cornwall, &c. It occurs generally in Serpentine.

An analysis of the mineral from Baste by Vauquelin gives—

Silica	62.00
Alumina	13.00
Magnesia	10.00
Lime	0.00
Oxide of Iron	13.00
	98.00

SCHIST, an Argillaceous Rock of a coarse laminated structure. [SLATE.]

SCHIZANDRA (from *σχίζω* and *ἀνδρῆς*), a genus of Plants belonging to the natural order *Schizandraceae*. The flowers are monœcious; sepals 9; no petals; the male flowers having 5 anthers, which are joined at the apex; female ones with an indefinite number of ovaries; berries arranged in spikes along an elongated receptacle.

S. coccinea, the Scarlet Schizandra, is one of our most beautiful greenhouse climbers. It has alternate oval-lanceolate leaves, pointed at both ends, rarely toothed, of a beautiful green, smooth above, and pale beneath; scarlet flowers disposed in spikes in the axils of the leaves. It is a North American plant, and is found in woods in Georgia, Florida, and Carolina.

SCHIZANDRACEÆ, a natural order of Exogenous Plants, consisting of trailing shrubs, with alternate exstipulate leaves, allied to *Anonaceæ*, but differing in their habit, their unisexual flowers, their imbricate aestivation, and their homogenous albumen. The stamens are often monadelphous, and the fruit consists of numerous baccate carpels. There are twelve known species, which occur in India, Japan, and the hotter parts of North America. They abound in an insipid mucus, and the fruit of some is edible. (Balfour, *Class-Book of Botany*.)

SCHIZOCARP. [FRUIT.]

SCHIZODESMA (Gray), a genus of *Mollusca* belonging to the family *Macluridae*.

SCHIZODON. [HYSTERICIDÆ.]

SCHIZODUS (Sowerby), a genus of Fossil *Conchifera*.

SCHIZOPODA. [STOMAPODA.]

SCHIZOPTERIS. [COAL-PLANTS.]

SCHIZOSTOMA (Brown), a genus of Fossil *Gasteropoda*.

SCHLEICHERA, a genus of Plants belonging to the natural order *Sapindaceæ*. It has a 5-toothed calyx. Petals absent; the disc occupying the bottom of the calyx. The stamens 6-10, inserted between the margin of the disc and the ovary. The ovary is 3-celled, with one erect ovule in each cell. The stigma 3-cleft. The fruit is an indehiscent drupe, with 1, 2, or rarely 3 cells. The seeds are solitary in each cell, and covered with a pulpy arillus; the embryo much curved. The species are trees; the leaves abruptly pinnate, the leaflets nearly opposite. The flowers are small, disposed in spike-like racemes.

S. trijuga has abruptly pinnate leaves from 8 to 16 inches long, the leaflets 2-4, opposite, sessile, broad, lanceolate, or oblong-entire, rather smooth on both sides the lower pairs, the smallest from 3 to 8 inches long. The petioles are a little downy, the stipules wanting. The racemes are axillary, or below the leaves round the base of the young shoots, solitary, in the male simple, in the hermaphrodite often compound, from 2 to 4 inches long. In the male flowers the calyx is cup-

like, and 5-toothed. The corolla wanting, the filaments 6-10, erect, and many times longer than the calyx. The anthers oval and erect; the pistil a mere rudiment. The hermaphrodite flowers on a separate tree. The calyx, corolla, and stamens as in the male flower. The disc a fleshy yellow ring, surrounding the insertions of the filaments. The ovary superior, ovate, 3-celled, with one ascending ovule in each cell. The style short, stigma 3-cleft, recurved, slender, and downy. The drupe about the size of a nutmeg, a little pointed, covered with a tender gray dry pericarp. The seeds are oblong, and surrounded with a whitish pulpy aril, which is of a pleasant acid taste, and most grateful during dry weather. It is a native of insular and continental India, where the astringent bark, mixed with oil, is used as a remedy for the itch.

(Lindley, *Flora Medica*; Lindley, *Vegetable Kingdom*.)

SCHMIEDELIA (in honour of Casimer Christopher Schmiedel, once a professor at Erlangen), a genus of Plants belonging to the natural order *Sapindaceæ*. It has a 4-parted unequal calyx, 4 petals, the 5th or superior one wanting. The disc incomplete, with 4 glands opposite the petals, 8 stamens inserted in the receptacle, and connate around the ovary at the base. The fruit is indehiscent, 1-, 2-, or rarely 3-lobed. The lobes roundish, fleshy, or dry, and 1-seeded. The seeds with or without an arillus. The species are trees or shrubs, usually with trifoliate, rarely with simple exstipulate leaves, and racemose white flowers. The racemes are axillary.

S. serrata has ternate leaves, the leaflets ovate, pointed, serrate, generally blistered, smooth on the back, and from 2 to 3 inches long. The racemes axillary, single, and erect. The flowers small, white, and polygamous. In the hermaphrodite flower the calyx is 4-leaved, and the petals 4, unilateral. The filaments very woolly near the base. The fruit is small, red, and succulent, and is eaten by the natives of Coromandel. The root is astringent, and is employed by the native practitioners in diarrhoea.

S. Cochinchinensis has its leaves on long petioles, with serrated leaflets, terminal racemes, pilose small petals. The flower is small and white. It is a native of Cochinchina, on the banks of rivers. The leaves are used as cataplasms in contusions.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica*.)

SCHOBERIA, a genus of Plants belonging to the natural order *Chenopodiaceæ*. It has a 5-parted perianth, without appendages, 5 stamens springing from the receptacle, and from 2 to 3 stigmas. The pericarp is membranous, the seed horizontal, the testa crustaceous.

S. fruticosa has an erect shrubby stem, with obtuse semi-cylindrical leaves, 3 styles, and smooth shining seeds. It is found on the south and east coasts of Great Britain.

S. maritima is found on the sea-shore in England. It has a procumbent stem, with numerous spreading branches, acute-semicylindrical leaves, 2 styles, with reticulate, striate shining seeds.

(Babington, *Manual of British Botany*.)

SCHOENANTHUS. [SPIKENARD.]

SCHOENUS, a genus of Plants belonging to the natural order *Cyperaceæ*. The spikelets are 2-ranked, 2-4-flowered. The glume 6-9, the lower one small and empty. Bristles few or wanting.

SCHÆPIA, a small genus of Plants belonging to the natural order *Lorantheæ*, named after Schöpf, a German botanist, who described the plants in the neighbourhood of Ulm. The genus is characterised by having the flowers hermaphrodite, margin of the calyx entire, tube adnate to the ovary, very narrow, caliculate at the base. Corolla tubular, united into one piece; limb 5 rarely 4-6 cleft. Stamens equal in number to the lobes of the corolla, and inserted before them into the tube of the corolla. Anthers ovate or roundish, dehiscing laterally by a double chink; style erect; stigma capitate or 3-lobed; ovary 3-celled, with an ovule in each. Leaves alternate, petiolate, entire, feather-nerved. Peduncle axillary, usually many-flowered. The genus *Schæpia* is found in the West Indies and in the Andes of Peru, also in the Pundua Mountains near Lower Assam, and in Nepaul, thus being common to both the Old and New World.

SCHOPS. [STRIGIDÆ.]

SCHORL. [TOURMALINE.]

SCHORLOMITE. [YTTRIUM.]

SCHRÖTTERITE, a Mineral resembling *Allophane*.

SCIENIDÆ, a family of Acanthopterygious Osseous Fishes, of which the genus *Sciæna* is the type. They are closely allied to the Perches, and resemble them in their general characters, but differ in having no teeth on the vomer and palatines. The preopercle is denticulated; the opercle is armed with spines; the bones of the face and head are often cavernous, forming a protruding snout.

The *Sciænidæ* are divided into those having two dorsal fins and such as have only one. A single species of *Sciæna*, the Maigre (*S. aquila*), occasionally wanders from the seas of southern Europe into our own. *Umbina vulgaris* is common on the coasts of Italy, France, and Spain, but not on our own. *Hamulon*, *Pristoma*, *Diagramma*, and *Amphiprion* are some of the many genera belonging to this family.

SCIÆNURUS. [FISH.]

SCILLA, or **SQUILLA**, a genus of Plants belonging to the natural order *Liliaceæ*. It has 3 sepals coloured and spreading; petals very like them, and scarcely broader; stamens 6, shorter than the perianth, filaments smooth, somewhat dilated at the base, acuminate, entire

ovary 3-parted, glandular, and melliferous at the apex; style smooth, simple; stigma obscurely 3-lobed, papillose; capsule rounded, 3-cornered, 3-celled; seeds numerous, in two rows, flattened with a membranous testa.

S. maritima, Squill, is found near the coast of the Mediterranean, in Portugal, and the Levant. It has a roundish ovate very large bulb, between globose and ovate, half above the ground, with the integuments either pale-green or red; leaves appearing long after the flowers, broad, lanceolate, channelled, spreading, recurved; scape about two feet high, terminated by a rather dense, long, ovate raceme; flowers about three-quarters of an inch across, spreading, pale yellowish-green, with a green stain along the middle of each segment; filaments shorter than the segments of the perianth. The bulb contains *Scillitin*, a very active medicinal agent. They are very acrid, and capable of vomiting. Squills are used as an emetic and expectorant.

S. Pancræon is found near Cadiz, at Malta, and probably other parts of the Mediterranean. The bulb is about half the size of the last species, pale-green or whitish-green, occasionally red. The leaves much shorter, more acute, erect, and narrower; stem more glaucous. Flowers smaller, more compactly arranged, with shorter bracts; flower-stalks shorter; flower-bud more blunt. In its effects this species is like the former, but milder.

S. Indica is found on the sandy shores of various parts of India. It has a round white perennial bulb, tunicated, about the size of a large apple; leaves numerous, radical, sub-bifarious, ensiform, nearly flat, smooth on both sides, from 6 to 18 inches long. When in blossom the plant is perfectly destitute of leaves; scape erect, round, smooth, naked, including the raceme from 2 to 3 feet long; raceme very long, erect; flowers remote, long, pedicelled, drooping. This species is supposed by Dr. Roxburgh to possess the same qualities as *S. maritima*. (Lindley, *Flora Medica*.)

SCINCIDÆ, SCINCROIDIANS, or LEPIDOSAURS, the names given by Gray, Oppel, Fitzinger, and Messrs. Duméril and Bihron to a family of Saurians.

This family, observe Messrs. Duméril and Bihron, seems to establish a sort of connection with or transition to the great division of Serpents, by the intervention of certain species, such as those of *Anguis* and *Acontias*. It is, they remark, a group of Lizards, whose numerous races are found spread over the most arid regions of temperate climates, as well as those where the temperature is always very high.

They join to the general character of the Saurians many peculiarities which distinguish them from the other families of that order. Thus, their cranium is covered with great plates, joined together at their edges, most frequently angular, whose sutures or lines of junction always remain distinct. Their trunk is completely covered with scales, more or less large and solid, of variable form, but always disposed like a coat of mail, placed quincuncially, and overlapping each other like tiles or slates, nearly like those of the greater part of the osseous fishes. The *Scincida* have besides the tongue free, fleshy, not of much thickness, slightly notched at the point, and covered totally or partially with scaly papillæ. Their belly is cylindrical, without lateral folds, and covered with scales, having the same disposition, and, in general, the same form as those of the back.

All these characters suffice to distinguish the *Scincida* from the whole of the other families. The great angular plates which are applied on the bones of the head and face are never seen in the *Chameleontidæ*, the *Gekkotidæ*, the *Crocodilidæ*, the *Varanidæ*, nor in the *Iguanidæ*. They are, it is true, found in the *Lacertidæ* and in the *Chalcididæ*, but the first have always the scales of the belly different from those of the upper part of the trunk, and in the others, besides the disposition of the horny lamellæ so as to form verticillations or transverse rings, there is most frequently a fold on their sides throughout their length, from the cranium to the origin of the tail.

The form and the mode of insertion of the tongue, which in one part is free, or not attached by its circumference to the concavity of the lower jaw, serve to distinguish the *Scincida* from the *Crocodilidæ*; on the other hand, as the tongue of the *Scincida* cannot be withdrawn into a sort of sheath, this conformation removes them from the *Chameleons*, which have the tongue very long, cylindrical, and terminated by a concave and viscous tubercle. The same conformation serves to separate the *Scincida* from the *Varanidæ*, which have this organ endowed with capability of re-entering into a sheath, at the same time that its free extremity is deeply divided into two points. Finally, the tongue of the *Scincida* is not free, or disengaged from adhesion at its point only, as in the *Gekkotidæ* and the *Iguanidæ*. The lateral walls of the trunk are not hollowed with a longitudinal furrow, as in the *Chalcididæ*, and the skin of the belly below is not furnished with plates with four principal faces, or with quadrilateral scales more or less elongated, and larger than those of the back, as may be observed in the True Lizards.

Messrs. Duméril and Bihron thus sum up the essential characters of the Reptiles which compose this family:—

1. Head covered above by horny plates, which are delicate, angular, and opposed to each other (affrontées) by their faces (pans) in a singular manner.

2. Neck of the same form and size as the breast.

3. Trunk and limbs entirely clothed with imbricated scales, with

many faces (pans), most frequently widened, and with the border slightly rounded, disposed quincuncially, back rounded, without crests or elevated spines, belly cylindrical, without any groove or lateral furrow.

4. Tongue free, flat, without a sheath, slightly notched in front, the surface covered entirely or partially with papillæ, ordinarily all in the form of scales, but occasionally some are squamiform and others filiform.

Cocteau presented in 1837 to the French Academy his great table of the classification of this extensive group. These 'Tahulo Synoptice Scincoideorum' formed the prodromus only of an extensive work undertaken for the classification of the species which belong to three of the tribes of the family which Cocteau named *Cyrrilepida*, or those covered with scales after the manner of a carp.

Messrs. Duméril and Bihron give the following synoptical analysis of this great work:—

Tetradactylus, *Seps*, *Siaphos*, *Heteromeles*, *Chelomeles*.

CYRILEPIDS	{	Podotes . . .	{	Tetrapodes . . .	{	Sauropthalmes.
		Apodes . . .		Dipodes . . .		Ophiophthalmes.
SAUROPTHALMES	{	Saurolites . . .	{	Teleodactyls . . .	{	Scincoids . . .
				Ateleodactyls . . .		Heterodactyls . . .
	{	Ophiolites . . .	{	Omodactyls . . .	{	<i>Heteropus</i> .
						<i>Champsodactylus</i> .
OPHIOPHTHALMES	{	Saurolites . . .	{	Teleodactyls . . .	{	<i>Tetradactylus</i> .
						<i>Tridactylus</i> .
	{	Ophiolites . . .	{	Ateleodactyls . . .	{	<i>Ablepharis</i> .
						<i>Gymnophthalmus</i> .
TYPHLOPHTHALMES.	{	Ophiolites . . .	{	Heterodactyls . . .	{	<i>Lerista</i> .

Messrs. Duméril and Bihron, like Cocteau, divide their Scincoidians or Lepidosauris into three great divisions:—1, Sauropthalmis; 2, Ophiophthalmis; and 3, Typhlophthalms; with the following genera, which are subdivided according to the conformation of the feet, toes, tail, rostral plate, muzzle, teeth, nostrils, and tongue:—

1. Sauropthalmis.—*Tropidophorus*, *Trachysaurus*, *Cyclodus*, *Scincus*, *Sphenops*, *Gongylus*, *Diploglossus*, *Amphiglossus*, *Heteropus*, *Champsodactylus*, *Tetradactylus*, *Hemiergis*, *Seps*, *Nessia*, *Heteromeles*, *Chelomeles*, *Brachymeles*, *Brachystopus*, *Evesia*, *Scelotes*, *Prapeditus*, *Ophiodes*, *Anguis*, *Ophiomorus*, *Acontias*.

2. Ophiophthalmis.—*Ablepharus*, *Gymnophthalmus*, *Lerista*, *Heteropus*, *Lialis*.

3. Typhlophthalms.—*Dibamus*, *Typhline*.

The following is Dr. J. E. Gray's arrangement of the genera of his family *Scincida*:—

1. Scales thin, smooth, not striated nor keeled. Nostrils in a single smooth plate, without any lunate groove behind. Tail round, tapering, unarmed.

A. Toes depressed, fringed on the sides. Head wedge-shaped. Rostral depressed, keeled in front. Nostril in the middle of the upper edge of the nasal, with a triangular supranasal above the rostral. *Scincina*.

1. *Scincus*.—Body fusiform, flat below. Toes 5-5.

B. Toes compressed, simple. Head subquadraugular. Rostral erect, triangular. Nostril in the middle of a shield.

a. Supranasal plate none.

* Body fusiform. Lower eyelid covered with scales; fronto-parietals, two.

2. *Minulia*.—Head subquadraugular. Heel surrounded with granules.

3. *Keneuxia*.—Head depressed in front. Rostral and labials low. Heel with a flat oval plate behind.

4. *Elania*.—Head conical. Rostral rather produced. Heel surrounded with granules.

** Body fusiform. Lower eyelid with a transparent disco.

5. *Mocca*.—Rostral erect, triangular. Palate toothless.

6. *Leilopisma*.—Rostral erect, triangular. Palate toothed. Parietal plates 2, large, square.

7. *Lipinia*.—Rostral depressed, large. Head flattened. Nasa lateral, square.

*** Body and tail cylindrical, elongate. Limbs 4, weak, far apart. Rostral erect, rounded. Fronto-nasals distinct.

† Toes elongate, unequal.

8. *Lygosoma*.—Toes 5-5. Lower eyelid scaly.

9. *Ristella* (?).—Toes 4-5. Lower eyelid — (?) Supranasal — (?)

10. *Tetradactylus*.—Toes 4-4, the third longest, the fourth short. Lower eyelid transparent.

11. *Hemiergis*.—Toes 3-3, unequal, middle one rather longest. Lower eyelid transparent.

12. *Chelomeles*.—Toes 2-2, unequal. Lower eyelid transparent.
 ++ Toes short, thick, subequal.
 13. *Omolepida*.—Toes 5-5, rather short, subequal. Lower eyelid scaly. Ear deep, simple in front.
 14. *Podophis*.—Toes 5-5, short, subequal. Lower eyelid scaly. Frontoparietal single.
 **** Body and tail cylindrical, elongate. Limbs rudimentary or wanting. Rostral rather produced; frontonasal very small, lateral. Head half conical.
 15. *Siaphos*.—Legs 4. Toes 3-3, very short, the middle longest.
 16. *Rhodona*.—Legs 4; fore legs rudimentary, undivided, clawless; hinder with 2 short, unequal, clawed toes.
 17. *Soridia*.—Legs none.

b. Supranasal plates 2, rarely 4 or 6.

- * Body fusiform. Tail tapering. Limbs strong. Supranasals 2.
 18. *Plestiodon*.—Lower eyelid scaly. Scales large. Body fusiform. Palate toothed. Frontoparietal double.
 19. *Eumeces*.—Lower eyelid scaly. Scales large. Body and tail elongate. Palate toothless. Frontoparietal double.
 20. *Otosaurus*.—Lower eyelid scaly. Scales small. Body fusiform. Palate toothless. Frontoparietal double.
 21. *Mabouya*.—Lower eyelid transparent.
 ** Body and tail elongate, subcylindrical. Legs 4, short. Toes compressed, unequal. Supranasal 1 pair.
 22. *Riopa*.—Toes 5-5, unequal.
 23. *Agria*.—Toes 5-4, unequal.
 24. *Chiamela*.—Toes 4-4, unequal.
 *** Body and tail elongate, subcylindrical. Legs 4, very short. Toes very short, subequal or rudimentary. Supranasals 1 pair.
 25. *Senira*.—Toes 5-5, rounded, thick, very short.
 26. *Brachymeles*.—Fore feet very short, with two very short toes; hinder tapering, undivided.
 **** Body and tail elongate, subcylindrical. Legs 2, posterior, or none. Supranasals 2 or 3 pair.
 27. *Ophiodes*.—Legs 2, on side of vent, undivided.
 28. *Anguis*.—Legs none external.

- II. Scales thick, hony, rugose, striated, or 1 or more keeled. Rostral rounded in front. Body fusiform. Limbs 4, strong. Toes 5-5, compressed.

- C. Tail compressed, keeled above. Scales of the tail keeled, spinose, of the body smooth. Head-shields rugose, closely applied to the skull. Temples shielded. Lower eyelid scaly. Preanal plates few, large.
 29. *Tribolonotus*.—Tail with 4 spinose keels above, and spinose on the sides. Preanal plates 2, large.
 30. *Tropidophorus*.—Tail with 4 spinose keels above, smooth on the sides. Preanal plates 3, large, central triangular.
 31. *Norbea*.—Tail with 2 close rows of keeled scales above, smooth on the sides. Preanal plates single, square, very large.
 D. Tail rounded, tapering, rarely spinose, not keeled above, thick, bony, rugose, or 3 or 5 keeled, rarely smoothish.

* Supranasal shields none.

- † Lower eyelid scaly. Toes 5-5. Nostril with a curved groove behind it.
 § Toes short, thick, subequal. Scales rugose, unarmed. Orbit with a series of plates beneath.
 32. *Trachydosaurus*.—Tail short, thick, depressed, truncated. Body fusiform. Scales very thick, rugose. Ears lobed in front.
 33. *Cyclodus*.—Tail moderate, round, tapering. Body fusiform. Scales moderate, subequal. Ears lobed in front.
 §§ Toes elongate, compressed, unequal. Scales 1-5-keeled. Orbits simple.
 34. *Silubosaurus*.—Tail short, depressed, spinose. Scales 1-keeled.
 35. *Egernia*.—Tail elongate, round, tapering, spinose. Scales 1-keeled, dagger-pointed.
 36. *Tropidolepisma*.—Tail elongate, round, tapering, armed. Scales 3- or 5-keeled, slightly toothed behind. Frontal short.
 37. *Lardella*.—Tail elongate, tapering, unarmed. Scales 2-keeled. Frontal very long.
 ++ Lower eyelid scaly. Toes 5-5. Nasal plate flat, without any groove behind it.
 38. *Ateuchosaurus*.
 +++ Lower eyelid transparent. Toes 4-5. Nasals — (?).
 39. *Heteropus*.—Tail and body elongate, subcylindrical. Scales 3-keeled. Legs weak. Ears — (?).
 ** Supranasals 1 pair. Scales moderate, 3-5-keeled. Palate toothed.
 40. *Dasia*.—Lower eyelid scaly. Toes dilated at the base.
 41. *Tiliqua*.—Lower eyelid scaly. Toes compressed the whole length.
 42. *Euprepis*.—Lower eyelid transparent. Ears ohlong, lobulated

in front, or covered with the scales of the temple. Toes compressed the whole length.

E. Tail round, tapering, unarmed, not keeled above. Scales minutely striated, and sometimes 1-keeled. Supranasals 2 pair.

43. *Microlepis*.—Body fusiform. Head depressed. Tail elongate, compressed.

44. *Celestus*.—Body fusiform. Tail tapering. Head depressed. Internasal and frontonasal united into 1 shield. Claws short.

45. *Camalia*.—Body fusiform. Tail tapering. Head square. Internasal and frontonasal separate. Claws broad, blunt.

46. *Diploglossus*.—Body and tail cylindrical, elongate.

The species of this family are spread over nearly the whole world, but they are found in greatest abundance in Australia. The locality of certain *Scincidæ* is far from being limited to any particular country of the globe: *Gongylus ocellatus*, *Seps chalcides*, *Anguis fragilis*, and *Ophiomorus miliaris* live in the south of Europe and in the north of Africa. The *Plestiodon quinquelineatus*, which was believed to be peculiar to North America, is found also in Japan; the *Lygosoma Quoyi*, *L. Labillardieri*, and many species of *Eumeces* are races common to Oceania and Australia; and, what is still more worthy of the attention of naturalists, *Ablepharus Kitaibelii* exists in Hungary, Greece, and Australia, whilst *A. Peronii* is found in both the two last countries equally, and also in the Mauritius and South America.

Europe possesses *Gongylus ocellatus*, *Seps chalcides*, *Ablepharus Menestriesii*, *A. Kitaibelii*, and *A. Peronii*, *Anguis fragilis*, and *Ophiomorus miliaris*.

Africa, with all these species except *Ablepharus Menestriesii* and *A. Kitaibelii*, produces 18 others, among which *Amphiglossus Goudotii* is a native of Madagascar, and *Ablepharus Peronii* and *Leiolopisma Telfairi* are natives of the Mauritius.

Seventeen species are peculiar to Asia, and three others, one of which is also found in America and the other two in Polynesia.

Fourteen Scincoidians are natives of America, and of America only; and there are two others, one of which, *Plestiodon lineatus*, also inhabits Asia, and the other, *Ablepharus Peronii*, Europe, Africa, and Australia.

Polynesia possesses 36 species, peculiar to itself, and to these must be added *Ablepharus Kitaibelii*, which is found also in Europe and in Asia; *A. Peronii*, which occurs also in Asia, Africa, and America; and *Lygosoma Quoyi* and *L. Labillardieri*, which belong also to Asia.

There is not a single Scincoidian whose geographical range is confined to Europe.

The genera *Scincus*, *Sphenops*, *Amphiglossus*, *Leiolopisma*, *Brachysotopus*, *Scelotes*, *Acontias*, and *Typhline*, are peculiar to Africa; and *Tropidophorus*, *Champsodactylus*, and *Brachymeles*, to Asia. The genera *Diploglossus*, *Ophiodes*, and *Gymnophthalmus*, are composed of American species exclusively; and *Tropidolepisma*, *Cyclodus*, *Trachysaurus*, *Heteropus*, *Tetradactylus*, *Hemiergis*, *Chelomeles*, *Nessia*, *Evesia*, *Prepeditus*, *Hysteropus*, *Lialis*, *Lerista*, and *Dibamus*, belong to Polynesia.

The sub-genus *Gongylus*, as well as the genera *Seps*, *Anguis*, and *Ophiomorus*, are common to Europe and Africa. *Eumeces* and *Lygosoma* are spread over Asia, America, and Polynesia. *Euprepis* is found in Africa, Asia, and Polynesia; *Plestiodon* in Africa, Asia, and America and *Ablepharus* in Europe, Asia, Africa, America, and Polynesia.

We now proceed to illustrate some of the forms of this numerous group, from the division of Saurophthalms.

Tropidophorus, Dum. and Bihr. (*Leposoma*, Cuv., not Spix).

T. Cocincinensis. Upper part of the body brown-yellow, or inclining to olive, banded on the neck and back with much deeper brown, disposed so as to represent great X placed one after the other. On the tail are spots, more or less large, of deep brown; and there is a row of whitish points along the lower region of the sides.

It is a native of Cochin China. (Dum. and Bihr.)

Tropidophorus Cocincinensis.

a, Head, seen from above; b, profile; mouth open to show the tongue.

Scincus. Fitzing.

S. officinalis, the Common Skink. Messrs. Duméril and Bibron remark that this species includes three varieties, which are very distinct in the colouring of their upper parts; for in all cases the lower and lateral regions, that is to say, the cheeks, the sides of the neck, those of the tail, as well as the sides, and very often the limbs, are of a silvery-white, more or less pure.

a. General colour of the neck, back, and tail, yellow, or clear silvery-gray, mixed with brown or blackish, which forms great spots dilated transversely, most frequently putting on the shape of transverse bands, the number of which is commonly seven or eight.

b. A yellow tint spread over the surface of the cranium. Neck, back, and a great part of the tail, chestnut-brown, sprinkled with very small obscure whitish spots, two or three on each scale. Across the back five or six large white bands, with an irregularly dilated black spot at each of their extremities. These spots are not situated on the back, but on the most elevated part of the lateral regions of the trunk.

c. All the scales of the neck, back, and first half of the upper surface of the tail, silvery-gray, widely radiated with white, with one or two brown spots on the posterior border of the radiations.

This species appears to be peculiar to Africa, inhabiting the western and northern parts, but particularly the latter. Bruce met with it in Syria and in Abyssinia. M. Rüppell observed it in the last country, and many travellers have seen it in Egypt, whence the greater portion of specimens with which collections are furnished are sent. It is at present rather common in Upper and Middle Egypt, and it appears from Belon and Rondeletius that it was there found abundantly in the 16th century, when it still was an object of commerce. In truth it was one of the most approved remedies in the ancient Pharmacopœias, and was considered a sort of universal medicine, a specific against all kinds of maladies. Pliny ('Nat. Hist.' xxviii. 8) proclaims the medicinal and renovating powers of the *Scincus*, and quotes Apelles for its efficacy against wounds inflicted by poisoned arrows.

The better opinion seems to be that this is the *Σκῆνος* of Dioscorides and the *Scincus* of Pliny; and though the descriptions given by the ancients are not sufficiently accurate to enable us to pronounce positively on its identity, enough remains in tracing its history downwards to render it highly probable that such is the fact.

Scincus officinalis. Five-ninths of natural size.

a, fore foot, seen from above.

Sphenops, Wagler.

S. capistratus. Colour ferruginous-gray, more or less yellow, or brownish on the upper parts. From 9 to 13 longitudinal stripes composed of so many successions of black points placed on the lateral borders of the scales. These stripes, which spring on the occiput and the posterior region of the temples, run along the neck, the back, and the tail throughout its whole length, or nearly so. The upper surface of the limbs presents also generally rows of black points. The scales are also fringed with brown. On the sides of the head is a small black band commencing at the nostril, passing upon the eye, traversing the temple, and losing itself upon the neck. The lower parts of the animal are white.

Head of *Sphenops capistratus*.

This species is widely spread in Egypt, the only country known to Messrs. Duméril and Bibron where it has yet been found. M. Rüppell and M. A. Lefebvre sent specimens—the last-named traveller the most

abundantly—to France, and M. Lefebvre informed Messrs. Duméril and Bibron that it was very common in the oasis of Bahrieh, at Zabou, Qasr, and Bahouet. He brought home more than a hundred individuals which he captured himself. Both M. Lefebvre and Cocteau state that the animal only burrows to a small depth, for the slightest disturbance made by the feet of the passer-by discovers its retreat.

Diploglossus, Wieg. (*Celestus*, part., *Tiliqua*, part., Gray).

D. Sagræ. Form resembling that of *Seps* in the slenderness of the body, the length of the tail, and the shortness of the limbs; colour brown-ash, with metallic reflections on the upper parts of the head, trunk, tail, and limbs, more or less deep in different individuals; on each side of the body a black band which springs on the frenal region passes on the eye and temple, extends the whole length of the side, and loses itself on the side of the tail, at some distance from its origin; the labial plates are yellowish, bordered with black, and the lower regions have also a yellowish tint, but with silvery reflections.

It is a native of Cuba, where it lives on land in cool places and light and humid lands. It is very quick in its motions.

Head of *Diploglossus Sagræ*. Mouth open to shew the tongue.

Gongylus, Dum. and Bibron.

G. ocellatus. The form of this species is heavy and stout, and it varies greatly in colour. Messrs. Duméril and Bibron record five varieties.

It is the *Scincus ocellatus* of authors; *Tiliqua ocellata*, and Lacépède's Galleywasp of Gray.

This species is spread over the whole of the shores of the Mediterranean; but it is in Sicily, Sardinia, Malta, Cyprus, and Egypt that it is especially found. Messrs. Quoy and Gaimard captured a specimen in the Isle of Teneriffe, and it is said to have been found in the south of France; but Messrs. Duméril and Bibron are not sure of this.

Dry and slightly elevated spots are chosen by this Skink, and there it hides itself in the sand or under stones. Its food consists of small insects, which it seizes after the manner of the true Lizards. It suffers itself to be caught without defending itself; and though its movements are not so rapid as those of the Lizards, it possesses more agility than its form would lead one to expect.

Gongylus ocellatus. Five-ninths of natural size.

Seps, Daudin (*Zynias*, Oken, Fitzing., Wieg.

S. chalcides, Bonap. Form slender and serpentine. Messrs. Duméril and Bibron enumerate six varieties. In all of them the lower parts are more or less grayish or whitish.

Seps chalcides.

The south of France, Italy, all the islands of the Mediterranean, Spain, and all the Mediterranean shore of Africa, claim this species as a resident. It is viviparous, and lives upon worms, small terrestrial molluscs, spiders, and, in short, all kinds of insects.

Acontias, Cuvier.

A. melagris. It is a native of South Africa; very common near the Cape of Good Hope. [MELEAGRIS; BLINDWORM; SEPSIDÆ.]

Head of *Acontias*.

a, seen from above; *b*, profile; *c*, the same view, with the mouth open to show the tongue.

SCINCOIDÆ, SCINCOIDEA, SCINCOIDÆ, SCINCOIDIANS.
[SCINCIDÆ.]

SCINK, or SKINK. [SCINCIDÆ.]

SCIRPUS, a genus of Plants belonging to the natural order *Cyperaceæ* and the tribe *Scirpeæ*. It has fertile nearly equal glumes; the lower ones are perhaps the largest, and one or two of them empty. The bristles are either absent, or about 6 in number. The nut is plano-convex, or trigonous, tipped with the filiform not dilated base of the style.

S. maritimus has stalked or sessile spikes in a dense terminal cluster, several foliaceous bracts, bifid glumes, with an intermediate point; acute segments and a trigonous smooth nut. The stem is from 1 to 3 feet high, and leafy. It is found in salt-marshes in Great Britain, and is much relished by cattle. Withering says that the roots of this species are esculent, and have been ground down and used instead of flour in times of scarcity.

S. lacustris, Bullrush, has a round stem from 4 to 6 feet high, naked, with one or two long sheaths at the base, the spikes in a terminal twice compound panicle; the glumes are emarginate, mucronate, glabrous, and fringed. The nut obtusely trigonous and obovate; stigmas 3. The panicle is not lateral, although the bract closely resembles a continuation of the stem. It is found in rivers and ponds in England. The root is astringent and diuretic, and was once used in medicine. The leaves are employed for making matting, chair bottoms, and many other domestic purposes.

S. triquetra has a stem acutely triquetrous throughout, flat or concave between the angles, with one or two long sheaths at the base, the upper one terminating in a very broad triquetrous leaf. The spikes are in a small cymose panicle, the glumes emarginate, mucronate, glabrous, and fringed; the lobes rounded-obtuse, and the nut roundish-obovate, plano-convex, and smooth. This species is found on the muddy banks of the Thames, near London, and the Arun, near Amberly, Sussex.

S. Holoschænus is the *Ὀλόσχαῖνος* of Theophrastus.

S. tuberosus is the Pi-Tsi, or Water-Chestnut, of the Chinese, and is cultivated by them for food in largo tanks, which are regularly manured and the water at intervals drawn off. The tubers are eaten both raw and cooked, and are esteemed both as food and medicine. There are 14 British species of *Scirpus*, none of which however are worth description on account of any qualities they possess.

(Bahington, *Manual of British Botany*; Lindley, *Vegetable Kingdom*; Burnett, *Outlines of Botany*.)

SCISSURELLA. [TURBINACEÆ.]

SCITAMINACEÆ, a natural order of Plants embracing the *Marantaceæ*, with 1 anther-valve, and the *Zingiberaceæ* with 2 anther-valves. The separation of these orders is now generally recognised. [MARANTACEÆ; ZINGIBERACEÆ.]

SCIURIDÆ, a family of Animals belonging to the order *Rodentia* [RODENTIA], and embracing the various forms of Squirrels. It has the following characters:—Molar teeth simple, with tuberculous crowns, five above, four below, on each side; the lower incisors very much compressed. Toes long, armed with sharp claws, four on the anterior and five on the posterior feet; anterior thumb very short. Tail long and tufted. Cheek-pouches in some. In others the skin of the sides extended between the anterior and posterior limbs.

The geographic range of the Squirrels is very wide both in the Old and New World. None appear to have been discovered in Australia.

The *Sciuridæ* have been divided into two principal groups:—

A. Squirrels with free limbs.

Genera.—*Tamias*, *Sciurus*, *Macrozous*, and *Anisomyx*.

B. Squirrels with their limbs invested in the skin of the sides.

Genera.—*Pteromys* and *Sciuropterus*.

The following dentition is given by M. F. Cuvier for *Tamias*, *Sciurus*, *Macrozous*, and *Sciuropterus*:—

$$\text{Incisors, } \frac{2}{2}; \text{ Molars, } \frac{5-5}{4-4} = 22.$$

Teeth of *Tamias*, *Sciurus*, *Macrozous*, and *Sciuropterus*.

The same author has published the following modification as characteristic of *Pteromys*, the numbers of the teeth being the same with those of the genera above-mentioned.

Teeth of *Pteromys*.

Tamias (Ground Squirrels).—Skull presenting a uniform curved line on its upper part when viewed in profile, and offering, when seen below, a very slender condition of all the anterior parts. Cerebral cavity but little extended, and advancing only to one half of the skull. The species are found in Europe, Asia, and North America.

T. striatus. Upper part of the body yellow-brown, with five brown longitudinal stripes and two white ones on the upper parts; white beneath; lumbar region rusty, as well as the tail, which is blackish above, and bordered with black below. Length rather more than 9 inches, including the tail, which measures about 3 inches.

Pallas states that this Ground-Squirrel burrows in woody districts, in small hillocks, or near the roots of trees; but never makes its nest in the trunks or branches of trees, like the Common Squirrels, although, when frightened from its hole, it climbs with ease, speedily making its way from branch to branch. The nest is reached by a winding tunnel, and there are generally two or three lateral chambers, for the stowage of winter food. It is allied in its habits to the Hamster and *Citellus* (*Spermophilus*), is connected with the latter by the convexity of its nose, and has cheek-pouches; but differs altogether in its manners from the Tree-Squirrels.

Sir John Richardson remarks that the *Sciurus (Tamaia) Lysteri* of Ray, the Hlackee of the United States, Ohioin of the Hurons, Striped Dormouse of Pennant, is considered by the author of the above description, and subsequent writers, to be the same with the Asiatic *S. striatus*; but he adds that the descriptions given of the latter do not exactly correspond with American specimens, and that he is not aware that the identity of the species on the two continents has been established by actual comparison. He allows however that the observations of Pallas regarding the manners and form of the Asiatic animal apply exactly to the American one.

The Hlackee, Sir John Richardson states, is common on the north shores of lakes Huron and Superior; but he does not believe that it exists in a higher latitude than the 50th parallel. Although very wild, it is, he says, fond of establishing its abode in the immediate vicinity of man, and multiplies greatly in cultivated places. ('Fauna Boreali-Americana.')

T. palmarum is the *Mustela Africana* of Clusius; *Sciurus palmarum* of Linnaeus; and *Le Palmiste* of Buffon. Pennant thus describes the species:—"Squirrel with plain ears; an obscure pale yellow stripe on the middle of the back, another on each side, a third on each side of the belly; the two last at times very faint; rest of the hair on the sides, back, and head, black and red, very closely mixed; that on the thighs and legs more red; belly pale yellow; hair on the tail does not lie flat, but encircles it, is coarse, and of a dirty yellow barred with black. Authors describe this kind with only three stripes: this had five, so possibly they vary." Length about 13 inches, of which the tail measures 6 inches.

Very they certainly do, for Mr. Bennett has figured two marked varieties in his 'Zoological Gardens.' One was perfectly black, and exhibited no traces of the usual stripes. The other variety had red eyes, and appeared to be an albino: it was of a dull reddish-white, marked with three very faint stripes of a still lighter hue. They were presented to the Zoological Society in 1828.

The Palm Squirrels, which derive their name from being often seen on those trees, are common about Indian towns and villages, dwelling about the roofs of houses and old walls. The female lays her young in holes of old walls. They are great destroyers of fruit, but are very familiar, entering houses to pick up the crumbs. Pennant states that Governor Loten informed him that they lived much in the coco-trees, and were very fond of the *Sury*, or palm-wine, which is procured from the tree; from which it obtained, among the Indians, the name of *Suricateje*, or the little cat of the *Sury*.

T. quadrivittatus, Four-Banded Pouched Squirrel, is the Four-Lined Squirrel of Godman, and *Sasacka-Wappissee* of the Cree Indians. Head long, tapering considerably from the eyes to the end of the nose, which is not however remarkably sharp. Mouth situated far back; whiskers black and rather shorter than the head; eyes small when compared with a true squirrel; ears erect, semi-ovate, obtuse, and flat, except a slight duplicature at the base of the anterior margin; it is covered on both sides with a coat of short hair; cheek-pouches extending to the angle of the jaw. Body more slender than that of the squirrels in general. Five blackish lines and four alternating white ones occupy the whole back; sides reddish-brown, under parts gray: tail long and slender, exhibiting dusky and light-brown colours. Length 9 inches 9 lines; of which the tail measures 4 inches 3 lines.

Sir John Richardson, from whose long and accurate description the above characters are drawn, states that this diminutive Ground-Squirrel is common throughout the woody districts, as far north as Great Slave Lake, if not farther. It is found, he tells us, at the south end of Lake Winipeg, in 50° N. lat., and, within that range, seems to replace *Sciurus Lysteri*. ('Fauna Boreali-Americana.')

Sciurus (True Squirrels). A slight depression of the frontal bones, and a very slight posterior projection of the same; profile of the face very nearly straight; cranial cavity as long as two-thirds of the face. No cheek-pouches. Tail distichous.

The species are found in Europe, Asia, India and Indian Islands, Africa, North America, South America, and West Indian Islands.

S. vulgaris (the Common Squirrel). It is the *Ecureuil* of the French; *Sciojattolo*, *Schiario*, and *Schiaratto* of the Italians; *Ard*, *Ardilla*, and *Esquilo* of the Spaniards; *Ciuro* of the Portuguese; *Eichhorn* and *Eichhörnchen* of the Germans; *Inkhooon* of the Dutch; *Ikorn* and *Graskin* of the Swedes; *Ekorn* of the Danes; and *Gwiwair* of the Welsh.

The length of the Common Squirrel, including the tail (which last measures about 6 inches 3 lines), is about 14 inches 9 lines. Mr. Bell, after stating that it is liable to considerable variety of colour, becoming gray in the northern regions, and quoting the passage in 'Lachesis Lapponica,' which relates how the inhabitants of the Lapland Alps procure a number of this species in their gray or winter clothing for the sake of their skins, proceeds to remark that even in this country a certain degree of change takes place in the colour of the fur in spring and autumn. Mr. Blyth informed him of this fact. In summer the fur is coarser and more uniformly red, and the pencils of hairs on the ears are lost; in winter a grayish tint appears on the sides, the pencils on the ears are long and well developed, and the fur is softer and fuller. In July, and not till then, the summer change is perfect. It is found generally in Europe and the north of Asia.

"This animal," says Pennant, "is remarkably neat, lively, active,

and provident; never leaves its food to chance, but secures in some hollow tree a vast magazine of nuts for winter provision. In the summer it feeds on the buds and young shoots, and is particularly fond of those of the fir and pine, and also of the young cones. It makes its nest of the moss or dry leaves, between the fork of two branches, and brings four or five young at a time. Squirrels are in heat early in the spring, when it is very diverting to see the female feigning an escape from the pursuit of two or three males, and to observe the various proofs they give of their agility, which is then exerted in full force."

S. cinereus, the Gray Squirrel. Ashy-gray on the upper surface and sides, each hair being marked by alternate rings of black and gray. Inner sides of the limbs and under surface of the body pure white. Tail nearly equal in length to the body, and when thoroughly developed, completely overshadowing it. Both surfaces of the tail similar in colour to the back and sides, the under surface being somewhat lighter; the long diverging hairs ringed in such a manner as to give the appearance of an external border of white, inclosing a broad band of grayish-black. No decided tinge of brown on the muzzle, nor on the sides of the body, but a slight intermixture of that colour is visible on the muzzle on close examination. Ears covered with very short close-set hairs, without any appearance of the bushy pencils which surmount those of the Common Squirrel. Size one-third larger than the last-named species. This species is found in nearly the whole of the United States of America. It is most abundant in Pennsylvania and the Carolinas.

The nest of the Gray Squirrel, which swarms in some of the localities where it is found, is made upon the extremities of branches of trees, and its food consists of buds, tender shoots, nuts, acorns, and grain. In winter the provident animal retires to hollow trunks where its stores have been laid up. The fur is sought after in the market, but the gray skins of the Common Squirrel are considered of more value. They are exceedingly destructive to the crops, especially of maize, and were proscribed accordingly. Pennant says that three pence per head was the reward for every one killed, and that such a number was destroyed in one year that Pennsylvania alone paid in rewards 8000*l.* of its currency.

S. niger, the Black Squirrel. "So much confusion," says Sir John Richardson, "has crept into the accounts of the American squirrels, that great uncertainty respecting the species alluded to by authors must exist until some resident naturalist favour the world with a good monograph of the squirrels of that country. The black squirrels have been considered by some to be a variety of the *S. cinereus*, or of the *S. vulpinus*, and by others have been referred to *S. capistratus*. M. Desmarest describes a small black squirrel, which is distinguished from the large black variety of the masked squirrel by the softness of its fur. Pennant's black squirrel is evidently the *S. capistratus* of later writers."

The Black Squirrel, is larger than the *Ecureuil Gris* de la Caroline of M. F. Cuvier (Lesser Gray Squirrel; Pennant, 'Hist. Quad.'), and rather smaller than the Large Gray Squirrel of Catesby. It is not an uncommon inhabitant of the northern shores of lakes Huron and Superior, where the greater and smaller Gray Squirrels are never seen, and is by far the largest squirrel existing on the eastern sides of the Rocky Mountains to the northward of the Great Lakes.

It is stated that the Gray Squirrel and Black Squirrel make excellent pies; the flesh tastes like that of the rabbit, but much more juicy. The Gray Squirrel is a common dish in Virginia. It is usually hroiled, and is very palatable.

S. maximus, the Malabar Squirrel. Upper parts and external surface of the limbs bright chocolate-brown, which colour terminates abruptly, and is joined by the pale yellowish-brown on the under parts, fore-arms, and internal surface of the limbs. Front of the fore-legs, neck, throat, face, and head between the ears, lighter in colour: a broad darker patch on the rest of the upper part of the head extends from the forehead to the middle of the nose. Back and shoulders sometimes deepening into black. Ears short, covered with long tufted hairs, and brush-like; from the longer part of each ear a narrow line of deep-brown passes downwards and backwards in an oblique direction. Whiskers scanty, long, and black. Claws incurved and strong, those of the anterior thumbs broad, short, and flattened. Tail distichous, the hairs expanding widely towards the extremity, bright chocolate-brown at the base, black in the middle, and chestnut in the extreme third part. Length about 33 inches, of which the tail measures rather more than one-half. It is a native of the Malabar Coast.

Sounerat appears to have been the first zoologist who observed this richly coloured species, the largest of the true Squirrels. It haunts among palm-trees, and is stated to be very fond of the milky juice of the cocoa-nut, as well as of the solid part of the nut. In captivity it is tame and familiar; but it tries its teeth upon most substances that come within its power, and should be guarded against accordingly.

S. Getulus, the Barbary, or White-Striped Squirrel; Barbarian Squirrel of Edwards; *Le Barbareque* of Buffon. Eyes full and black, with white orbits. Head, body, feet, and tail, cinereous inclining to red: lightest on the legs; sides marked lengthwise with two white stripes: belly white; tail bushy, marked regularly with shades

of black, one beneath the other: size of the Common Squirrel. (Pennant.) It is a native of the north of Africa, especially Barbary, where it lives in trees, preferring those of the Palm tribe.

S. Cepapi. Ochrey-yellow above, slightly marbled with blackish-brown; sides of the body and feet ochrey-yellow; upper lip, superciliary stripe, and lower parts of the body white, belly tinged with yellow; tail distichous, ochrey-yellow varied with blackish-brown; ears short, with obtuse apices, the external margin notched near the point; eyes brown. Figure slender. Head small. Legs long. Tail depressed, narrow, slightly distichous, and pointed at its extremity. The tints vary in different specimens. Length 14 inches 9 lines, the tail being 7 inches long. Female resembling the male in colour and size. (Smith.) It is a native of South Africa.

Dr. Smith, who named this species, and has described and figured it in his 'Illustrations of the Zoology of South Africa,' observed it for the first time upon the immediate banks of the Limpopo River, in about 24° 20' S. lat. It was occasionally discovered upon the ground, but more frequently upon trees; and when it happened to be surprised in the former situation, it invariably endeavoured to reach the latter, and, if successful, either attempted to conceal itself in the forks of the branches, or in holes, if any existed, in the trunks or other parts. Its flight, when on the ground, was effected with amazing rapidity, and the perpendicular ascent of the tree was accomplished with equal facility. Dr. Smith concludes by stating that it feeds by day, and, according to the natives, also by night, and that in all the specimens he obtained the stomachs were fully distended with berries, &c.

Macroxus.—Frontal bones very much depressed: nasal bones but little elongated; a deep depression between the cranium and the face. Tail round. No cheek-pouches. The species are natives of Sumatra, India, Africa, and South America.

Anisomyx.—Teeth like those of the squirrels. No cheek-pouches. All the feet with five toes; the two internal toes of the anterior feet very short. Claws very long. Tail distichous. A genus, considered as not certain, established by M. Rafinesque for the reception of animals approximating to the Squirrels and the Marmots, from which they differ in the number and form of the toes. The species are natives of Columbia.

Pteromys.—Posterior part of the nasal bones a little convex; the frontal bones strongly depressed in their middle and rising slightly afterwards; the posterior parts of the head do not begin sensibly to curve downwards before the middle of the parietal bones; cerebral cavity small, only half the length of the head. The species are natives of Asia, the Moluccas, the Philippine Islands, and Java.

P. Sabrinus, var. *β. alpinus*, Rocky Mountain Flying-Squirrel. Yellowish brown above; tail flat, longer than the body, blackish-gray; flying membrane with a straight border. Length 14 inches 3 lines;

Rocky Mountain Flying Squirrel (*Pteromys alpinus*), or *Pteromys Sabrinus*, var. *β.* (Richardson, 'Fauna-Boreali-Americana.')

of which the tail, including fur, measures 6 inches 3 lines. This is the *P. alpinus* of Richardson.

Sir John Richardson observes that this animal was discovered by Mr. Drummond, on the Rocky Mountains, living in dense pine-forests, and seldom venturing from its retreats, except in the night. He had received specimens of it from the head of the Elk River, and also from the south branch of the Mackenzie. It approaches, he says, nearer to the *P. volans* of Siberia in the colour of its fur than to *P. Sabrinus*, but it has much resemblance to the latter in its form. It is, he adds, entirely destitute of any rounded process of the flying membrane behind the fore leg, and when its skull is compared with that of *P. Sabrinus*, the frontal bone between the orbits appears narrower. The size of its limbs and tail is also greater.

The habits of these animals are well described by Mr. Bennett in his account of another species. "The group to which this attractive little animal belongs," says Mr. Bennett, in his description of the American *Pteromys Volucella*, "are principally distinguished from the Common Squirrels by what is usually termed their flying membrane. This apparatus consists of a folding of the skin along either side so as to form broad lateral expansions, supported anteriorly and posteriorly by the limbs between which they are extended, and by peculiar bony processes arising from the feet. These expansions are not naked and membranous, like those of the Bats, but are actual continuations of the skin, clothed externally by a dense fur similar to that which invests every other part of the body. Neither do they serve, like the flying membranes of many of the Bats, the purposes of wings; their functions being limited to that of a parachute, giving to the animal a considerable degree of buoyancy, and thus enabling it to take leaps of almost incredible extent, through which it passes with the velocity of an arrow. The name of Flying-Squirrels is consequently founded on an erroneous assumption; but it may nevertheless be admitted as a metaphorical expression of their most distinguishing peculiarity." ('Zoological Gardens.')

Sciuropterus.—Differing from *Pteromys* in having the anterior part of the profile line of the head straight to the middle of the frontal bones, where it takes a curved direction, very much arched, without any intermediate depression. Occiput projecting; frontal bones elongated; and the capacity of the cranium comprising three-fifths of the length of the head. The species are found in Northern Asia and North America.

S. Sibiricus. It is the *Mus Ponticus* vel *Scythicus* of Gesner; *Sciurus Petaurista volans* of Klein; *Sciurus volans* of Linnaeus; *Sciurus Sibiricus volans* of Brisson; *Quadrupes volatilis Russica* of the 'Acta Petropolitana'; Polatucha and Letaga of the Russians; Polatouche of the French; König der Grauerwerke (King of the Squirrels) of the Germans; Wielviorka Lataica at the Poles; and European Flying-Squirrel and Minco of English authors. Eyes full, the lids edged with black. Membranes extending to the base of the fore feet, and forming a large wing-like expansion on each side. Tail full and rounded at the extremity. Body, above, of a fine gray colour, resembling the hue on the back of a sea-gull; beneath, pure-white. Total length about 9½ inches, of which the tail, measured to the end of the hair, is 5 inches. It is a native of Finland, Lapland, the Russian dominions from Livonia to the river Kolyma, or Kowyoua, in the north-east of Siberia.

This species haunts the woody mountainous country, feeding on the buds and fruit of the birch-trees and on the cones of the fir tribe. It is a solitary animal, and does not affect the company of others of its own kind, nor does it retire in the winter, at which season it wanders about. Its dwelling is in the hollows of trees, and its nest is generally made of moss from the birch. It raises the tail when at rest, but when it takes its flying leaps, extends that member.

S. Sagitta (*Sciurus Sagitta*, Linn.; *Pteromys Sagitta*, Geoff.). This seems to be the *Sciurus maximus volans*, seu *Felis volans*, of Brisson; Le Taguan ou Grand Ecureuil Volant of Buffon.

This squirrel has a small rounded head; cloven upper lip; small blunt ears; two small warts at the outmost corner of each eye, with hairs growing out of them; neck short. Four toes on the fore feet; and instead of a thumb, a slender bone, 2½ inches long, lodged under the lateral membrane, serving to stretch it out; thence to the hind legs extends the membrane, which is broad, and a continuation of the skin of the sides and belly; the membrane extends along the fore legs, and stretches out near the joint in a winged form: five toes on the hind feet, and on all the toes sharp compressed bent claws. Tail covered with long hairs disposed horizontally. Colour of the head, body, and tail a bright bay, in some parts inclining to orange; breast and belly of a yellowish-white. Length, from nose to tail, 13 inches; tail, 15 inches. (Pennant.)

This species inhabits Java and others of the Indian Islands. It leaps from tree to tree as if it flew; and will catch hold of the boughs with its tail. It differs in size; that described by Linnaeus was the size of our squirrel, whilst that killed by Sir Edward Michelbourne in one of the Indian islands was greater than a hare. Nieuhoff describes this species under the name of the Flying Cat, and says the back is black. He has given two very good figures of it—one in his frontispiece, the other in the page he describes it in. (Pennant.)

In the description of Pennant, above given, there are two points which deserve consideration: that which describes the animal as

catching hold of boughs with its tail, and that which states its difference in size. The first is given on the authority of Sir Edward Michelbourne's voyage, in Purchas's 'Pilgrims,' and should be received with caution. The second would lead to the conclusion that more than one species had been included under the name of the animal now under discussion.

We accordingly find that Dr. Horsfield, in his valuable 'Zoological Researches in Java,' describes two Flying Squirrels (*Pteromys genibarbis* and *P. lepidus*), both nocturnal in their habits, nearly approaching to *S. Sagitta*. He describes the first as living on fruits; the second as found in the closest Javanese forests, where the height of the trees and the luxuriance of the foliage effectually conceal it. Some have thought these two were only one species. In the work last above referred to, Dr. Horsfield has given a 'General Enumeration of Indian Sauri,' well worthy of the attention of the zoologist. He enumerates 16 species of *Sciuri*, 4 of which were first described by himself. These do not include the Flying Squirrels.

SCLERANTHACEÆ, *Sclerantha*, a natural order of Ficoidae Exogenous Plants, consisting of small inconspicuous herbs. Leaves opposite, without stipules. Flowers minute, axillary, and sessile; calyx 4-5-toothed, with a stiff tube; stamens 1-10, inserted into the orifice of the tube; ovary simple, superior, 1-seeded; styles 1-2, emarginate at the apex; ovules 1-2, amphitropal, hanging down from the point of a slender cord, which rises from the base of the ovary. This order seems to be allied to *Chenopodiaceæ*. The species occur in barren places in various parts of the world. They are all uninteresting weeds of no known use.

SCLERANTHUS (from *σκληρός*, hard, and *ἄθος*, a flower, in reference to the dry juiceless calyx), a genus of Plants belonging to the natural order *Scleranthaceæ*. It has a permanent 5-cleft calyx, with an uncorolate tube contracted at the mouth with a glandular ring; the petals are absent; the stamens inserted in the throat of the calyx. The fruit membranous, 1-seeded, indehiscent, included in the hardened calyx. The species are small herbs, with opposite linear leaves, which are rather connate at the base. The flowers are small, greenish-white, and sessile in the axils of the forks of the branches.

S. annuus, the Annual Kuawel, has subdecandrous flowers; segments of the calyx of the fruit patent acute, with a very membranous margin as long as their tube; the styles are longer than the stamens; the stem green and repeatedly dichotomous. The flower green, often solitary. It is found in sandy fields in Great Britain. The Swedes and Germans inhale the vapour arising from a decoction of this plant as a cure for the toothache.

S. perennis has decandrous flowers; the lobes of the calyx of the fruit closed, obtuse, with white and membranous edges; the styles are usually shorter than the stamens; the stem nearly simple, or irregularly branched, procumbent, and glaucous. The flowers green and white variegated. It is found in sandy places in Europe, the Levant, and in England. The Polish Cochineal (*Coccus Polonicus*) is frequently found on the roots and leaves of this plant in the summer months.

(Babington, *Manual of British Botany*.)

SCLEROCHLOA (from *σκληρός*, hard, and *χλόη*, grass), a genus of Grasses belonging to the tribe *Festucineæ*. It has unequal acute membranous glumes; the outer palea with 5 faint but distinct and parallel nerves, membranous, cylindrical below, unarched, often keeled at the tip or with a very minute mucro; the styles are terminal.

S. maritima has a branched panicle; the lowermost branches in pairs or simple; the branches alternately erect; the spikelets linear, adpressed, 4-8-flowered; the rachis terete; the outer palea obtuse, apiculate; the midrib not reaching the apex; the root stoloniferous, fibrous, with rooting or ascending scions. It is found on sea-coasts and damp places in Great Britain.

S. distans is the *Glyceria* of Smith. It has a branched panicle; the branches elongated, ultimately spreading or deflexed, the lowermost in fours or fives; the spikelets linear, 3-6-flowered; the outer palea obtuse; the midrib not reaching to the apex; the root fibrous without rooting scions. It is found on sandy sea-shores in England.

S. procumbens is known by its ovate lanceolate compact panicle; linear-lanceolate spikelets of about 4 flowers; the rachis terete, angular; the outer palea obtuse, with an apiculus formed by the extremity of the dorsal nerve; the root is fibrous; the flower large. It is found in salt-marshes in Great Britain.

There are 6 British species of this genus.

SCLERODERMI, the second family of Plectognathous Fishes (such as have incomplete and soldered jaws). The *Sclerodermi* are distinguished by their conical or pyramidal snouts, ending in a small mouth, with distinct teeth in each jaw. The skin is rough, or covered with large hard scales.

The first division of *Plectognathi* is named *Gymnodontes*. The fishes included in it have no true teeth, but a substitute in a lamellated substance resembling ivory, which covers the jaws. It includes the *Tetradon*, the *Diodon*, the *Orthogoriscus*, or Sun-Fish, and other genera. [ORTHOGORISCUS.]

The *Sclerodermi* are mostly tropical fishes, and are remarkable for their brilliant colours. One genus only occurs in the British seas, and that but very rarely; the *Balistes*, or File-Fish, is the one alluded to. The *Ostracion* is remarkable for having its body clothed in an inflexible

armour of hard plates, the tail-fins, mouth, and gill-openings, passing through holes in its coat of mail.

SCLEROTUS, a genus of Fossil Fishes. [FISIL.]

SCLEROTICA. [EYE.]

SCOLÉCITE. [NATROLITE.]

SCOLIADÆ, a family of Fossorial Hymenopterous Insects, distinguished by the following characters combined:—Antennæ thick in the females, shorter than the head and thorax; femora bent near the apex, and compressed; legs short and stout, and densely clothed with spiny hairs; the thorax is often short, and produced on each side.

The family *Scoliadæ* is thus subdivided by Latreille:—

I. Palpi always very short. Ligula with three linear divisions. Abdomen of the male terminated by three spines. Stigma replaced by a small cell. *Scolio*.

II. Maxillary palpi generally elongated. Ligula broad and expanded at the apex; a recurved spine at the apex of the abdomen in the males. Stigma distinct.

A. Second joint of the antennæ exposed; two complete cubital cells, or sometimes three, in which case the central cell is small and petiolated.

a. Without incomplete cubital cell closed by the posterior border of the wing. Radial cell either wanting or open in the females. *Tiphia*, Fab., and *Meria*, Illiger.

b. With an incomplete cubital cell closed by the posterior margin of the wing. *Tengyra*, Latr.

B. Second joint of the antennæ inclosed in the basal joint. Cubital cells four in number, of which the last is completed by the posterior margin of the wing in the males; none of them petiolated. *Myzine*, Latr.

SCOLOPACIDÆ, a family of Birds belonging to the order *Grallatores*.

The genus *Scolopax* of Linnaeus consisted of the following species:—*Guarauna*, *Madagascariensis*, *arguta*, *Phœopus*, *fusca*, *rusticola*, *Gallinago*, *Gallinula*, *Fedoa*, *Glottis*, *Calidris*, *Totanus*, *limosa*, *capensis*, *Laponica*, *Ægeophala*, *alba*, and *candida*. ('Sys. Nat.' ed. xii.)

According to Cuvier, this genus comprehends the following subgenera:—*Scolopax*, *Ibis*, *Numenius*, *Rhynchœa*, *Limosa*, *Calidris* (Cuv., *Tringa*, Temm.), *Arenaria* (Bechst., *Calidris*, Vig.), *Pelidna*, *Falcinellus*, *Machetes*, *Euryrhynchus*, *Phalaropus*, *Strepsilas*, *Totanus*, *Lobipes*, and *Himantopus*. ('Règne Animal,' ed. 1829.)

Mr. G. R. Gray divides the *Scolopacideæ* into the following subfamilies and genera:—

I. *Numeninae*.—*Numenius*, Ray; *Limosa*, Briss.; *Terekia*, Bonap.; *Erolia*, Vieill.; *Ibidorhyncha*, Vig.

II. *Totantinae*.—*Totanus*, Ray; *Glottis*, Nils.; *Guinetta*, Briss.; *Actitis*, Bonap.; *Catoptrophorus*, Bonap.

III. *Recurvirostrinae*.—*Recurvirostra*, Linn.; *Cladorhynchus*, Gray; *Himantopus*, Briss.

IV. *Tringinae*.—*Hemipalmata*, Bonap.; *Heteropoda*, Bonap.; *Tringa*, Linn.; *Machetes*, Cuv.; *Pelidna*, Cuv.; (1) *Coccyz*, Cuv.; *Euryrhynchus*, Nils.; *Ereunetes*, Ill.; *Calidris*, Ill.

V. *Scelopacinae*.—*Macrorhamphus*, Leach; *Rhynchœa*, Cuv.; *Scelopax*, Linn.; *Rusticola*, Vieill.; *Homoptilura*, Gray; *Telmatias*, Boié; *Gallinago*, Ray.

VI. *Strepsilinae*.—*Strepsilas*, Ill.

VII. *Phalaropodinae*.—*Steganopus*, Vieill.; *Phalaropus*, Briss.; *Lobipes*, Cuv.

We now proceed to illustrate the principal genera of this family:—

Scelopax.—Bill long, straight, compressed, soft, the point enlarged; the two mandibles furrowed for half their length; point of the upper mandible longer than the lower, the enlarged end forming a blunt hook; arête elevated at the base, projecting. Nostrils lateral, basal, slit longitudinally near the borders of the mandible, and covered by a membrane. Feet moderate, slender, naked space above the knee very small; three toes before entirely divided, the external and middle toe united; a hind toe. Wings moderate, first quill rather shorter than or of the same length as the second, which is the longest. (Temminck.)

S. rusticola, the Woodcock, is the Bécasse of the French; Beccaccia of the Italians; Waldschneppfe of the Germans; Holt Sneppe of the Danes; Morkulla of the Swedes; Blom-Rokke, Rutte, and Krogquist, of the Norwegians; and Cyfflog of the Welsh. It is most probable the *Σκολοπαξ* of Aristotle.

The male has the upper parts varied with ruddy, yellowish, and ash, and marked by great black spots; lower parts yellowish-red, with brown zigzags; quills striped with red and black on their external barbs; tail-feathers terminated above with gray and below with white; feet livid. Length about 13 inches.

The female is rather stouter and larger, but her colours are less vivid, and the wing-coverts have many white spots.

The distribution of this bird is very wide. The species is found in Western Lapland beyond the arctic circle, in Finland, Russia, Siberia, rarely in Germany, and more rarely in France. A few have been known to breed in Switzerland. It is very common in Italy and at

Madeira. Barbary, Athens, Smyrna, Aleppo, Egypt, Cashmere, and Japan, are other localities.

It feeds on worms, small snails or slugs, and (according to Temminck) small beetles; but earthworms appear to be its favourite nonishment. For these it bores with its long and sensitive bill with unerring certainty. The Woodcock breeds occasionally, not to say frequently, in this country, in Scotland especially. The nest is placed on the ground in a dry warm spot among herbage, and is loosely fabricated of dead leaves, of the common fern principally, and unlined.

Woodcock (*Scolopax rusticola*).

The eggs, three or four in number, are pale yellowish-white, blotched, and spotted at the larger end with ash-gray, and two shades of reddish-yellow brown, according to Yarrell; of a dirty yellow sprinkled with small spots of pale brown, according to Temminck. When surprised, the old birds have been known to carry off their young in their bills and claws.

We need hardly add that the bird, served with its trail in, is a delicious dish.

The Snipes belong to this section. Those most familiar to the English sportsman and ornithologist are the Common Snipe, the Jack Snipe, and the Solitary Snipe: Sabine's Snipe (*S. Sabini*) is of very rare occurrence, and indeed the Solitary Snipe is far from common.

S. Gallinago, Linn., *Gallinago scolopacinus*, Bonap., the Common Snipe. It is the Beccacino and Pizzarda of the Italians; Bécassine, or Bécasseau, and Chèvre Volant, of the French; Heer Schnepfe and Himels Ziege of the Dutch; Watersnep of the Netherlands; Myr Snippe of the Icelanders; Horsgök of the Swedes; Hossegioeg of the Danes; and Ysnittan y Fyniar of the Welsh.

The normal number of tail-feathers is 14, varying to 16 (Brehm's Snipe) and 12 (Delamotte's Snipe). Upper parts variegated very nearly as in the Solitary Snipe; neck and breast striped longitudinally; sides striped transversely with white and blackish; middle of the belly and abdomen spotless, pure white; base of the bill ash-colour, the rest brown; feet pale-greenish; length about 10½ inches, of which the bill measures about 2½ inches.

Head and Foot of the Common Snipe.

The colours of the plumage, after the spring moult, are brighter and

more brilliant with brouze reflections than after the autumnal moult: in winter the hue becomes more ashy.

Varieties.—Pure white; reddish-white; the feathers sprinkled or blotched with white, or some part of the plumage white.

Mr. Gould ('Birds of Europe') states that, although the contrary has been long stated by naturalists, he conceives that the natural range of the Common Snipe is comparatively limited; and that the Snipes from India, Africa, and North America, which have been regarded as identical with our bird, will be found, on examination, to be specifically distinct.

The following localities have been given as the range of the Common Snipe in Europe and Asia:—Russia and Siberia, from Scona to Lapland, Norway, Sweden, Denmark, Faroe Islands, Iceland and Greenland, Germany, Holland, British Islands, France, Spain, Provence, Switzerland, Italy, Hungary, and Illyria.

Marshes, moist meadows, and, in frosty weather, the edges of rushy rills, are the haunts of the Snipe. In such situations they have been seen pushing their bills, by means of repeated thrusts, quite up to the hase in the mud, drawing them back with great quickness, and shifting their ground every now and then. Their food consists of such worms, insects, and small molluscs as haunt such miry places, and they have been shot in the act of feeding on leeches.

Few birds are better eating than a fresh Snipe. The old quatrain says:—

"Le bécasseau est de fort bon manger,
Duquel la chair resucille l'appetit.
Il est oiseau passager et petit:
Et par son goust fait des vins bien juger."

'Snypes' were among the birds admitted to the Earl of Northumberland's table ('Household,' 1512), and were then charged at threepence a dozen.

S. major (*Gallinago major*, Bonap.), the Solitary, Double, or Great Snipe, is the Grand or Double Bécassine of the French; Beccacino Maggiore, Pizzardone, and Croccolone, of the Italians; Mittelschnepfe and Doppelschnepfe of the Germans; Poelsnep of the Netherlands; Great Snipe, Double Snipe, and Solitary Snipe, of the English; and Ysnid of the Welsh.

The tail is composed of 16 feathers; midrib of the first quill whitish; the black of the top of the head divided by a band of yellowish-white; eyebrows of that colour; upper parts variegated with black and bright rusty, the last-named colour disposed longitudinally; lower parts whitish-rusty; belly and sides striped with black bands; bill inclining to reddish, brown at the point; feet greenish-ash. (Temm.)

The head-quarters of this bird is the north of Europe.

In the British Islands the bird has been killed in Lancashire (the specimen from which Pennant first described it, and which was preserved in the Leverian Museum), and has been noticed as not uncommon in Norfolk. It has been very rarely seen in Ireland.

Solitary or Double Snipe (*Scolopax major*).

Sir Humphry Davy, who notices the fact of this Snipe's breeding in the great royal decoy or marsh-preserve near Hanover, says that they require solitude and perfect quiet, and that, their food being peculiar, they require a great extent of marshy meadow. They feed on the larvæ of *Tipule* (commonly called Father Long-Legs), or congenerous flies; and their stomach, the same author tells us, is the thinnest among the *Scolopax* tribe.

The rude nest of the Double Snipe, which is very like that of the Common Snipe, is generally placed on a hummock or tuft of grass, or a bunch of rushes on the borders of a swamp, often near willow bushes. Eggs three or four in number, yellowish olive-brown, with great spots of reddish-brown; length, 1 inch 9 lines; breadth, 1 inch 2 lines. They breed in considerable numbers in the mountainous parts of Norway and Sweden as high as the range of birch-woods extend.

Mr. Gould observes that there are two other snipes which exceed this in size, found in the hilly districts of India; and a third from Mexico, whose size is superior to that of a woodcock. ('Birds of Europe.')

Macroramphus, Leach; *M. griseus*, *Scolopax grisea*, Auct.; Brown Snipe of Pennant. Temminck places the genus *Streptilas* in this family, but the species are more closely allied to the Oyster-Catchers. [CHARADRIADÆ.]

Totanus.—It has the bill moderate, straight, sometimes slightly recurved, firm, rounded, the upper mandible grooved and with its tip curving over the lower mandible; nostrils lateral, basal, linear, longitudinally cleft in the furrow of the mandible; legs long, slender, naked above the knee; toes three before, united at the base by a small membrane, and one behind, which is short; wings moderate.

Such is the character of those *Scolopacidae* which are termed by the English Redshanks, Greenshanks, &c., and by the French Chevaliers.

T. stagnatilis. This bird is subject to considerable variations. In the first year they are the *Scolopax Totanus* of Linnæus. In their summer plumage they are the *Totanus stagnatilis* of Leisler. It is found in the north of Europe, on the borders of rivers, migrates along the eastern provinces of Europe to the Mediterranean, but never along the maritime coasts of the ocean. (Temm.)

Totanus stagnatilis.

Machetes.—Bill straight, rather slender, with a smooth and dilated tip; nostrils basal, lateral, linear, situated in the commencement of the groove; wings long and sharp-pointed; first and second quills equal and longest. Legs long, slender, and naked high above the tarsal joint; three anterior toes, one posterior, which is short; outer toe connected to the middle toe by a membrane as far as the first joint.

M. pugnax, the Ruff. It is the Combattant and Paon de Mer of the French; Salsarola and Uccello Muto of the Italians; Bruusbane of the Danes; Bruusbane of the Swedes; Streitschnepfe and Rumpfhühnlein of the Germans; Ruff (male), Reeve (female), of the English; and Yr Ymladdgar of the Welsh.

Male Ruff (*Machetes pugnax*), in Winter Plumage.

The tail rounded, the two middle feathers striped; the three lateral feathers always uniform in colour. The hues of the plumage so

variable, that it is almost impossible to find two individuals which perfectly resemble each other.

Male Ruff (*Machetes pugnax*), in his Summer dress.

The plumage of the male differs much in summer and winter. In his autumn or winter plumage he is the *Tringa variegata* of Brunwich. In his summer or nuptial plumage the male is the *Tringa pugnax* of Linnæus.

The young of the year much resembles the female in winter plumage. In this state the bird is the *Tringa littorea* of Linnæus; Le Chevalier Varié of Buffon; Shore Sandpiper and Greenwich Sandpiper of Latham.

The adult female and the young after the autumnal moult are the *Tringa equestris*, Equestrian Sandpiper of Latham; Le Chevalier Commun of Buffon; and Le Chevalier Ordinaire of Gérard. (Temm.) This bird is found in Iceland, Lapland, Scandinavia, Denmark, Siberia, Russia, France, Provence, Switzerland, Italy, Malta, Tunis, Trebizond, and the neighbourhood of the Caucasus. In Ireland the Ruff appears occasionally in spring and autumn. (Thompson.) In England it arrives in spring about April, and departs in autumn.

The food of the Ruff consists of worms and such insects as it can pick up in moist and marshy places; in the spring it is rarely found on the shores of the sea.

At one time a considerable trade was carried on in Ruffs in the fens of Lincolnshire, as they are regarded by some as delicate food. The Ruffs were caught by persons who made a living by catching them. Montagu gives a full account of these people, and their mode of catching the Ruffs, which is done by nets, the birds being decoyed by stuffed individuals.

The males arrive in England several days before the females. According to Colonel Montagu, the Reeves begin laying their eggs the first or second week in May, and he found their nests with young as early as the 3rd of June. By that time the males ceased to 'hill.' The nest was usually placed upon a stump in the most swampy places, surrounded by coarse grass, of which it was also formed. The same author describes the eggs as four in number, nearly similar in colour to those of the Snipe and Redshank, both of which breed in the same wet places, and make similar nests. The eggs of the Ruff are however, he observes, superior in size to those of the Snipe; and are known from those of the Redshank by the ground being of a greenish hue instead of rufous-white; but individuals assimilate so nearly to each other as not to be distinguished, especially as the dusky and brown spots and blotches are similar.

The food offered to the Ruffs in captivity,—and they will go greedily to it and fight for it immediately after their capture,—is bread and milk, or boiled wheat.

Phalaropus.—Bill long, slender, weak, straight, depressed at its base, the two mandibles furrowed up to the point; extremity of the upper mandible curved over the lower one, obtuse; point of the lower

Bill and Foot of Red-Necked Phalarope (*Phalaropus hyperboreus*).

mandible awl-shaped. Nostrils basal, lateral, oval, prominent, surrounded with a membrane; feet moderate, slender, tarsi compressed; three toes before and one behind; the anterior toes united up to the first joint, the rest of them furnished with festooned or lobated membranes dentilated on the edges; hind toe without a membrane, articulated on the inner side. Wings moderate, first and second quills longest. (Temm.)

P. platyrhynchus, the Gray Phalarope. Bill wide, depressed, flattened at the base; tail long, very much rounded.

The male and female in winter plumage are the *Phalaropus lobatus* of Latham; *Tringa lobata*, Linn.; Phalarope à Festons Dentelés, Buff.; Le Phalarope Gris, Cuv.; and Gray Coot-Footed Tringa, Edwards.

Gray Phalarope (*Phalaropus platyrhynchus*), in Winter Plumage.

The young before the moult are the Gray Phalarope of Latham. The summer or nuptial plumage is the *Tringa Fulicaria* of Brunnich; *Phalaropus rufus* of Bechstein; *Tringa hyberborca* of Linnæus; Le Phalarope Rouge of Buffon and Cuvier; Phalarope Roussâtre of Brisson; Red Coot-Footed Tringa of Edwards. This bird is found within the arctic circle; the eastern parts of the north of Europe; on the Caspian Sea; and in America. It is rare in Switzerland, on the Lake of Geneva; with us it is a winter visitor. It appears to be spread generally from the northern towards the intertropical regions.

Gray Phalarope (*Phalaropus platyrhynchus*), in Summer Plumage.

Insects or crustaceans principally, which live on the surface of the water, form the principal food of the Gray Phalarope, and it rarely seeks for its nourishment on the banks or on land.

The eggs are greenish-ash, spotted and dotted with black.

Numenius.—Bill long, slender, curved, compressed, hard at the point, and subobtusae; upper mandible exceeding the lower, rounded towards the end, canaliculated for three-fourths of its length; nostrils lateral, linear, pierced in the canaliculation; face feathered, space between the eye and the bill covered with feathers. Feet slender, naked above the knee; three toes before and one behind, which last is articulated on the tarsus and touches the ground, the anterior toes united up to the first joint by a membrane. Wings moderate; first quill longest.

N. arquatus, the Curlew. It is the Courlis of the French; Ciarlotta, Ciarlotta Spadone, and Chiurle Maggiore of the Italians; Heel-Spove of the Danes; Der Grosse Krumschühliche Schnepfe and Keilhacke of the Germans; and Gylfinhir of the Welsh.

The male has the whole plumage bright ash-colour, with longitudinal brown spots on the head and breast, some of the feathers of those parts clouded with red; belly white, with longitudinal spots; feathers of the back and scapulars black in the middle and bordered with red; tail whitish ash, striped with brown bands disposed transversely; upper mandible blackish-brown; the lower mandible flesh-colour; iris brown; feet deep ash; length two feet and upwards. The female with the tints more ash-coloured; the red which borders the feathers of the back and scapulars less pure.

It is equally diffused from the sultry portion of the torrid zone to

the frozen countries of the north: the islands of the Pacific Ocean, particularly Australia, are not devoid of its presence, and we also possess examples from China, Nepal, &c. (Gould, 'Birds of Europe.') Dr. Andrew Smith brought individuals from South Africa.

Curlew (*Numenius arquatus*).

The food of this well-known and wary bird, which in Scotland is called the Whaup, consists of earth-worms, slugs, small testaceans, and insects.

The nest, which consists of a few dried leaves, &c., carelessly put together, is placed among rushes or long grass and heath; Temminck says, often in the downs which border the sea. The egg, which is large (2 inches 7 lines long, 1 inch 11 lines broad), is olive-green, blotched, and spotted with darker green and deep-brown. It breeds in these islands.

N. phaeopus, Auct., *Scolopax phaeopus*, Linn.; genus *Phaeopus*, Cuv. This is Lo Petit Courlis, or Courlieu, of the French; Chiurlo Piccolo, Chiurlo Minore, and Mengotto, of the Italians; Regen Brachvogel, Kleine Art Brachvogel, Regenvogel, and Kleiner Gossier, of the Germans; De Kleine of Regenwulp of the Netherlanders; Mellum-Spove of the Danes; Smaae Spue of the Norwegians; Whimbrel, Curlew-Knot, Curlew-Jack, Jack-Curlew, Half-Curlew, Titterel, Chikereel, and Tang-Whaup of the English; and Coeg Ylfinhir of the Welsh.

All the plumage bright ash-colour; longitudinal brown spots on the neck and breast; on the middle of the head a longitudinal band of yellowish-white, with another twice as wide and brown on each side; belly and abdomen white; feathers of the back and scapulars very deep-brown in the middle, and bordered with brighter brown; tail ash-brown, streaked with brown bands disposed obliquely; bill blackish, but reddish at its base; iris brown; feet lead-colour. Length of male 16 inches, bill 3 inches; of female 18 inches, bill 3½ inches.

Whimbrel (*Numenius phaeopus*).

The young of the year have the bill short, hardly an inch and a half long: this organ curves in proportion as the bird grows older.

There can be little doubt that Whimbrels were the 'Curlew Knaves' of the old Household Books.

It is very widely distributed. Denmark, Sweden, Norway, Lapland, Faroe Islands, Iceland, Germany, Holland, France (but more common in Holland than in France or Germany), Italy, Spain, Provence, Madeira, and the central part of North Africa. Asia—Caucasus, Himalaya Mountains, Bengal, and Japan.

In the British Islands (it is found in Orkney and Shetland, and has been known to breed in the latter locality) the Whimbrel occurs most plentifully in May and autumn, the periods of its northward and southward migration; but they have been seen occasionally on our shores in winter.

Their food consists of insects, small crustaceans, and worms: they breed in the north: the nest is exposed on wild heaths and moors, and the number of eggs, which are dark olive-brown, blotched with darker brown, pear-shaped, and strongly resembling those of the Curlew, but smaller, is generally four: they are sought as delicacies.

In the 'Portraits d'Oyseaux' the following quatrain appears under the figure of the Curlew, which was highly esteemed for the table:--

"De son erier le Coriis a le nom,
Duquel le bec est tourné, et voutté.
De demi pied long. Il est appresté
Es grands banquets, comme oiseau de renom."

Limosa.—Bill very long, more or less curved upwards, soft and flexible throughout its length, depressed, and flattened towards the point; the two mandibles furrowed throughout their length, the point flat, dilated, and obtuse. Nostrils lateral, longitudinally slit in the furrow, pierced through and through. Feet long, slender; a great naked space above the knee; three toes before and one behind; middle toe united to the external one by a membrane which extends up to the first joint; the posterior toe articulated upon the tarsus. Wings moderate; first quill longest. (Temm.)

All known species of the Godwits undergo a double moult, which changes nearly entirely the colour of the plumage. The females are always larger than the males, and lay very large eggs in proportion to their size; and their periodical moult takes place later than that of the males, indeed after they have assumed their new dress. (Temm.)

L. melanura, the Godwit. Bill straight; tail uniform black, with a base of pure white; claw of the middle toe long and denticulated; a white beauty-spot (miroir) on the wings.

Head and Foot of Godwit (*Limosa melanura*).

In their winter plumage they are *Limosa melanura* of Leisler; *Scolopax limosa* of Linnaeus; *Totanus limosa* of Bechstein; La Barge on Barge Commune of Buffon; Jadreka Snipe of Latham.

The young before their first moult is *Totanus rufus* of Bechstein.

In its nuptial plumage the bird is *Scolopax belgica*, and *Scolopax agocephala* of Gmelin; *Totanus agocephalus* of Bechstein; La Grande Barge Rousse of Buffon; Red Godwit of Latham; and Dunkelfussiger Wasserläufer of Meyer.

Mr. Gould says that this bird inhabits the whole of the European continent, and that examples are found in most collections from Africa and India. With us they are most frequently seen in spring and autumn. They breed mostly in high northern latitudes, but occasionally in England. In Ireland the species is but seldom seen.

The food consists of insects and their larvae, worms, &c. The nest is formed of dry grass and herbage, and the four eggs are light olive-brown, blotched and spotted with darker brown.

Godwits were formerly considered most delicious eating ('The Devil is an Ass,' iii. 3; Sir Thomas Browne, and others); but though they are now sometimes fattened with bread and milk, like Ruffs, they are not held in half the estimation that Ruffs are.

Cladorhynchus, G. R. Gray.—This genus, which closely approximates *Himantopus*, was first characterised by the Chevalier B. Dubus, under the name of *Leptorhynchus*. Mr. Gould published a description and part figure of the species here noticed, in his 'Synopsis of the Birds of Australia,' as *Himantopus palmatus*. *Leptorhynchus* had been pre-occupied in ornithology; and therefore, as Mr. Gould observes, Mr. G. R. Gray's name must stand.

C. pectoralis; *Leptorhynchus pectoralis*, Dubus. Body white; breast crossed by a broad band of chestnut, bordered anteriorly with black; wings and centre of the abdomen black; bill black; legs reddish-

yellow. In a specimen presumed to be the female, the band on the chest was grayish-brown instead of chestnut, and there was no appearance of the black mark on the centre of the abdomen; and in another the pectoral band was apparently disappearing, from which Mr. Gould infers that this mark only exists in the breeding season. It is a native of southern and western Australia and Rottneest Island.

Cladorhynchus pectoralis.

Himantopus, Briss.—Bill long, slender, cylindrical, flattened at its base and compressed at the point; both mandibles channelled to the extent of half their length from the base. Nostrils lateral, linear. Tarsi very long and slender. Toes three before, the external and middle toe united by a membrane; nails small and flat. Wings very long, the first quill-feather the longest. (Gould.)

H. melanopterus, the *H. rufipes*, Bechst.; *Hyperbates Himantopus* of Naumann, and *Himantopus longipes* of Brehm.; *Charadrius Himantopus*, Linn. It is L'Echasse and Echasse à Manteau Noir of the French; Cavaliere Grande Italiano and Cavaliere d'Italia of the Italians; Schwarzflügelige Strandreuter of the Germans; Long-Legged Plover, Stilt, and Longshanks of the English; Cwtyn Hlrgoes of the Welsh.

Face, neck, and all the lower parts pure white, assuming a rosy tint on the breast and belly; occiput and nape black or blackish, with white spots; back and wings black, glossed with green; tail ash-colour; bill black; iris crimson; feet vermilion. Length from the point of the bill to the extremity of the tail about 14 inches, and to the claws about 19 inches.

The very old male has the uape, and even sometimes the occiput, quite white.

The female is less than the male; the black of the mantle and wings has no greenish reflexions; and her general tint is browner.

The feet of the young are orange; their mantle and wings brown, with whitish edges; feathers of the upper part of the head, occiput, and nape blackish-ash with whitish borders. (*Himantopus Mexicanus*, Brist.) (Temm.)

Belon, in the 'Portraits d'Oyseaux,' subscribes a hy no means bad figure with the following synonyms:—"Grec. *μυρρῶνος*; Italien, Merlo aquaiolo grando; François, Lon pourroit dire le Grand Chevalier d'Italie." Beneath the cut he informs us that the *Himantopus*, like the *Hamatopus*, has only three toes, but that one is a river and the other a sea-bird, and that the former is often seen in all the countries along the river which passes by Castel Durante in the duchy of Urbino. It is there called, he says, Merlo Aquaiolo Graude, in contradistinction to another bird which is simply called Merlo Aquaiolo (our Water-Ouzel, *Cinclus*!). There is no bird, says Belon, in continuation, which has such long legs with reference to the size of its body; for, having the body of a pigeon, its red legs are a cubit long. The name *Himantopus* is taken from Pliny; and, by an awkward metaphor, implies that the legs are as slender and pliant as if cut out of a thong of leather.

Peonant says, "These birds are extremely rare in these islands. Sir Robert Sibbald records a brace that were shot in Scotland; another was shot a few years ago at Stanton-Harcourt Common near Oxford; and we have seen them often in the cabinets of the curious at Paris, taken on the French coasts."

Mr. Gould ('Birds of Europe') states that the genus *Himantopus*, although widely distributed, contains, he believes, only two well authenticated species, namely, *H. melanogaster* and the North American species. "This bird," says Mr. Gould, in continuation, "so singular in its appearance from the extraordinary length and slenderness of

its legs, has been often killed in England; but it must be classed among those birds whose visits are accidental and uncertain. It is equally scarce in Holland and the northern portion of Europe; in fact, though apparently abundant nowhere, it exhibits so wide a range, that its deficiency in point of number in any given locality is counterbalanced by its almost universal distribution."

Black-Bellied Plover (*Himantopus melanogaster*).

Tringa.—Beak of moderate length, about as long as the head, sometimes slightly curved, rather flexible, compressed at the base, depressed, dilated and blunt towards the point; both mandibles grooved along the sides; nostrils lateral, pierced in the membrane lining the groove. Legs slender; lower part of tibia naked; three toes before, one behind, those in front entirely divided to their origin; the hind toe articulated upon the tarsus. Wings of moderate size, pointed, the first feather always the longest.

T. cinerea, the Knot. It is the *T. grisea* and *T. Canutus* of Linnaeus and Gmelin; *Calidris Canutus* of Cuvier: the Maubèche Grise, Maubèche Tachetée, and Le Canut of the French; Chinro, Piovanello Maggiore, and Paginella Maggiore, of the Italians; Rotbraune Strandläufer, Aschgrau Strandläufer, and Hochköpfige Strandläufer of the Germans; Sidlingar-Kall of the Icelanders; Fiære-Pist, Fiære-Kuro, and Fiære-Mnus, of the Norwegians; Y Cnut of the Welsh.

Several other scientific names have been given to this bird according to the different stages of its plumage, such stages having been mistaken by the describers for specific differences. (Temminck, 'Mannal'.)

The Knot (*Tringa cinerea*).

Upper figure, summer plumage; lower figure, winter plumage. (Gould.)

Male and Female in Winter.—Bill straight, a little longer than the head, very much dilated and convex towards the tip; all the tail-feathers of equal length. Throat, middle of the belly, and abdomen, pure white; forehead, eyebrows, sides and front of the neck, breast, and flanks, white also, but varied with small brown longitudinal lines,

NAT. HIST. DIV. VOL. IV.

and transversal and zigzag bands of ashy-brown; head, neck, back, and scapulars, bright ash with brown stems; rump and upper tail-coverts white, with black crescents and zigzags; wing-coverts ash, bordered with white and with brown stems; tail-feathers ash variegated with white; bill and feet greenish-black; iris brown. Length about 10 inches.

Summer or Nuptial Plumage.—Large eyebrows, throat, sides and front of the neck, breast, belly, and flanks, of a rusty or coppery ruddy; nape ruddy, with small longitudinal lines; top of the head, back, and scapulars, deep black; all these feathers bordered with vivid ruddy; on the scapulars great oval spots of the same ruddy colour; abdomen white, speckled with ruddy and blotched with black; upper coverts of the tail white, with black crescents and ruddy blotches; tail-feathers blackish-ash, variegated with whitish. Such are the old birds when in perfect plumage. (Temm.)

This bird is found in Iceland, Greenland, North Georgian Islands, Duke of York's Bay, Melville Peninsula, Hudson's Bay, Sweden and Norway, Holland in spring and autumn, the British Islands (but not known to breed there), rare in Germany, France, and the south of Europe.

According to Captain Lyon, who saw it breeding in Melville Peninsula, the Knot lays four eggs on a tuft of withered grass, without forming any nest. The eggs are of a light yellowish-brown, spotted with gray and reddish at the larger end, so as to form a sort of zone, more or less. There are but few spots towards the point.

The food of the Knot consists principally of worms, and also occasionally of small river and marsh insects, little marine crustaceans, and very small bivalve molluscs.

It is one of the most delicious of birds, and when fattened is preferred by epicures to the most insoucious ruff. Camden says they derive their name from King Canute, Knute, or Knout, as he is sometimes called, probably because they were a favourite dish of that monarch.

Drayton says of this bird—

"The Knot, that called was Canutus bird of old,
Of that great king of Danes his name that still doth hold,
His appetite to please, that farre and neere was sought,
For him, as some have said, from Denmarke hither brought."

('Polyolbion'—23th Song.)

T. minuta, the Little Sandpiper (Fleming). It is the *T. pusilla* of Linnaeus, Latham, and Pennant; the Stint of Bewick; the Miunte Tringa of Selby; the Little Stint of Jeunys; the Pigmy Sandpiper of Richardson; the Bécasseau Echasses of Temmiuck; Gambecchio and Culetto of the Italians; Der Hochbeinige Strandläufer and Der Kleine Schlammläufer and Zwerg Schlammläufer of the Germans; Stint of Zeeleerik of the Netherlands; and Y Pibhydd Lleiaf of the Welsh.

Little Sandpiper (*Tringa minuta*).

Lower figure to the left, winter plumage; upper figure, summer plumage; lower figure to the right, young of the year. (Gould.)

It has the bill straight, shorter than the head; tail doubly forked, lateral feathers brown-ash, all variegated with white; tarsus 10 lines long.

This bird is found at Hudson's Bay, in India, South Africa, North America, and Europe. In the British Islands they have been noticed in the vicinity of the Solway, in the west of Lancashire; and on the coasts of Suffolk, Norfolk, Yorkshire, and Durham in the autumn. A small number are seen every year in Belfast Bay, according to Mr. W. Thompson.

This species haunts sandy shores, the banks of large rivers, and salt-marshes. In this country it is mostly found in company with the Dunlin and Sanderling on the sandy sea-shore.

The flesh of the Little Stint much resembles that of its congeners, but it must not be confounded with the Stint of the old feasts, which appears to have been the Dunlin or Purre.

Drayton thus celebrates it in the 'Five-and-Twentieth Song' of his 'Polyolbion':—

"The Puet, Godwit, Stint, the pallat that allure
The miser and doe make a wasteful epicure."

Tantalus, Linnæus.—This genus stands between the genera *Ardea* and *Scolopax*, in the twelfth edition of the 'Systema Naturæ.'

Cuvier places the genus *Tantalus* between the Open-Beaks (*Hians*, Lacép.; *Anastomus*, Ill.) and the Spoonbills (*Platalea*, Linn.). He characterises the genus as having the feet, the nostrils, and the bill of a stork; but the back of the bill is, he observes, rounded, and its point curved downwards and slightly notched on each side; a portion of the head, and sometimes of the neck, is, he adds, denuded of feathers. He notices the following species:—The American *Tantalus*, *T. locustator*, Linn.; the African *Tantalus*, *T. Ibis*, Linn.; and the Ceylonese Ibis, *T. leucocephalus*, the largest of all.

T. Ibis is white slightly clouded with purple on the wings, with a yellow beak, and the skin of the face naked and red. Cuvier says that it was for a long time regarded by naturalists as the bird so much revered by the ancient Egyptians under the name of *Ibis*, but that recent researches had proved that the *Ibis* is a much smaller species, of which he intends to treat hereafter. This species, he states, is not commonly found in Egypt, but that it had been brought from Seuegal. *Tantalus* he arranges in the family *Culirostres*.

Ibis (Cuv.) finds a place in the 'Règne Animal' as the second genus of Cuvier's *Longirostres*, between *Scolopax* and *Numenius* (Cuv.).

The bill is slender, cylindrical, and arched from the base; nostrils basal, lateral. Wings broad, ample; the second and third quills longest.

Cuvier states that he has separated the Ibises from the *Tantali* of Gmelin, because their bill, arched like that of the *Tantali*, is nevertheless much more feeble, and without any notch at the point, whilst the nostrils, pierced towards the back of its base, are each prolonged into a furrow which continues to the tip. The bill, he adds, is rather thick, and nearly square at its base. There is always, he further remarks, some part of the head, or even of the neck, denuded of feathers. The external toes are notably palmated at their base, and the hind toe is sufficiently long to touch the earth. Some of the species, he observes, have the legs short and reticulated: these are the most robust and have the largest bill.

I. religiosa, the Sacred Ibis. Abou-Hanner, Bruce; *Tantalus Æthiopicus* of Latham; *I. Ibis* Sacré, Cuv.

Sacred Ibis (*Ibis religiosa*), Cuv.—Adult.

"This," says Cuvier, "is the most celebrated species: it was reared in the temples of ancient Egypt, with veneration which approached to worship; and it was embalmed after its death, as some said, because it devoured the serpents which would otherwise have become dangerous to the country: according to others, because there was a resemblance between its plumage and some of the phases of the moon: finally, according to other some, because its advent announced the rising of the Nile. For a long time it was thought that this Ibis of the Egyptians was the *Tantalus* of Africa: we now know that it belongs to the genus of which we are treating. It is as large as a hen, with white plumage, except the end of the wing-feathers, which is black; the last coverts have their barbs elongated, loose, black, with violet

reflections, and thus covering the end of the wings and tail. The bill and the feet are black, as well as all the naked part of the head and neck: this part is covered in youth, at least on its upper surface, with small blackish feathers. The species is found throughout the extent of Africa." [ABOU-HANNER.]

The other species noticed by Cuvier are—*L'ibis Rouge* (*Scolopax ruber*, Linn.; *Tantalus ruber*, Gm.) and *L'ibis Vert*, vulg. Courlis Vert (*Scolopax falcinellus*, Linn.). ('Règne Animal.')

I. falcinellus, *L'ibis Vert*, is purplish chestnut, with a deep-green mantle. The young with the head and neck sprinkled with whitish. It is a native of the south of Europe and north of Africa.

This, Cuvier observes, is to all appearance the species which the ancients called the Black Ibis. [ABOU-HANNER.]

I. ruber, the Scarlet Ibis, *Tantalus ruber* of Linnæus, Red Curlew of Catesby. This species is 23 inches in length and 37 in alarexent. Bill 5 inches long, thick, and of a somewhat square form at the base, gradually bent downwards and sharply ridged; black, except near the base, where it inclines to red. Iris dark-hazel. The face naked, slightly wrinkled, pale-red. Chin bare, wrinkled also. Plumage rich, glowing scarlet, except about three inches of the extremities of the four outer quill-feathers, which are deep steel-blue. Legs pale red; the three anterior toes united by a membrane as far as the first joint. (Nuttall.)

"This brilliant and exclusively American species inhabits chiefly," says Nuttall, "within the tropics, abounding in the West India and Bahama Islands, and south of the equator, at least as far as Brazil. They migrate in the course of the summer (about July and August) into Florida, Alabama, Georgia, and South Carolina; but retire into Mexico, or the Caribbean Islands, at the approach of cool weather. They generally associate in numbers, frequenting the borders of the sea, and the banks and estuaries of neighbouring rivers, feeding on small fry, shell-fish, crustacea, worms, and insects, which they collect at the ebbing of the tide. They are said to be in the habit of perching on trees in companies; but they lay their eggs, which are greenish, on the ground, amidst the tall grass of the marshes, on a slight nest of leaves. When just hatched the young are black, soon changing to gray, but are nearly white before they are able to fly; by degrees they attain their red plumage, which is not complete until the third year. The young and old associate in distinct bands. In the countries where they abound they are sometimes domesticated, and accompany the poultry. The Ibis shows great courage in attacking the fowls, and will even defend itself from the insidious attacks of the cat. It is generally esteemed as good food; and its rich and gaudy plumage is used by the Brazilians for various ornaments." (Nuttall, 'Manual of the Ornithology of the United States and of Canada'.)

The following is Mr. G. R. Gray's arrangement of the British species of this family in the collection of the British Museum. He refers the genus *Ibis* to the family *Ardeide*, and to the tribe *Tantalina*, the only British species of which is *I. falcinellus*, the Glossy Ibis:—

SCOLOPACIDÆ.

I. *Limosina*.

Numenius arquata, the Common Curlew.
N. phaeopus, the Whimbrel.
Limosa lapponica, the Bar-Tailed Godwit.
L. algocephala, the Black-Tailed Godwit.

II. *Totantina*.

Totanus fuscus, the Spotted Redshank.
T. calidris, the Common Redshank.
T. ochropus, the Green-Sandpiper.
T. glareola, the Wood-Sandpiper.
T. glottis, the Greenshank.
Tringoides macularia, the Spotted-Sandpiper.
T. hypoleuca, the Common Sandpiper.
T. rufescens, the Buff-Breasted Sandpiper.

III. *Recurvirostrina*.

Recurvirostra avocetta, the Avocet. [AVOCET.]
Himantopus candidus, the Black-Winged Stilt.

IV. *Tringina*.

Philomachus pugnax, the Ruff.
Tringa canutus, the Knot.
T. maritima, the Purple Sandpiper.
T. pectoralis, the Pectoral Sandpiper.
T. schinzii, Schinz's Sandpiper.
T. alpina, the Dunlin.
T. minuta, the Little Stint.
T. temminckii, Temminck's Stint.
T. subarquata, the Curlew Sandpiper.
T. pygmaea, the Broad-Billed Sandpiper.
Calidris arenaria, the Sanderling.

V. *Scolopacina*.

Macrorhamphus griseus, the Brown Snipe.
Gallinago major, the Great Snipe.

G. Sabinii, Sabin's Snipe.
G. media, the Common Snipe.
G. Brehmii, Brehm's Snipe.
G. gallinula, the Jack-Snipe.
Scolopax rusticola, the Woodcock.

VI. Phalaropodinae.

Phalaropus fulicarius, the Gray Phalarope.
P. hyperboreus, the Red-Necked Phalarope.

SCOLOPENDRA, Latreille, a genus of Animals belonging to the order *Myriapoda*, and belonging to a section of that order termed *Chilopoda*. The species of the genus *Scolopendra*, as now restricted, are distinguished from others of the section of which they form a part, by their possessing at least twenty-one pairs of legs, and there are more segments apparent on the upper surface of the body than on the under; the antennae are composed of seventeen joints; the eyes are distinct, and are four in number on each side. The species inhabit the southern parts of Europe, and all the tropical portions of the globe; their mandibles (which, strictly speaking, it would appear are formed by the second pair of legs) are terminated by a sharp hook, which is pierced for the transmission of a venomous fluid. The *Scolopendras* have the body long, slender, and depressed, and protected by coriaceous plates: they run very fast, and shun the light, living for the most part under logs of wood and the loose bark of decayed trees. [MYRIAPODA.]

SCOLOPENDRIUM, a genus of Ferns belonging to the natural order *Filices* and tribe *Aspleniceae*. The sori elongate, straight, and two together; the indusia of each pair opening towards each other.

S. vulgare, Hart's Tongue, is a particularly handsome and ornamental fern, and very different from every other British species. It is universally and abundantly distributed throughout the British Isles. It is very commonly found on old walls and ruins. It is also found in Europe, sparingly towards the north, and in the United States. It is not however described as growing in Africa, Asia, or South America. The roots are black, stout, and very long and strong; the rhizoma is tufted, blackish, scaly, almost spherical; the young fronds make their appearance in April, growing in an erect position; by degrees they become horizontal, and at length pendulous. They arrive at maturity at the end of September, and continue in full vigour throughout the whole winter. The form of the frond is linear, elongated, and quite undivided, acute at the apex, and cordate at the base. This fern is the *Phyllitis* of Ray and all older botanists. It was once much in vogue as a medicine; Ray mentions it as an astringent, and speaks of its healing powers, applied as an ointment to wounds and ulcers. Lightfoot says it is used by the country people of Scotland as a vulnerary for burns and scalds, and we learn from the '*Flore Française*' that it is used in France as an astringent in cases of diarrhoea and hæmorrhage.

(Newman, *British Ferns*; Bahington, *Manual of British Botany*.)

SCOLOPHORUS. [ANTILOPEÆ.]

SCOMBER. [SCOMBRIDÆ.]

SCOMBERESOX, a genus of Fishes belonging to the family *Esocidae*. The only British species of this genus is the Gar Pike or Skipper, called also Gowdnook in Scotland. It was first described as a British species by Ray. It is not an abundant fish, but has been taken off Berwick and Yarmouth, and Portland Island, and on some occasions, has been even plentiful on the coasts of Scotland. [ESOX.]

SCOMBRIDÆ, a family of Fishes of the section *Acanthopterygii*, of which the Common Mackerel may be regarded as a type: the Tunny, Sword-Fish, Dory, and Boar-Fish, also belong to this group, which contains a multitude of species and many genera. The body is generally covered with small scales; the tail is usually very powerful and deeply cleft: in most of the species the pectoral fins are long, narrow, and pointed; the dorsal fins are two in number, the foremost of them being composed of bony rays; the hinder dorsal is chiefly supported by soft rays, and is often divided into numerous small false fins. They are provided with numerous cæca, and these are often united in clusters.

In the genus *Scomber*, as now restricted, the body is covered with small smooth scales; the dorsal fins are widely separated; the hinder part of the second dorsal, as well as of the anal fin, is divided into numerous small spurious fins or finlets, which extend along the hinder part of the body, above and beneath, almost to the tail; the sides of the tail are carinated, and the body is elongated and tapering at both extremities.

S. Scomber, Linnaeus (*S. vulgaris*, of some authors), the Common Mackerel, is a fish too well known to require to be described here. "This fish," Mr. Yarrell observes, "it is probable inhabits almost the whole of the European seas; and the law of nature which obliges it and many others to visit the shallower waters of the shores at a particular season, appears to be one of those wise and bountiful provisions of the Creator by which not only is the species perpetuated with the greatest certainty, but a large portion of the parent animals are thus brought within the reach of man, who, but for the action of this law, would be deprived of many of those species most valuable to him as food." It may be further observed, says the same author, that there is scarcely a month throughout the year in which the fishes of

some one or more species are not brought within the reach of man by the operation of this law. "On the coast of Ireland the mackerel is taken from the county of Kerry on the west, along the southern shore, eastward to Cork and Waterford; thence northward to Antrim, and north-west to Londonderry and Donegal. Dr. McCulloch says it visits some of the lochs of the Western Islands, but is not considered very abundant. On the Cornish coast, this fish in some seasons occurs as early as the month of March, and appears to be pursuing a course from west to east. They are plentiful on the Devonshire coast, and swarm in West Bay about June. On the Hampshire and Sussex coast, particularly the latter, they arrive as early as March, and sometimes even in February; and the earlier in the year the fishermen go to look for them, the farther from the shore do they seek for and find them. Duhamel says the mackerel are caught earlier at Dunkirk than at Dieppe or Havre: up our own eastern coast however the fishing is later. The fishermen of Lowestoft and Yarmouth gain their great harvest from the mackerel in May and June. Mr. Neill says they occur in the Forth at the end of summer; and Mr. Lowe, in his '*Fauna Orcadensis*,' states that they do not make their appearance there till the last week in July or the first week in August.

"The most common way of fishing for mackerel, and the way in which the greatest numbers are taken, is by drift-nets. The drift-net is twenty feet deep, by one hundred and twenty feet long; well corked at the top, but without lead at the bottom. They are made of small fine twine, which is tanned of a reddish-brown colour, to preserve it from the action of the sea-water; and it is thereby rendered much more durable."

S. colias, the Spanish Mackerel, is a rare fish on the British coasts. It is the *Colias Rondeletii* of Ray.

Thynnus has the form of the body like the Mackerel, but less compressed, with numerous scales surrounding the thorax, and the first dorsal fin extending nearly to the second.

T. vulgaris, Cuvier (*Scomber Thynnus*, Linnaeus), the Tunny. It is taken in large numbers in the Mediterranean, but is seldom fished for on the British coasts, although in some parts it is said to exist in abundance. Like the Mackerel, they come in shoals to the shallow parts of the water to deposit their spawn. They sometimes attain a great size, weighing above four hundred pounds and measuring nearly eight feet in length.

T. pelamys, the Bonito, *Scomber pelamys* of Linnaeus, is an occasional visitor to the coasts of England, but its true realm is in the tropics. It is a very beautiful fish of a fine blue colour, with four dark lines extending from the pectorals along the side of the belly to the tail. It rarely exceeds 30 inches in length. The Bonito of the Mediterranean, a fish of equal beauty, is a distinct species, and is the *Pelamys Sarda* of Cuvier. Its back and sides are marked by dark oblique transverse bands. It has much stronger teeth than the Bonito of the tropics.

Auzis has a nearly cylindrical body; the two dorsal fins widely separated; one row of minute teeth in each jaw.

A. vulgaris, Cuvier, *Thynnus Rocheanus* of Risso, the Plain Bonito, is also a native of the Mediterranean. It is only a straggler on the British coasts.

Xiphias has the upper jaw elongated, forming a sword.

X. gladius, Linnaeus, the Sword-Fish, is an inhabitant of the Mediterranean and Atlantic, occasionally visiting our coast. It measures from 10 to 15 feet in length. Its body is lengthy and covered with minute scales, the sword forming three-tenths of its length. On its back it bears a single long elevated dorsal fin; there are no central fins. The tail is keeled. The lower jaw is sharp; the mouth without teeth. The upper part of the fish is bluish-black merging into silver below.

The Sword-Fish is said to attack the whale, wounding it with its beak. There are many well-authenticated instances of the planks of ships being perforated by the upper jaw of this powerful creature, which it has been supposed occasionally attacks the hulls of ships in mistake for the whale. Specimens of ships' timbers penetrated by its sword are preserved in many museums. The *Xiphias* is mentioned by Aristotle ('Hist. Anim.' viii. 19), who notices the fact of its striking vessels. The young fish is said to be good eating. When very young the body is covered with small tubercles, which disappear before it attains the length of three feet.

The other British fishes belonging to this family are—*Lampris guttatus*, the Opah or King-Fish [LAMPRIS]; *Capros aper*, the Boar-Fish [CAPROS]; *Zeus faber*, the Dory [ZEUS]; *Centrolophus pompilus*, the Black Fish [CENTROLOPHUS]; *Caranx trachurus*, the Scad or Horse-Mackerel [CARANX]; and *Naucratus ductor*, the Pilot-Fish [NAUCRATES].

SCOPELIDÆ, a family of Malacopterygious Abdominal Fishes. This family is closely allied to the *Salmonidæ*. They have the snout short, the mouth deeply cleft, the teeth rather small and sharp; the branchial rays 8 to 15; the first dorsal behind the ventral; the body in some is semitransparent.

The genus *Scopelus* is found in the Mediterranean.

(*Manual of Natural History*.)

SCOPOPHORUS. [ANTILOPEÆ.]

SCOPS. [STRIGIDÆ.]

SCORODITE. [IRON.]

SCORPÆNA, a genus of Acanthopterygious Oseous Fishes of the family *Loricati*. Their heads are large, compressed, and more or less armed with spines or tubercles; the body is oblong and scaly. On the back is a single dorsal fin; the branchiostegous membrane has seven rays; and the jaws and palatines are armed with velvety teeth. They reside mostly on rocky grounds, feeding on *Crustacea* and small fish.

S. Norvegica; *Sebastes Norvegica*, the Bergylt, or Norway Haddock, is a fish resembling the perch, and attaining a length of two feet and more. It is sometimes taken in the British seas. Some beautifully-coloured species of this genus are found in the Mediterranean.

SCORPIO. [SCORPIONIDÆ.]

SCORPION. [SCORPIONIDÆ.]

SCORPION-GRASS. [MYOSOTIS.]

SCORPION, WATER. [NEPA.]

SCORPIONIDÆ, a family of the class *Arachnida*, order *Pulmonaria*, and section *Pedipalpi*. The animals of this family, commonly called Scorpions, are distinguished from other groups of spiders by their having the abdomen articulated and terminated by a curved spur at the extremity; the palpi are very large, and the terminal segment assumes the form of the lobster's claw, being in like manner provided with pincers; the stigmata are eight in number, and situated along the inferior and lateral part of the abdomen; on the under side of the thorax are two comb-like appendages. The number of the eyes varies from eight to twelve in different species, and some sub-genera have been established upon this character. Those to which the term *Scorpio* is used in its most restricted sense have only six eyes; those Scorpions which have eight eyes constitute the sub-genus *Bathus*; and those which have twelve eyes, *Androctonus*.

"These Arachnides," says Latreille, "inhabit the hot countries of both hemispheres, live on the ground, conceal themselves under stones and other bodies, most commonly in ruins, dark and cool places, and even in houses. They run with considerable swiftness, curving the tail over the back—this they can turn in every direction, and use for the purposes of attack and defence. With their forceps they seize various insects, on which they feed after having pierced them with their sting. They are particularly fond of the eggs of spiders and insects.

The wound occasioned by the species found in the southern parts of Europe (*Scorpio Europæus*), is not usually dangerous; but according to the experiments of Dr. Maccahy, made upon himself, the sting of some other and larger species produces serious and alarming symptoms, and the older the animal the more active seems to be the poison. The remedy employed is the volatile alkali, used externally and internally.

The young Scorpions are produced at various intervals, and are carried by the parent for several days upon her back, during which time she never leaves her retreat.

SCORZONERA, a genus of Plants belonging to the natural order *Asteraceæ*. The pappus is feathery, in several rows. Bracts imbricated. Receptacle naked. Achænia neither stalked nor beaked, with a lateral scar.

S. Hispanica, *Viper's-Grass*, has a cylindrical succulent root, branches monocephalous; leaves amplexicaul, lanceolate, wavy; involucre smooth; flowers yellow. It is found in Spain and the south of Europe. The root is said to be sudorific. It is delicate and eatable, and is supposed to be a specific against viper bites.

S. gladiifolia has roots similar in quality.

S. delicosa is cultivated as an esculent at Palermo, and the gummy root of *S. tuberosa* is eaten by the Kalmucks.

SCOTER. [DUCK.]

SCOTOPHILUS. [CHEIROPTERA.]

SCOTORNIS. [CAPRIMULGIDÆ; STERNAIDÆ.]

SCREAMER. [PALAMEDEA.]

SCREW-PINES. [PANDANACEÆ.]

SCROPHULARIA (so named from its supposed use in cases of scrofula), a genus of Plants belonging to the natural order *Scrophulariaceæ*. It has a 5-parted nearly equal calyx, a globose corolla, with a short 5-lobed limb, the segments of which are rounded, and the uppermost united into an upper lip. The style is simple, thickened at the apex, the stigma emarginate. There are 4 fertile didynamous declinate stamens, with the rudiment of a fifth appearing. The species are herbs or undershrubs with an unpleasant smell.

S. peregrina, Figwort, has cordate shining glabrous leaves, alternate peduncles, 2-5 flowered, the lobes of the calyx not membranous, glabrous and acute. The stem is acute-angled at the base, but obtuse-angled at the apex, and of a dark purple. The leaves are full of pellucid dots. The corollas small, purple, and velvety, the lobes all denticulated. This species is the *Galadifis* of Dioscorides, l. v. 95.

S. nodosa has a nearly smooth herbage, which when bruised smells like elder. The root is whitish, tubular, and beset with fleshy knots. The leaves are stalked ovate-oblong, acute, sharply and unequally serrated, heart-shaped at the base, where they are cut away as it were to the two small lateral ribs. The flowers are a little drooping, the corollas of a dull-green, with a livid purple lip, the calyx is smooth, the capsule ovate-oblong. The leaves and roots are said to be purgative and emetic. They have a bitter taste and a disagreeable smell. A decoction is used by farmers to cure the scab in swine. Wasps

greatly resort to the flowers. Goats eat the plant, but all other animals refuse it. It is native mostly throughout Europe.

S. aquatica has an entirely fibrous root. It is a smooth plant of a deep shining green-colour, the stem is quadrangular downy, the leaves copiously and finely serrated, heart-shaped at the base. The flowers are in clusters, their tube is green, the corolla of a deep red. The capsule globular. This plant is called Water-Betony, Bishop's-Leaves, and Broadwort. Its medicinal properties are the same as those of *S. nodosa*. It is called by the French *Herbe du Siège*, because during the siege of Rochelle by Cardinal Richelieu in 1623 the garrison supported themselves in extremity by eating the roots.

There are 73 species of Figwort; of these six are recognised British plants.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Burnett, *Outlines of Botany*.)

SCROPHULARIACEÆ, *Figworts*, a natural order of Plants belonging to the dicarpous group of Monopetalous Exogens. The plants of this order are herbaceous or shrubby, with round and knotless or square and nodose stems. Leaves alternate, undivided or lobed, sometimes collateral; the floral ones sometimes double, and placed near each other. The inflorescence is variable, usually spicate, racemose or paniculate, seldom solitary. The calyx is 5-parted, seldom 4-parted; the sepals often unequal, the upper one being largest, the two lowest smaller, the lateral ones smallest; corolla 4-5-parted, tube short or long, limb flat or erect, nearly equally divided or labiate, imbricate in aestivation; stamens 2-4, didynamous, rarely equal, alternate with the lobes of the corolla, the fifth stamen and sometimes the three upper ones abortive; anthers 2-celled, or sometimes growing together 1-celled, opening longitudinally; ovary superior, 2-celled, many-seeded; style simple; stigma mostly simple, entire, emarginate or bifid, often flattened, occasionally double at the points of the divisions of the style; fruit capsular, seldom berried, bicarpellary, 2-celled, sometimes with 2 entire or bifid valves, sometimes with 4 entire ones, sometimes opening by pores or lids, dissepiment parallel or opposite to the valves, finally loose in the centre, or altogether; placentæ adhering to the dissepiment; seeds indefinite, aluminous.

Scrophulariaceæ are nearly allied to *Solanaceæ*, and in some instances it is difficult to say to which of these two orders plants may belong. Bentham separates these orders by a purely artificial distinction, considering as *Solanaceæ* such genera as have a plaited corolla and 5 stamens, and as *Scrophulariaceæ* all those in which either the fifth stamen is wanting or the aestivation of the corolla is imbricated. Of the orders with irregular flowers, those which may be mistaken for *Scrophulariaceæ* are *Geraneaceæ* and *Orobanchaceæ*, which are distinguished by their unilocular ovary with parietal placentæ; and the *Bignoniaceæ*, *Cyrtandraceæ*, and *Pedaliaceæ*, which have seeds without albumen, and the two latter have a unilocular or spuriously 2-4-locular fruit. *Lentibulaceæ* are closely allied to this order, but are distinguished by their unilocular fruit, free central placentæ, and minute embryo.

Rhinanthus hirsuta.

a, cutting, showing leaves and inflorescence; b, corolla opened, showing didynamous stamens; c, personate corolla, and calyx; d, pistil; e, fruit; f, seed with embryo lying in the albumen.

The *Scrophulariaceæ* are very widely diffused over the surface of the earth, being found in the whole range of climate between the

coldest point at which vegetation occurs at the poles, and the hottest parts of the tropics. In the torrid zone of both worlds they are very abundant, and form a 26th part of the flowering plants of Europe and a 36th of those of North America. In Australia and New Zealand they are common, and the barren shores of Tierra del Fuego produce several species. *Scrophulariaceae* are in general suspicious plants. Several of them are active poisons, and though all do not possess deleterious properties, they are all more or less acrid. Some are esculent, but they require great caution in their preparation as food: heat or vinegar appears to lessen or destroy their injurious principles, and these agents should be employed in preparing them for use. Amongst those which are edible are the *Mimulus lutea* and *M. guttatus*, the former being eaten as a pot-herb in Peru, and the latter as a salad. [MIMULUS.] *Achimenes Cochinchinensis*, when pickled, is much esteemed in the country where it grows as an article of diet. Many of the species of this order are used in medicine: the *Digitalis purpurea*, or Purple Foxglove, has a powerful influence on the system; and is a valuable remedy in many diseases. [DIGITALIS.] *Gratiola officinalis*, the Hedge Hyssop, is also an active medicine, and so efficacious was it once esteemed that it received the name of *Gratia Dei*. *Scrophularia*, the genus which is the type of the order, derives its name from the resemblance of the tumid roots of some of the species to scrophulous swellings of the neck, to which they were applied upon the absurd supposition that nature thus pointed out the remedies for diseases. *S. nodosa* has a bitter taste, and a decoction of its leaves is used for curing the scab in swine. *S. aquatica* is called by the French Herbe du Siège. [SCROPHULARIA.] There are 176 genera and 1814 species—14 are British genera.

SCRUPARIA. [POLYZOA.]

SCRUPOCELLARIA. [POLYZOA.]

SCURVY-GRASS. [COCHLEARIA.]

SCUTELLA. [ECHINIDÆ.]

SCUTELLARIA (from the Latin 'Scutella,' a little saucer, in reference to the form of the calyx), a genus of Plants belonging to the natural order *Labiatae*. It has a campanulate bilabiate calyx, the lips entire, the upper one with a concave scale on its back. The tube of the corolla much exerted, 2-lipped, the upper lip concave. The filaments simple; the anthers of the two longer and inferior stamens 1-celled, of the shorter and superior stamens 2-celled. The species are annual or perennial herbs, rarely shrubs.

S. galericulata, Skullcap, has branched divaricate stems, leaves on short petioles, oblong, lanceolate, cordate below, crenate, serrate; flowers axillary, opposite, and on short pedicels. The corolla is large and blue. The whole genus is remarkable for being provided with a curved elongated support to its nut. This species was once considered efficacious in certain fevers. It is plentiful in Europe, Asia, and North America, in humid places, and in Britain.

S. minor, Smaller Skullcap, is a humble glabrous plant, with its leaves on short petioles, the lower ones broadly ovate, the middle ones ovate-lanceolate with the base cordate, the upper ones lanceolate, rounded at the base; the flowers axillary, opposite, secured; the corolla almost glabrous, with the throat hardly dilated. It is a native of Europe and Siberia, in damp places, and of Great Britain.

S. lateriflora has erect fleshy stems, petiolate, ovate-lanceolate acuminate leaves rounded at the base; the upper floral leaves hardly exceeding the calyxes, the racemes axillary and terminal, the flowers opposite and secund. It is a native of North America, on the margins of ponds, and was once extolled as a remedy for hydrophobia, but on no good grounds.

Most of the species of *Scutellaria* are very pretty ornamental plants, and will grow in any common soil.

(Bakington, *Manual of British Botany*; Lindley, *Flora Medica*.)

SCUTIBRANCHIATA. [MALACOLOGY.]

SCYLLARIDÆ, or SCYLLARIANS, a tribe of Macrurous Decapods, established by M. Milne-Edwards on the genus *Scyllarus* of Fabricius, and forming one of the most remarkable groups, distinguished at the first glance by the singular conformation of the external antennæ.

Jaw-Foot of *Scyllarus*.

The antennæ are inserted on the same line below the eyes; the first pair are slender, and present nothing remarkable; their first joint is nearly cylindrical and much stouter than the two following ones; finally, they terminate by two very short multi-articulate filaments. The external antennæ are foliaceous and extremely wide; the piece which carries the auditory tubercle is confounded with the epistome, and followed by four joints, the second and fourth of which are

lamellar and extremely large. The huccal frame is small, and the jaw-feet are moderate and nearly pediform.

M. Milne-Edwards divides the tribe into three genera, *Scyllarus*, *Thenus*, and *Ibacus*.

Scyllarus, Fabr.—The *Scyllari*, properly so called, differ, observes Milne-Edwards, from the other crustaceans of the same tribe in the general form of their body, which is much more elongated than that of the others, and diminishes but very little in width towards the tail. The carapace is much longer than it is wide; the lateral borders are parallel. The orbits are situated very far away from the median line, very near the external angle of the carapace, but not reaching it; they are circular, and directed upwards.

S. equinoxialis is of a yellowish colour mingled with red. Length about a foot. It is a native of the Antilles.

Scyllarus equinoxialis.

Thenus (*Scyllarus*, Fabr.; *Thenus* (?), Leach). Body very much depressed, and much narrowed from before backwards. Ocular peduncles very long. Eyes going beyond the carapace laterally; the orbits, directed outwards, occupy the external angle. Sternum much wider than in *Scyllarus*. Abdomen with nearly the same proportional length as in those crustaceans.

T. orientalis. Length about eight inches.

Thenus orientalis.

Ibacus, Leach.—Carapace much wider than it is long, and with a lamellar prolongation on each side, which covers the greater portion of the feet. The orbits, instead of being placed near the external

angle of the carapace, are very far distant from it. The abdomen is very short, and is suddenly narrowed from before backwards.

Carapace of *Ibaeus*, seen from above.

I. Peronii. Length about five inches. It inhabits the seas of Australasia.

Ibaeus Peronii.

SCYLLARUS. [SCYLLARIDÆ.]

SCYLLI'ODUS, a genus of Fossil Fishes. [FISH.]

SCYLLIUM. [SQUALIDÆ.]

SCYMNUS. [SQUALIDÆ.]

SCYPHIA, a Fossil genus of *Spongiada*.

SCY'TALE. [BOIDÆ.]

SCYTHIAN LAMB. [BAROMETZ.]

SCYTHROPS (Latham), an Australian genus of Birds allied to the Toncan.

SEA-ADDER, a name given to the Fifteen-Spined Stickleback.

[GASTEROSTEUS.]

SEA-APE. [SQUALIDÆ.]

SEA-BEAR. [BEAR.]

SEA-BREAM. [PAGELLUS.]

SEA-BUCKTHORN. [HIPPOPHAE.]

SEA-CALF. [PHOCIDÆ.]

SEA-COW. [PHOCIDÆ.]

SEA-CRAWFISIL. [PALINURUS.]

SEA-DACE. [LABRAX.]

SEA-DEVIL. [LOPHUS.]

SEA-DUCKS. [DUCKS.]

SEA-EAR. [HALIOTIDÆ.]

SEA-EGGS. [ECHINIDÆ.]

SEA-ELEPHANT. [PHOCIDÆ.]

SEA-FAN. [POLYPIPERA.]

SEA-FOX. [SQUALIDÆ.]

SEA-FROTH. [MEERSCHAUM.]

SEA-HOLLY. [ERYNGIUM.]

SEA-HORSE. [HIPPOPOTAMUS.]

SEA-KALE. [CRAMEZ.]

SEA-LAVENDER. [STATICE.]

SEA-LEOPARD. [PHOCIDÆ.]

SEA-LION. [PHOCIDÆ.]

SEA-MOUSE. [ANNELIDA.]

SEA-NEEDLE, a name for the Gar-Fish. [ESOX.]

SEA-NETTLE. [ACINIA.]

SEA-NETTLES. [ACALEPHÆ.]

SEA-OWL. [CYCLOPTERUS.]

SEA-PEA. [LATHYRUS.]

SEA-PEN. [POLYPIPERA.]

SEA-PIE. [CHARADRIADÆ.]

SEA-PIKE. [BELONE.]

SEA-POACHER. [ASPIDIPTERUS.]

SEA-RADISH. [RAPHANUS.]

SEA-REED. [PSAMMA.]

SEA-ROCKET. [CAKILE.]

SEA-SCORPION. [COTTUS.]

SEA-SNAIL. [DISCOBOLL.]

SEA-SNIPE. [CENTRISCUS.]

SEA-STARS. [ASTERIADÆ; ECHINODERMATA.]

SEA-SWALLOWS. [STERNIDÆ.]

SEA-URCHINS. [ECHINIDÆ.]

SEA-WEEDS. [ALGÆ.]

SEA-WIFE. [LABRIDÆ.]

SEA-WOLF. [ANARRHICAS.]

SEAFORTHIA, a genus of Plants belonging to the natural order *Palmaceæ*, indigenous to the eastern coast of tropical Australia, and found also in the nearest Asiatic islands, named by Mr. Brown in honour of Francis, Lord Seaforth, a patron of botany. The species are elegant in appearance, with pinnate fronds, the flowers polygamomonoëcious, sessile on a branched spadix, with several incomplete spathes, the male flowers above, and with two supporting each female flower. The calyx and corolla are trifid. The male flowers with numerous stamens, and the rudiment of a pistil; the female flowers without any rudiments of stamens; ovary 1-celled. Style very short; stigmas 3, spreading; berry fibrous, small, oval, 1-seeded; albumen ruminate; embryo basilary. The genus is described by Labillardière under the name of *Psychosperma*.

SEALS. [PHOCIDÆ.]

SEBASTES. [SCORPENA.]

SEBESTEN. [CORDIA.]

SEBESTENS, Lindley's name for the order *Cordiaceæ*. [CORDIACEÆ.]

SECALE, a genus of Grasses, to which the cultivated Rye belongs. The flowers are arranged on a spike; the spikelets are 2-flowered, with a long stalked rudiment of a third floret; the glumes are subulate. In other respects this genus strongly resembles *Triticum*, to which the Common Wheat and Couch-Grass belong. [TRITICUM.]

S. cereale, Rye, has the glumes 1-nerved and shorter than the spikelet; the rachis is very tough. This plant is extensively cultivated in Europe, and nowhere has been observed in a truly wild state, away from the possibility of escape from cultivation, being sown by the agency of man. [RYE, in ARTS AND SC. DIV.]

S. montanum has the rachis hairy, brittle; glumes with a short point; the root fibrous. It is found on the gravelly mountains of Sicily.

S. villosum is also a European species, in which the spikelets are 4-flowered, and the glumes have 2 or 3 strong ribs. It is found in France.

(Wood, *Tourists' Flora*.)

SECAMO'NE, a genus of Plants belonging to the natural order *Asclepiadaceæ*, found in the warm parts of India, Africa, Australia, and in the West Indies. The name is probably derived from the Arabic Sukmoonya, as this is the proper name in Prosper Alpinus of the *Secamone Alpinii*, or *Periploca Secamone* of Linnæus. The genus *Secamone* is characterised by having a quinquefid calyx and corolla, the latter being rotate; staminate crown 5-leaved, with the leaflets compressed laterally; pollen masses 20, erect; stigma connate at top; follicles smooth; seeds numerous, hairy at the umbilicus. The species form erect or climbing smooth shrubs with opposite leaves; the flowers are small, and the inflorescence in cymes, which are dichotomous, arising from between the petioles.

Some of the species of *Secamone* secrete a considerable quantity of an acrid principle, which makes them useful as medicines. Thus the roots of *S. emetica*, being emetic in action, are employed as a substitute for *Ipecacuanha*; whilst the substance called *Smyrna Scammony* is said to be obtained from the Egyptian species, *S. Alpini* of Roemer and Schultes, the *S. Aegyptiaca* of Brown.

SECRETARY-BIRD. [GYROGERANUS.]

SECRETING GLANDS. [GLAND; SECRETION.]

SECRETION, in the Animal Kingdom, is that process by which substances are separated from the blood, either for some ulterior purpose in the body, or to be thrown off as useless and effete matter. The term 'secretions' is often applied to those substances alone which are separated from the body for the purpose of being thrown off, but everything that is formed or separated from the blood by the action of the cells should be regarded as a secretion. The term 'excretion' is applied to those secretions which are thrown off from the body, as the urine, perspiration, &c.

The process of secretion in animals is less complicated generally than the same process in plants; for whilst in the plant all the materials for its nutrition must undergo a process of change, this is only the case with a certain number of the secretions of animals. In the great proportion of cases of nutrition effected by secretions in the animal, it consists in merely separating the materials of growth from the blood, where they already exist. It is more especially in the case of materials that are to be got rid of from the animal system that the greatest amount of chemical change is observed, as in bile, milk, saliva, &c. But even in some of these cases, as in the uric acid, and urea of the urine, and carbonic acid from the lungs, the substances got rid of seem previously formed in the blood.

In all cases the secretions of the animal body are found to take place in organs presenting three elementary conditions:—1, Cells; 2, a Basement Membrane; 3, Bloodvessels. Of these the only element universally necessary is the cell. As we find that, amongst the lowest

animals, where neither bloodvessels nor basement membranes are present, the cell has the power of forming special products, and separating them from the fluid by which it may be surrounded. [CELLS; GLANDS; MEMBRANE; INTESTINES.]

On the surface of serous membranes a serous liquid is formed, which is supposed to be simply an exudation or oozing from the vessels supplying the membrane. Whether such exudations are entitled to the name of secretions is doubtful. Various circumstances influence the function of secretion in the higher animals. Among these may be mentioned:—

1. The quantity of blood.
2. The composition of the blood.
3. The state of the nervous system.

An increased supply of blood generally increases secretion. At the same time an increased secretion from a part will draw a larger quantity of blood to a part, so that these conditions react on each other. There are however diseased conditions in which an increased supply of blood to an organ suspends altogether secretion from a part. This is the case in some stages of inflammation of the mucous membranes.

That secretion is dependent on the supply of materials in the blood is frequently observed. Thus when one kidney is diseased the blood gets a larger supply of urea, and the other kidney throws off a much larger quantity than it otherwise would do. The kidney also grows larger, and this indicates the relation between nutrition and secretion. At the same time in diseased conditions we have exceptions. In gout the kidneys seem unable to carry off the lithic acid from the blood, whilst in rheumatism the lithic acid is so freely carried off that none is found in the blood.

The nervous system in the higher animals exerts a powerful influence on the secretions. Excitement of the mind will produce tears. Fear and anxiety increase the intestinal and urinary secretions. Injuries to the spinal cord increase the phosphate in the urine. The thought of food increases the flow of saliva. The mother's breast fills with milk at the thought of or sight of her infant. Under the influence of passion or fear the milk becomes changed in composition, and injurious.

The purposes which the secretions serve are various. Some, as already stated, have no other purpose than to moisten the several parts of the body; others are appropriated to the service of important functions, as the saliva, the gastric juice, the bile, and the pancreatic and intestinal fluids, which all assist in digestion. Such also are the tears, which serve for the cleansing of the front of the eye; the milk for the food of the offspring; and various materials for the defence and comfort of the animal, and for the propagation of the species. Other secretions again, which are commonly called excretions, are the refuse of the blood, and if retained in it would exercise an injurious influence on the whole economy; such are the cutaneous perspiration, the urine, and those parts of the bile and intestinal fluids which are not used in digestion. [BILE; GLAND; INTESTINES; LIVER; MAMMARY GLAND; MILK; MUCUS; PANCREAS; SALIVA; SKIN; STOMACH.]

SECRECTIONS OF PLANTS are those substances which are found in Plants, and which have been formed by the action of the cells upon the compounds which have been taken up into the plant as food. [SAP.] From this point of view all substances, whether composing a part of the tissue of plants or thrown out upon their surface, are regarded as secretions.

Although the term secretion is generally connected with the idea of separating for the purpose of throwing off, or getting rid of a product, it is very manifest that such a use of the term would restrict its application to the substances which, amongst animals, are called excretions. It does not appear that any one class of substances can be called excretions more than another in the vegetable kingdom. It is true that a theory of the practice of 'rotation of crops' supposes it to depend on poisonous excretions given off by the roots of one plant which are not poisonous to another. But the facts brought forward to support this theory are doubtful, and other explanations of the necessity of rotation have been given. [ROOT.]

In plants the organs of secretion are simpler than those of animals, as they have no fixed reservoir from which to draw the materials of secretion, as the blood. This function however seems to be performed in both plants and animals on the same general plan. It is in both cases in the interior of the cell that the most remarkable instance of the process takes place. In the plant the compounds changed are simpler, whilst the chemical forces in action during secretion are stronger than in animals. All the important secretions of plants are compounds of the four organic elements: carbon, hydrogen, oxygen, and nitrogen. These enter the plant in the form of carbonic acid and ammonia. Out of these compounds the various substances that give the hardness to the wood of plants, the nutritive value to their seeds, roots, and other parts, the colour and scents of their leaves and flowers, with the medicinal virtues of many special plants, are formed. The substances thus produced are easily distinguishable, and may be divided into two great classes.

First, Nutritive or Assimilable Secretions, that is, substances which having been formed in the plant, are used for forming its tissues, and constructing the mass of which it is composed. The principal substances which are thus employed are cellulose, starch, sugar, oil, and

protein. The first four are distinguished by containing the elements carbon, hydrogen, and oxygen, whilst the latter contains in addition nitrogen. [CELLULOSE; DEXTRINE; STARCH; SUGAR; OIL; PROTEIN.]

These substances are found universally in the vegetable kingdom. No cell can be formed without one of the ternary compounds, and a portion of the quaternary substance in some form. Hence they are called in relation to the plant Nutritive Secretions. These substances are also easily convertible the one into the other; the sugar may be converted into starch or cellulose, and vice versa, and thus their powers and properties are essentially connected with the assimilative processes of the plant.

The second class of substances are called Non-Assimilable or Special Secretions of Plants. They are substances which are not found in every part of every plant. When once formed also they are not liable to change, and are certainly never converted into the nutritive secretions; hence they are called non-assimilable. Some of these substances are very generally diffused amongst plants, as chlorophyll, which is the substance which gives the peculiar green to the leaves and other parts of plants. [CHLOROPHYLL.]

These secretions are very numerous, and may be classed under certain general heads.

1. Colouring matters. To this head may be referred chlorophyll; the colouring principle of the petals of plants seems also to be a modification of this substance. There are however other colouring matters in plants, such as those used by the dyer, and which do not give any colour to the plants in which they exist, which have nevertheless a very definite chemical composition, and by combining with various other substances produce the colours used by the manufacturers of coloured cotton, linen, silk, and woollen cloths of various kinds. These colouring matters would appear to arise from the decomposition of the assimilable secretions, as many of them bear a close relation to both the ternary and quaternary forms of these secretions.

2. Acids. Substances having an acid reaction, and capable of combining with the oxides of the metals, are very common in the vegetable kingdom. The most familiar forms are those which occur in fruits, as the oxalic, citric, malic, and tartaric acids. Oxalic acid is found in the *Oxalis Acetosella*, hence its name, and other forms of *Oxalidaceae*. It is also found in the *Cactaceae* and *Polygonaceae*. In the latter order it exists in the species of *Rheum* (*Rhubarb*), used for making pies, and also in the *Sorrels* (*Rumex*). In all these cases it is combined with the oxide of some metal, either potassium or calcium. In *Sorrel* (*Rumex acetosa*) it exists as a quinoxalate or superoxalate of potash, which, when separated, is called Salts of Sorrel. In the *Cactaceae* it exists as an insoluble oxalate of lime, in the form of raphides. These bodies, which are merely needle-like crystals of this salt, are very common in the vegetable kingdom. Citric Acid is found in the fruits of the order *Aurantiaceae*, as the lemon, orange, lime, shaddock, &c. It is easily separated from these fruits in a crystalline form. It is soluble in all its combinations with the oxides of the metals, hence it does not occur as oxalic acid in the form of raphides. Tartaric Acid is found in the juice of the grape. Though closely resembling citric acid, it differs in forming an insoluble compound with potash. This compound is the supertartrate of potash, or cream of tartar of the shops. This salt is deposited whenever grape-juice is allowed to stand. It forms the basis of the tartar of wine procured from the lees. This property of tartaric acid makes the juice of the grape the most efficient compound from which to make wine. The juice of fruits containing citric acid, whose salts are soluble, are much less fitted for wine-making. Malic Acid is the acid found in the apple, and which gives the sour taste to verjuice, as also to the fermented juices of the apple and pear—cider and perry.

The chemist has described a very large number of organic acids as present in plants, and every day is increasing their number. Many of the colouring matters appear to be acids, which assume their particular colours by combination with metallic oxides, such as the leucanoric, orsellic, erythric, and parellic acids, obtained from lichens, used in making eudhear and archil. The vegetable alkalis, or alkaloids, are also found in combination with acids; thus, aconitine is found in combination with aconitic acid, morphia with meconic acid, and a variety of others.

The acids generally occur in combination, and sometimes supplant each other. Even mineral acids will sometimes take the place of organic acids; thus sulphuric acid is sometimes found combined with morphia in the place of meconic acid. On the other hand, the metallic oxides will sometimes take the place of the alkaloid, and be found in combination with the organic acid. In the instance however of gallic and tannic acids, there appears to be no combination with alkalies or alkaloids. Tannic acid, formerly called tannine, is found very generally present in the woody parts of plants. It is supposed to result from the decomposition of cellulose. Theoretically, it may easily be formed out of carbonic acid and water. Whether it passes through the stage of cellulose is doubtful. It is of great use in the arts, especially in tanning and dyeing, and for these purposes it is obtained from the bark of oak, elm, willow, sumach, and other trees. It exists in the fruits of the *Chrysobalanaceae*, and the legumes which are called 'divi divi.' The vegetable extracts called catechu, or cutch, and the exudations which are sold by the name of kino consist

principally of tannic acid. This acid is converted into gallic acid by oxidation. Such a process takes place during the formation of the galls produced by the puncture of insects in the buds of many of the species of *Quercus*, especially *Q. infectoria*. These excrescences are called gall-nuts, and from the presence of this acid in them it has been called gallic acid. [GALLS; QUERCUS; ACACIA; LTEROCARPUS.]

The alkaloids are substances found in the leaves, fruits, bark, and other parts of plants. They are some of them peculiar to particular species of plants, whilst others are more generally diffused. Many of them possess extraordinary properties in relation to the animal kingdom, producing poisonous effects: such are strychnia, from the *Strychnos Nux Vomica*; morphia, from the *Papaver somniferum*; conia, from the *Conium maculatum*. These substances are always found in combination with organic or mineral acids. There is however another class of substances closely resembling these in their composition and action, which do not combine with acids. These are called neutral principles: such is theine, the principle found in tea, coffee, and Paraguay tea; and theobromine, the principle of cocoa.

The volatile oils are another group of secretions of great interest. They differ in composition and character from the mixed oils, and do not appear to belong to the assimilable secretions. They are many of them used as perfumes—others as stimulant medicines, and are remarkable for the interesting compounds they can be broken up into by the agency of chemistry. Their investigation is throwing much light on vegetable chemistry. [OILS.]

The resins are a group of substances standing in a similar relation to the fixed oils, as the volatile oils. They do not appear to be assimilable, they are only occasionally formed, and present special properties in particular plants. They are often combined with gum, forming the substances called gum-resins, and from this combination it may be supposed they are directly formed from the ternary assimilable secretions. When occurring with gum, as in the case of the gum-resins of the *Umbellifera*, or without gum, as in the resins of the *Conifera* and in Myrrh, they are combined with volatile oils, which appears to give them their peculiar odours, flavours, and action. In the *Conifera* the volatile oil they are combined with is the same in most species, and is used in the arts under the name of oil or spirits of turpentine. [CONIFERÆ.] Wax is another substance very commonly found in plants, and having relation with the fixed oils. [WAX.] Caoutchouc and Gutta-Percha are also compounds belonging to the non-assimilable group of vegetable secretions, and are remarkable for the absence of either oxygen or nitrogen. [INDIA RUBBER; ISONANDRA.]

Although the processes by which these products may be gradually elaborated in the vegetable kingdom may be very numerous and much more complicated than any processes with which we are at present acquainted, we can readily explain their formation from the carbonic acid, water, and ammonia, taken up by plants, and the loss of oxygen.

The following tables illustrate this process, with regard to several of the substances mentioned:—

TABLE OF SUBSTANCES FORMED FROM CARBONIC ACID AND WATER, BY THE LOSS OF OXYGEN.

Substance formed.		Carbonic Acid used in eqs.	Water used in eqs.	Oxygen lost in eqs.
Name.	Formula.			
Oxalic Acid (dry) . .	C_2, H, O	2	1	1
Gallic Acid	C_7, H_3, O_8	7	3	12
Tartaric Acid . . .	C_4, H_4, O_6	8	8	10
Malic Acid	C_4, H_4, O_5	8	6	12
Citric Acid	C_6, H_8, O_{11}	12	8	18
Meconic Acid . . .	C_{11}, H_8, O_{11}	14	4	18
Cellulose	C_{12}, H_{10}, O_8	12	8	24
Starch	C_{12}, H_{10}, O_{12}	12	10	24
Cane Sugar	C_{12}, H_{22}, O_{11}	12	11	24
Glucose (dry) . . .	C_{12}, H_{22}, O_{12}	12	12	24
Quassine	C_{22}, H_{16}, O_8	20	12	46
Salleine	C_{22}, H_{16}, O_{11}	26	18	50
Oil of Turpentine . .	C_{10}, H_8	10	8	28
Oil of Lemons . . .	C_8, H_4	5	4	14
Oil of Juniper . . .	C_{15}, H_{12}	15	12	42

TABLE OF SUBSTANCES FORMED FROM CARBONIC ACID, AMMONIA, AND WATER, BY THE LOSS OF OXYGEN.

Substance formed.		Carbonic Acid used in eqs.	Water used in eqs.	Ammonia used in eqs.	Oxygen lost in eqs.
Name.	Formula.				
Asparagine	C_4, N_2, H_{10}, O_5	8	4	2	13
Indigo	C_{16}, N, H_7, O_2	16	3	1	33
Nicotine	C_{10}, N, H_8	10	8	1	28
Conine	C_{11}, N, H_{16}	16	16	1	48
Morphine	C_{17}, N, H_{15}, O_4	35	17	1	81
Quinine	C_{20}, N, H_{12}, O_6	20	9	1	43
Strychnine	C_{15}, N_2, H_{10}, O_4	41	16	2	106
Theine	C_{17}, N_2, H_{14}, O_4	10	0	0	28
Albumen	$C_{216}, N_{27}, H_{128}, O_{87}$	216	83	27	452
Caseine	$C_{256}, N_{36}, H_{128}, O_{66}$	256	120	36	612

It should not however be lost sight of that other elements besides the four organic are constantly found present in the secretions of plants. Sulphur and phosphorus are found in fibrine, caseine, and albumen. The alkalies and alkaline earths are found very commonly associated with all these secretions, and it is very certain that plants will not form their secretions unless the inorganic elements are present. [SAP; ROOT.]

SECRETIONS, VEGETABLE. [SECRETIONS OF PLANTS.]

SECUNDINES. [REPRODUCTION IN PLANTS AND ANIMALS.]

SECURIFERA, a family of Hymenopterous Insects of the section *Terebrantia*, the species of which are chiefly distinguished by their having the abdomen sessile, or joined to the thorax so as to appear a continuation of that part, and not separated by a slender peduncle. In the females, the abdomen is provided with a saw-like apparatus, which not only serves for depositing the eggs, but for preparing a place for their reception. The larvæ greatly resemble those of lepidopterous insects, and, like them, feed upon plants; they are cylindrical, soft, and fleshy; have the head vertical, and the three thoracic segments each provided with a pair of legs; besides these, the abdomen is often provided with pro-legs.

The *Securifera* are divided by Latreille into two sections, the *Tenthredinete* and the *Urocerata*. The first corresponds with the genus *Tenthredo* of Linnæus, the species of which have the mandibles elongated and compressed; the maxillary palpi are six-jointed, and the labial have four joints; the four wings are always divided by the nervures into numerous cells. The abdomen is composed of nine segments, the last of which is provided with an oviduct composed of two serrated lamellæ; these are pointed and lodged between two others forming a kind of sheath. By means of this saw-like ovipositor the female *Tenthredo* bores holes in the stems and other parts of plants, in which she deposits her eggs. In each hole, after the egg or eggs are deposited, a liquid is injected, the use of which, it is supposed, is to prevent the closing of the opening. The wounds thus made increase in volume, and form excrescences, which are either hard, or soft and pulpy, according to the nature of the plant or of the part wounded. These tumours then form the domicile of the larvæ, which inhabit them either solitarily or in society, and in them undergo their metamorphosis. Generally however the larvæ of the *Tenthredinidae* live exposed on the leaves of the plants upon which they feed, and these larvæ are usually observed with the body more or less rolled in a spiral manner. When about to assume the pupa state, they inclose themselves in a cocoon which is sometimes fixed to the plant, but frequently they bury themselves in the ground previously to assuming the pupa state.

The second section (*Urocerata*) is distinguished from the preceding by the mandibles being short and stout, the ligula entire; the ovipositor of the females is sometimes exerted and composed of three slender appendages, and sometimes spirally rolled within the abdomen. It is composed chiefly of the Linnæan genus *Sira*.

SEDGE. [CLADIUM; CAREX.]

SEDGE-WARBLERS. [SYLVIADÆ.]

SEDGES. [CYPERACEÆ.]

SEDUM, a genus of Plants belonging to the natural order *Crassulaceæ*. It is known by possessing a 5-parted calyx with ovate usually turgid leaf-shaped sepals; five petals, which are usually spreading; ten stamens, an hypogynous scale at the base of each carpel; five carpels. They are mostly herbs or shrubby plants, with stems usually branched from the base. The flowerless stems are crowded with leaves, which are alternate, seldom opposite, fleshy, terete or flat, and entire. The flowers are commonly yellow, sometimes white or blue, and are arrayed in cymes. The species of *Sedum* are inhabitants of the temperate and warmer parts of the earth, and are mostly found in dry, barren, rocky, or arid situations where nothing else will grow. Their roots appear to serve only the purpose of holding them in the ground, whilst their leaves are so constructed that they absorb moisture from the air, and prevent its being again evaporated.

S. Rhodiola, Rose-Root Stonecrop, or Rhodiola. Leaves flat, oblong, serrated at the apex, glabrous, glaucous; root tuberous; stems single; flowers with 4 petals, 8 anthers, and dioecious from abortion. It is a native of mountainous districts of the middle of Europe, of Siberia, and north America. In Great Britain it is found on mountains in the north of England, Scotland, and Wales. It is a glaucous plant with yellow flowers. The root, when dried, has a sweet taste and smell, and hence its common name. The leaves have been used as a cathartic in headache, and the root has been supposed to possess antiscorbutic qualities. In Greenland it is eaten as a salad. This and some allied species constituted the genus *Rhodiola*, but the difference between them and *Sedum* does not justify the separation.

S. Telephium, Orpine, or Tuberous Stonecrop. Leaves oblong or oval, attenuated at the base, flat, toothed, glabrous; stems erect; cymes corymbose, terminal; stamens equal in number with the petals. It is found on rocks, walls, and dry stony places in most parts of Europe; in Great Britain it is met with on the borders of fields, in hedges and bushy places, on a gravelly or chalky soil. Several varieties have been described, and sometimes as species. The most frequent is one with purple flowers, *S. T. purpureum*. The leaves of this plant are sometimes eaten as a salad; and in former times the roots were in request as a remedy in hæmorrhoids and other diseases.

S. Anacampseros, Anacampseros, or Evergreen Orpine. Leaves

wedge-shaped, obtuse, entire, nearly sessile, alternate, flat, smooth; stems decumbent; flowers corymbose. It is a native of rocks on the higher mountains of Piedmont, Savoy, Switzerland, &c. It is often cultivated in gardens. It is a trailing plant, with beautiful purple flowers. It was also formerly used in medicine.

S. acre, Acid Stonecrop. Stems rather creeping; branches erect; leaves ovate, fleshy, sessile, suberect, alternate, glabrous; flowers sessile, on a trifid cyme; petals lanceolate, acuminate. It is one of the most common of the genus, and is found on walls, roofs of houses, rocks, and dry places, all over Europe. When chewed in the mouth, it has a hot biting taste; hence it is frequently called Walk-*Pepper*. When applied to the skin, it produces vesication; and, taken internally, it causes vomiting.

S. album, White Stonecrop. Branches perennial, rooting; leaves club-shaped, green, flattish, glabrous; cymes branched, terminal, sub-corymbose; petals bluntish. The flowers are cymose and white. It is a native of Europe, in dry meadows, on walls and rocks. It is rare in England. With many of the more common Stonecrops, this species has been used in medicine, and also eaten cooked, or as a salad.

SEED, in Botany, is that part of a plant which contains, within several coverings, the embryo or young plant, and is itself covered over with the various parts of the pericarp or fruit. The seed in its young state is called the Ovule, or Seed-Bud, which is found in the interior of the Ovary, or Germen, at a very early period of its growth. When the ovules are first seen they are like little warty excrescences on the inside of the Ovarium, composed of delicate cellular tissue. As they increase in size they elongate, and may then be divided into two parts, a central portion, consisting of cellular tissue, called the Nucleus, and an external covering consisting of two membranes, the outer one of which is called Primine and the inner one Secundine. At one end the two membranes are open, forming a hole called the Foramen, from which the nucleus projects more or less in the early stages of its growth. As the ovule increases in size the foramen is almost closed, and in the matured seed it is called the Micropyle. The base of the ovule is attached to a membrane of the ovarium called the Placenta, and as the ovule increases in size the portion of its tissues that connects it with the ovary becomes, relatively to the ovule, small and cord-like, and hence has been called the Funiculus, or Umbilical Cord. The point where this cord unites with the ovule becomes in the seed the Hilum, and it is at this point also that a number of spiral vessels and ducts are observed to pass to the base of the seed, which has been called the Chalaza. In the progress of the growth of the ovule the nucleus increases in size, and becomes hollow inside, forming a little sub-sac, which forms a kind of third membrane, called Tercine. In the interior of this sac another is formed, which, as it contains or forms a part of the embryo or young plant, is called the Sac of the Embryo. Whilst growing the parts do not always maintain the same relations to each other that we have described, and from this circumstance Mirbel has proposed a classification of ovules. When the ovule has grown regularly with the hilum and chalaza at the base and the foramen at the apex, it is called a Straight or Orthotropous Ovule. Although this appears to be the normal mode of growth, it is not the most frequent. It is seen in the walnut. If in the course of growth the ovule is bent round, so that the foramen is brought near to its base, where the hilum and chalaza exist, it is called a Curved or Campylotropous Ovule. This is seen in the *Brassicaceae*, *Papilionaceae*, and *Caryophyllaceae*. When one part of the ovule grows faster than the other, the nucleus loses its relative position,—its point is in this instance directed towards the base, and the foramen is found near the hilum, and the base of the nucleus becomes situated where its apex originally was, and it carries to this point the chalaza, which is continued from the cord by means of a set of vessels called the Raphé. This forms a third class of ovules, called Contorted or Anatroplus Ovules. It is seen in *Liliaceae*, *Rosaceae*, *Ranunculaceae*, &c. Mirbel maintains that all ovules are originally straight, but Link doubts this. (Link, 'Grundrissen der Kräuterkunde,' Theil ii., p. 231.)

The position of the ovule in relation to the ovary is a point of some importance in systematic botany. When it arises up from the base of the ovarium, it is called Erect; when it originates a little above the base, ascending; when it hangs from the apex of the cavity, Pendulous; when it hangs from any point below the very apex, Suspended.

Their number is also a point of value, and when there are only few and easily counted, they are said to be Definite. When their number is too great to be counted, they are called Indefinite.

Such is the state of the young seed up to the time of the influence of the pollen upon the stigma. Soon after this action takes place a minute vesicle makes its appearance on the summit of the inner sac of the nucleus. This vesicle increases in size, and is developed into three parts, a descending portion, called the Radicle, and which always points to the foramen; an ascending portion, the Plumule; and lateral or enveloping portions, the Cotyledons; the whole constituting the Embryo, or young plant.

Whilst the embryo is growing, the membranes which immediately surround it increase in size, and frequently become the seat of the deposition of a large quantity of amylaceous and other matters, called Albumen, or Endosperm, which is deposited for the purpose of supplying the young plant with nutriment during its growth. This nutri-

tive matter however is not always deposited around the embryo, but in many cases in the cotyledons of the embryo itself, where it performs the same functions as when deposited in the tercio, or sac of the embryo. The former takes place in *Ranunculaceae*, *Papaveraceae*, and all that group of plants named by Lindley *Albuminosae*, whilst the latter is seen in *Leguminosae* and other orders.

When the embryo is fully grown the ovule has no further need of connection with the placenta, the funiculus or cord therefore dries up, and the scar which is left on the seed at its point of union with it is the Hilum or Eye; and when this is fully formed, and the embryo is capable of independent growth, the ovule becomes a Seed. Sometimes the umbilical cord, instead of disappearing, increases in size, forming a membrane which entirely envelopes the seed, and is called an Aril. One of the most remarkable instances of its existence is in the nutmeg, around which a thick aril is formed, which forms the mace of the shops. It is also well seen in the *Euonymus*, or Common Spindle-Tree, where it forms a beautiful orange-coloured mantle around the seed. It also exists in the Passion-Flower. Its uses are unknown.

The external coverings of the seed, which are called primine and secundine in the ovule, are called the Testa, Perisperm, or Spermoderm, and are nothing more than a hardened state of the ovular membranes. Whatever may be the number of these coverings in the ovule, they are seldom discernible in the seed. In the Walnut however two integuments can be plainly seen, one brown and tough, the other light and filmy; also in the Almond and some other seeds. In most instances the testa of the seed is perfectly smooth, but in others it is covered over with hair and other appendages. The cotton that is so extensively used for the manufacture of clothing is the production of the outer covering of the seeds of the cotton-plant. The Oleander is supplied with hairs at a particular part of the plant, that facilitate the moving of the seed from place to place through the air. In some instances the seeds have broad membranous expansions of the testa, called Wings, by which means they fly from one spot to another, as in the *Bignonia*. Many seeds are beautifully marked with veins running in all directions; others have minute elevations and depressions, presenting a remarkable regularity and beauty of structure.

When the seed is stripped of its testa it presents either the albumen surrounding the embryo, or the embryo itself. When the albumen is present, it varies much in character, being of a bony, oily, fleshy, or mealy consistence. These differences depend on the nature of the peculiar secretions which are mixed with fecula, or starch, in the albumen. There is a peculiar form of the albumen, which is called Ruminated, and which takes place in consequence of the abstraction of certain parts by absorption and their not being again filled up. This is the case with the Nutmeg.

There is sometimes found in seeds an organ between the albumen and embryo, which is the innermost membrane, in a state of induration and increased in size; it occurs in all the species of the Ginger tribe, and also in *Nymphaea lutea*, the Yellow Water-Lily. It is called the Vitellus.

The embryo is the most internal of all the parts of a seed. It consists, as before stated, of the radicle, plumule, and cotyledons, to which some add the Cauliculus, or Neck, which is only the point at which the radicle and plumule meet. The direction which the embryo takes varies much in different orders and genera of plants. Its directions are divided by botanists into Absolute and Relative. The absolute directions are explained by the terms straight, curved, falcate, uncinat, coiled up, folded up, spiral, bent at right angles, and serpentine. Terms have been devised also to express the relative positions of the embryo; but it is much more general for botanists to use the terms which we have referred to in speaking of the form of the ovule, and therefore we shall not explain these.

The seed-like fruits of *Lamiaceae*, *Boraginaceae*, *Graminaceae*, and *Cyperaceae* were supposed by Linnaeus and his followers to be Naked Seeds. But as these have been discovered to possess a pericarpial covering, it was thought that naked seeds could not exist. This opinion however has been shown by Brown to be incorrect, as he has demonstrated that the seeds of *Coniferae* and *Cycadaceae* are from their youngest state destitute of pericarp, and receive impregnation through their integuments, without the intervention of style, stigma, or stigmatic surface. [REPRODUCTION IN PLANTS AND ANIMALS; GERMINATION.]

SEISUR'RA (Vigors and Horsfield), a genus of Birds.

S. volitans is the *Turdus volitans* of Latam; Dishwasher of the colonists of New South Wales. It is constantly in motion, displaying its tail and uttering a sound analogous to that made by sharpening an instrument on a whetstone.

SEIU'RUS. [SYLVIADÆ.]

SELAGINA'CEÆ. [GLOBULARIACEÆ.]

SELENITE. [GYPSUM.]

SELENIUM, a non-metallic solid elementary body, discovered by Berzelius in the Iron Pyrites of Falun in 1818. It is not found pure in nature, but in the form of selenides of the metals copper, lead, mercury, and silver. [COPPER; LEAD; MERCURY; SILVER.]

SELF-HEAL. [PRUNELLA.]

SEMECARPUS, a very small and entirely Indian genus of Plants belonging to the natural order *Terebinthaceae*, of which the name is derived from *σμεῖον*, a mark, and *καρπός*, fruit, from the remarkable property possessed by the juice of the fruit, whence it is commonly

called Marking-Nut. The genus is characterised by having polygamous flowers; calyx 5-cleft; petals 5, oblong, sessile; stamens 5; disc urceolar; ovary free, sessile, girded by a tumid ring; styles 3; stigmas obtuse, emarginate. Nut compressed, heart-shaped, seated on a depressed thickened torus. Pericarp hard and thick, containing between the inner and outer layers cells full of a corrosive resinous juice.

S. Anacardium has long been known for the corrosive resinous juice contained in the nut. This juice is at first of a pale milk-colour, but when the fruit is perfectly ripe it is of a pure black colour and very acrid, and in both respects resembles that of several other plants of the same family, as in the Cashew-Nut species of *Rhus* and some of the varnish-trees. The juice is employed in medicine by the natives of India, and to mark all kinds of cotton-cloth. The colour is improved and fixed by a mixture of quicklime and water.

SEMIONOTUS. [FISH.]

SEMIPAL. [OPAL.]

SEMIPHYLLIDIANS, the third division of Lamarck's Gastropods, consisting of those whose branchiae are placed under the border of the mantle and disposed in a longitudinal series on the right side of the body alone. The Semiphyllidians respire water only. The two genera placed by Lamarck under this division are *Pleurobranchus* and *Umbrella*.

The *Inferobranchiata* of Cuvier consisted of the genera *Phyllidia* and *Diphyllidia* only; but M. Rang arranges under that order the Semiphyllidians as well as the Phyllidians, and the following is his definition of the *Inferobranchiata*:—

Animal furnished with a foot for creeping, always very large; branchiae in the form of a long succession of foliations, at the lower part of the body between the projecting border of the mantle and that of the foot, either all round the body or on the right of it only; the organs of generation always on the same individual; one or two pairs of tentacles.

Sometimes a shell either internal or external.

M. Rang thus defines his second family of the *Inferobranchiata*:—

Animal with the branchiae on the right side only (with the exception of the genus *Ancylus*, which is sinister).

Sometimes a shell, either internal or external, and in the last case set on the back (*recouvrante*).

Under the Semiphyllidians M. Rang arranges the following genera:—*Ancylus*, *Pleurobrancha*, *Pleurobranchus*, *Spiricella*, *Umbrella*, and *Siphonaria*.

Ancylus, Geoffroy.—Animal oval, conical, slightly recurved backwards; mantle not ample, not covering the head, and delicate upon the borders; head very large, furnished with two tentacles, which are stout, cylindrical, contractile, with eyes at their internal base, and approximated at their external side by a foliaceous appendage; mouth below, with some appearances of labial appendages on each side, foot elliptical, large; branchiae in a sort of cavity in the middle of the right side, between the foot and the mantle; vent at the left side.

Shell delicate, covering the animal, nearly symmetrical, obliquely conical backwards; the base oval, more or less elongated; the apex pointed, but not marginal, and rather inclined to the right. (Rang.)

The species are found in fresh-water springs and streams; they creep on stones and aquatic plants.

A. irroratus. Animal pale yellowish, obscurely sprinkled with black; front and abdomen reddish; eyes black; sole of the foot spotted and palid.

Shell concentrically plaited, subdiaphanous; epidermis black-green sprinkled with black; apex sub-obtuse, posterior; aperture roundish, elliptical. Length three lines.

It is found plentifully in the ditches of the island of St. Vincent, closely adhering to dried leaves by excluding the air.

Ancylus irroratus.

1, animal creeping, magnified; 2, animal reversed; 3, 4, shell; 5, figure of the foot; 6, branchiae in situ; 7, animal with the shell taken off.

A. radiatus. Animal yellowish, sprinkled with black, with three or four great pale spots on the back; face reddish; abdomen obscure.

Shell oval-elliptical, glassy, diaphanous, concentrically sub-plaited, radially striated; epidermis evanescent.

It is found with the preceding.

Ancylus radiatus.

a, animal creeping, magnified; b, natural length of the shell; c, shell magnified. (Goulding.)

There are 14 recent species of *Ancylus*, and 8 fossil.

Pleurobrancha, Meckel.—Animal oval, elongated, flat below, convex above, pointed behind; no trace of a mantle, only a slight long and narrow expansion of the skin at the middle of the right side. Head very large, with the mouth at the extremity of a proboscis. Two pairs of auriform tentacles; the anterior ones at the extremity of a muscular transverse frontal band; the posterior ones rather farther backwards, and very much separated from each other. Foot very large, more extended behind than before; a single branchia fixed at the right side and entirely exposed. Termination of the organs of generation in a common tubercle in front of the branchiae; the anus above these, and in the middle of their length. (Rang, after De Blainville.)

P. Meckeli, *Pleurobranchidium Meckeli* De Blainv., is an example.

Pleurobrancha Meckeli.

Pleurobranchus, Cuv.—Animal oblong, fleshy, convex above, with a very large and overspreading mantle. Foot large, equally outspreading, and thus leaving a wide canal all round the body. Head distinct, furnished with a veil uniting on each side with the borders of the foot, and with two tubular tentacles, which are split anteriorly; mouth at the extremity of a proboscis; branchium composed of a double row of lamellae, forming a plume on the posterior right side, between the mantle and the foot; anus carried by a small tube behind the branchium. Organs of generation in front.

Shell sometimes rudimentary membranous, with a tolerably distinct apex, hidden in the thickness of the mantle.

Pleurobranchus, side view.

b, veil; c, mouth at the extremity of a proboscis; e, tentacles; g, branchia; h, orifice of the organs of generation; i, position of the anus; k, mantle; l, foot. (Rang.)

Such is the definition of M. Rang, who includes *Berthella* under the genus.

The *Pleurobranchi* have been found at depths varying from the surface to 30 fathoms on rocky coasts, stones, and sea-weeds.

Shell of *Pleurobranchus membranaceus*.
a, external view; b, internal view.

P. reticulatus. This species is not noticed in the last edition of Lamarck.

There are about 20 species of *Pleurobranchus*.

Pleurobranchus reticulatus, seen from above. (Guerin.)

Spiricella (Rang) is a fossil genus. The shell is very much flattened, elongated, bent (arquée), with sharp edges; apex spiral, sinistrorsal, horizontal, situated backwards and to the left, open on the lower surface; an indistinct impression, but appearing to occupy the posterior part of the shell, where it shows itself nearly parallel to the border.

The only species is *S. Unguiculus*.

Umbrella, Lam. (*Gastroplicar*, De Blainv.).—Animal oblong, very much depressed, convex above, very flat and fleshy below. Mantle not much extended. Head not distinct; mouth situated at the bottom of a narrow and deep notch in front of the foot, which has thick edges, and is raised all round. Four tentacles: two superior, truncated, slit, and lamellose, as it were, internally; two smaller, in form of pediculated crests, on each side of the mouth. Foot very large, spreading out on all sides, smooth and flat. Branchiæ foliaceous, disposed in a cordon all along the right side, and reaching even a little to the left in passing by the front; anus in the form of a small tube behind the branchiæ. Organs of generation very much approximated, situated to the right and forwards.

Shell external, calcareous, very much depressed, nearly entirely flat, irregularly circular, slightly convex above and concave below; apex excentric, conical, and slightly inflected; concentrically striated and radiated; edge treuchant, fixed to the dorsal part, which it covers. (Rang.)

The species are littoral. Depth, &c., much the same as in *Pleurobranchus*.

Two species only appear to be known—*U. Indica* and *U. Mediterranea*.

U. Mediterranea has the umbrella with a flattened shell; the disc of the lower surface not radiated.

Umbrella Mediterranea, with the shell in the proper position. *a*, shell; *b*, gills; *c*, head, viewed from above. (Phillippl.)

Shell of *Umbrella Indica*.
a, inside; *b*, outside.

Siphonaria, Sowerby.—Animal oval, sub-depressed; the head subdivided into two equal lobes, without tentacles or apparent eyes. Borders of the mantle crenulated. A branchia in form of a square membrane, in the sinus formed at the right, between the foot and the mantle.

Shell patelloid, elliptical, with the apex well marked, slightly to the left and posterior; a sort of canal or gutter on the right side; muscular impression of a horse-shoe shape, the right lobe divided into two by the canal. (De Blainv.)

Shell of *Siphonaria Siphonaria*.
a, outside; *b*, inside.

Small species of *Siphonaria*, with the animal in the shell.
1, lateral view; 2, ventral view; *a*, breathing aperture; *b*, head; *c*, mantle.

The species are littoral. Depth, &c., much the same as in *Pleurobranchus* and *Umbrella*. They are found in Brazil, the West Indies, Senegal, and Tristan d'Acunha. (Sowerby.)

M. Deshayes, in his Tables, makes the number of living species of *Siphonaria* 21, and that of the fossil species (tertiary) 3. In the last edition of Lamarck the number of living species recorded is 19.

SEMNOPITHECUS, F. Cuvier's name for a genus of Molluscs.

The canines are much longer than the incisors; head round; facial angle more open than that of the Orang's; face flat. Limbs very long in proportion to the body; anterior thumbs very short. Cheek-pouches small or null. Callosities. Tail very long and slender.

Dental Formula:—Incisors, $\frac{4}{4}$; Canines, $\frac{1-1}{1-1}$; Molars, $\frac{5-5}{5-5} = 32$.

F. Cuvier observes that the canines are often much larger than the rest of the teeth, and consequently than they are here represented. This is exemplified in the case of *S. Maurus*.

Teeth of *Semnopithecus*. (F. Cuv.)

This genus is remarkable for the large size and complication of its stomach. This was first pointed out by Professor Otto.

In 1833 the dissection of two species from the collection of the Zoological Society of London (*S. Entellus* and *S. fascicularis*) enabled Professor Owen to lay before that society an account of the structure of this genus of animals, which was published in the first volume of the 'Zoological Transactions.'

Professor Owen remarks that the genus *Semnopithecus*, which in the system of Cuvier ranks only fifth in the descending scale from man, is of late formation, and not entirely the result of newly-discovered materials. On the contrary, several species were for a long time ranked with the Guenons, in which the stomach is of the usual simple construction.

The larger of the two stomachs which formed the subjects of Professor Owen's examination was taken from a full-grown female *Entellus* Monkey (*S. Entellus*, F. Cuvier), which measured from the end of the nose to the root of the tail 1 foot 8 inches. The admeasurements of the stomach, distended and dried, were—

	Ft.	In.	Lin.
Length along the greater curvature	2	7	0
Length along the lesser curvature	1	0	0
Greatest circumference, a little to the right of the cardia	1	0	6
Smallest circumference (at about two inches from the pylorus)	0	3	8

Professor Owen states that this stomach may be regarded as consisting of three divisions:—1st, a cardiac pouch, with smooth and simple parietes, slightly bifid at the extremity; 2nd, a middle very wide and sacculated portion; and 3rd, a narrow elongated canal, sacculated at its commencement, and of simple structure towards its termination. The latter division, from its greater vascularity, and the more abundant distribution of the nerves of the eighth pair upon it, is regarded by the Professor as the true digestive stomach. The preceding divisions appeared to him to be preparatory receptacles or reservoirs.

Professor Owen guards against the inference that, in considering this stomach as being made up of three principal divisions, he is to be understood as supposing them to be equally distinct with the different cavities of a ruminant or cetaceous stomach. They were not characterised by any essential difference of structure, for none of them possessed a cuticular lining. The three divisions were however sufficiently obvious to justify their separate consideration for the facility of the description of so complicated an organ.

In the other species (*S. fascicularis*, the Croo of Sumatra, and *S. comatus*, Desm.) examined by Professor Owen, the stomach presented precisely the same structure as the preceding. Its dimensions however were not quite so large in proportion to the size of the animal. The individual examined was younger than the *Entellus*.

Professor Owen remarks that in consequence of the disproportionate size of the stomach in these animals, some differences are met with in the disposition of the other viscera of the abdominal cavity. The

liver, instead of crossing the epigastrium to the left hypochondriac region, extends downwards from the right hypochondriac to the right lumbar region, the whole of the opposite side of the abdomen, with the epigastric region being occupied by the enormous stomach. The liver is proportionately smaller in *Semnopithecus* than in *Cercopithecus* or *Macacus*. The spleen is of a more triangular shape, and is attached to the omentum continued from the left side of the stomach. The pancreas, on the contrary, is proportionately larger than in those genera. Both the biliary and pancreatic secretions enter the duodenum together, about three inches from the pylorus. Were it not for the insertion of these ducts, Professor Owen observes that one might almost suppose that what has been regarded as the true stomach was a portion of the intestinal canal.

"What then," asks Professor Owen, "are the natural habits and food of this genus? Will future observers of these Slow Monkeys, as F. Cuvier denominates them, be able to ascertain that their natural food is more strictly vegetable than that of the *Cercopithecus*, &c.? And that, like the Sloths of the New Continent, so remarkable for their complex stomachs, they also crop the tender shoots and leaves of the trees in which they habitually reside? *Cercopithecus* and *Macacus* are provided by nature with receptacles (the cheek-pouches) for storing away ill-gotten food, hastily plucked from the cultivated grounds which they invade, and which they are thus enabled to carry off in sufficient quantity, and masticate and prepare for digestion in a place of safety. The complicated stomachs of the timid Ruminants are adapted to a similar end, allowing them to accumulate their requisite quantity of herbage from exposed pastures, which they then carry off to more secure situations, and remasticate at leisure. Now, in the *Semnopithecus* it is remarkable that the cheek-pouches are very small, or are wanting altogether. I have often fed the *Entellus* Monkey with nuts, and have observed that, while his more fortunate neighbours the Green Monkey (*Cercopithecus Sabaeus*, Geoff.) and Chinese Bonneted Monkey (*Macacus Sinicus*, Lacép.) were stowing them quickly away by the dozen into their cheek-pouches, he could not cram more than two in the same situation, and was equally averse to swallowing anything but the kernel. In this case the complicated stomach did not serve him as a substitute; but I think it very probable that it may compensate for the want of cheek-pouches when he is in a situation to collect together a quantity of soft fruits or herbs. In the gardens of the Society the *Semnopithecus* which have been there exhibited are fed exactly in the same manner as the other monkeys; and the keepers have not observed anything like rumination in them. In both the species which I have dissected, where illness and gradual decay preceded death, the stomachs were almost empty." (1833.)

Mr. Ogilby, in his 'Natural History of Monkeys,' alludes to the bezoars reported by many travellers to exist in the stomachs and intestines of the Asiatic monkeys, as confirmatory of Professor Owen's views; and adds that the bezoars produced by the monkeys of the Malay peninsula, and which can scarcely belong to a genus different from the *Semnopithecus*, are described as being smaller, rounder, and more powerful in their qualities than those obtained from ruminating animals.

The other zoological characters of this genus are thus graphically given by Mr. Ogilby in the same work:—"The extremities of the *Semnopithecus* are of great length, compared with the dimensions of the body. This is another instance in which the *Semnopithecus* resembles the Gibbons, as well as in the slender and elongated form of the body itself; but there is this remarkable distinction, that, whilst the anterior pair of extremities in the Gibbons is beyond all proportion longer than the posterior, the proportions are reversed in the *Semnopithecus*, and it is the posterior extremities which exceed the anterior in length. Still the disproportion is by no means so great as that which exists in the Gibbons, nor does it in the slightest degree impede the quadruped motion of the animals, when they are forced to resort to that mode of progression; but it becomes an additional evidence, particularly when taken in conjunction with other traits, of the superior development of the abdominal over the pectoral members, and the consequent degradation of the animals in the scale of existence. This evidence is still further strengthened by the very limited development of the thumb on the anterior extremities, which, as has been already observed, scarcely exceeds the tuberculous form, and enters but slightly into the functions of prehension and manipulation: thus, as it were, preparing the way for its entire disappearance in the Colobus. The organ consists nevertheless of the ordinary number of phalanges of which it is composed in other cases; but they are greatly abridged in their dimensions, both as regards thickness and length, and form a remarkable contrast to the rather immoderate development which marks the rest of the members. The tails likewise are much longer in the *Semnopithecus* than in any of the ordinary monkeys. Though slender however, they possess a very considerable degree of muscular power, and enter as a very important constituent into the motions and progression of the animals. When at rest and unemployed they are allowed to hang down perpendicularly, and, from their great length, which considerably exceeds that of the animal's body, have a very droll effect, which is heightened by the natural apathy and imperturbable gravity of the creatures themselves. This, when unemployed, is their natural position. They exhibit the very picture of sadness and melancholy, and appear as if perfectly regardless of everything

that passes around them; but when roused or excited they are nevertheless capable of the most surprising exertions, and astonish the spectator by a rapidity, variety, and precision of movements, which could scarcely be anticipated from creatures apparently so apathetic in mind and delicate in body. They are in reality far from meriting the name of Slow Monkeys, which some zoologists have given them; their slowness is exhibited in disposition rather than in action, and is an attribute of character rather than of structure. When young they are readily domesticated; but being less petulant, curious, and restless than the Cercopithecus and Baboons, are supposed to exhibit less intelligence, though their mental qualities, as well as their physical structure, closely assimilate them to the real Apes: the old males become morose, sullen, and mischievous."

S. Maurus, the Budeng of the Javanese, Lutung itam Maure of the Malays and Europeans, Lotong of the natives of Sumatra.

Skull and canine tooth of *Semnopithecus Maurus*. (Horsf.)

Dr. Horsfield describes this species as being on the whole of a stouter make than *S. melalophos*, and as having more robust extremities. One of the specimens in the museum at the India House measures 2 feet 3 inches from the tip of the nose to the root of the tail. The face is regularly circumscribed by hairs, which are long, and closely applied to the head; the forehead, which is gradually sloping, is entirely concealed by them. The general facial character is a flatness above, and a protrusion of the maxillæ; but the appearance of the face differs greatly in old and young subjects. The maxillæ become extended as the animal advances in age, and in young subjects the facial angle is proportionally greater. The orbits of the eyes are rather prominent, and the bones of the nose short. The nose consists of an angular ridge, which is considerably elevated between the eyes, and terminates, without any fleshy protuberance, by a membrane which is gradually attenuated below, and on each side of which the nostrils are placed. From the termination of the nose to the mouth a considerable space intervenes: the lips are small and thin. The chin is short and small; a circle of gray hairs incloses the mouth in the adult animal; and on the chin the hairs have a disposition downward, so as to exhibit the appearance of a beard. The upper part of the face is nearly naked; a few straggling stiff hairs are scattered on the cheeks and the upper lip, and on the more prominent part of the nose an interrupted series is observed. Irides of the eye dark brown. Ears concealed from view by the long hairs which cover the lateral parts of the head; they are margined, and both in form and disposition of external parts closely resemble those of man. The neck is short and considerably contracted. The trunk is of great length, broad and robust about the shoulders and the breast, and gradually of smaller dimensions towards the loins. Buttocks with very large rough callosities. Mamme of the adult female lengthened and cylindrical. Tail as long as the body and head taken together: in some individuals, and particularly in young subjects, it exceeds those parts in length: it is cylindrical for the greatest portion of its length; the base tapering gradually, and the tip is thickened and terminated by a close tuft of long hairs of an ovate form.

Colour of Adult.—Intensely black, except the breast, the abdomen, the inner side of the extremities, and the root of the tail, which are gray. On the crown of the head the black hairs are slightly tipped with gray; and as age advances the gray portion becomes more extensive, and also shows itself on the upper parts of the body; but the extremities externally, and the tail, even in the oldest subjects, retain their blackness. The hairs are remarkably long, delicate, soft, and silky.

Colour of Young.—Immediately after birth, of a fulvous or reddish colour; with advancing age, a gray discolouration first appears on the hands, the forehead, and the tip of the tail; from these parts it

gradually extends to the neck, the shoulders, and the flanks, assuming from time to time a darker hue, until the coat of the animal is jet black above and gray beneath. (Horsf.)

Budeag (*Semnopithecus Maurus*); adult and young. (Horsf.)

Dr. Horsfield states that the Budeng, or black species, is much more abundant than the red species, or Lutung of the Javanese (*S. Pyrrhus*); but the latter, both on account of its variety and comparative beauty, is a favourite among the natives. "Whenever an individual is obtained," says Dr. Horsfield, "care is taken to domesticate it, and it is treated with kindness and attention. The Budeng, on the contrary, is neglected and despised. It requires much patience in any degree to improve the natural sullenness of its temper. In confinement it remains during many months grave and morose; and as it contributes nothing to the amusement of the natives, it is rarely found in the villages or about the dwellings. This does not arise from any aversion on the part of the Javaese to the monkey race. The most common species of the island, *Cercopithecus Aggula* of Geoffroy, the Egret Monkey of Pennant, is very generally domesticated; and a favourite custom of the natives is to associate it with the horse. In every stable, from that of a prince to that of a mantry, or chief of a village, one of these monkeys is found; but I never observed the Budeng thus distinguished.

"The *Semnopithecus Maurus*," he continues, "is found in abundance in the extensive forests of Java; it forms its dwellings on trees, and associates in numerous societies. Troops, consisting of more than fifty individuals, are often found together. In meeting them in the forests it is prudent to observe them at a distance. They emit loud screams on the approach of man, and by the violent bustle and commotion excited by their movements, branches of decaying trees are not unfrequently detached, and precipitated on the spectators. They are often chased by the natives for the purpose of obtaining their fur; in these pursuits, which are generally ordered and attended by the chiefs, the animals are attacked with cudgels and stones, and cruelly destroyed in great numbers. The skins are prepared by a simple process which the natives have acquired from the Europeans, and they conduct it at present with great skill. It affords a fur of a jet-black colour, covered with long silky hairs, which is usefully employed both by the natives and Europeans in preparing riding equipages and military decorations. The Budeng, during its young state, feeds on tender leaves of plants and trees; and when adult, on wild fruits of every description, which are found in great abundance in the forests which it inhabits." ("Zoological Researches in Java.")

S. melalophos. Brilliant yellow-red above, whitish below; a tuft of black hairs on the forehead in form of a bandeau; face blue.

This is the Simpai of the Malays; and in this species the great length of body and slenderness of the extremities, so characteristic of the *Semnopithecus*, are manifested in the highest degree. It is found in the forests of Sumatra.

S. Entellus, the Hoonumau (Houlmau of M. Duvaucel) of the Hindoos, Lungar of the Hill Tribes.

Semnopithecus melalophus.

The young are remarkable for the disproportionate length of the extremities, the deliberate air of their movements, and the tranquillity of their eyes and physiognomy generally. Face and hands black; body and limbs light gray or straw-colour; hair surrounding the face, and forming a projecting bandeau over the eyebrows; a peaked beard directed outwards beneath the chin. The colour always darker on the loins and along the spine, and becoming deeper as the animal advances in age, till finally the fur, becoming mixed with numerous black hairs, is of a rusty brown. The body at the same time becomes more developed and muscular, and the animal, when at its full size, is 4½ feet from the extremity of the muzzle to the origin of the tail, which is considerably longer than the body, of the same colour, and ends in a tuft of hair rather longer and darker than the general hue. It is a native of Bengal, the Himalayan Mountains, Nepaul, and Bootan.

This monkey is remarkably interwoven with the religion of the country where it is found. M. Duvaucel has given an interesting account of the careful watch which the Bengalees kept over him to prevent his killing this sacred animal, holding a high place among the thirty millions of Indian gods, and to save himself from dying within the year, which, according to popular belief, is sure to be the fate of one who puts an Entellus Monkey to death. He was harangued by the Hindoos upon the danger of injuring animals which were no other than princes and heroes under the operation of the metempsychosis. Unmoved by their eloquence, and eager to possess a specimen, he levelled and brought down a 'princess.' But the acquisition was dearly bought. The ill-fated creature had a young one on her back, and, though shot through the heart, the mother exhausted her remains of life in throwing it into the branches of a neighbouring tree; then fell and expired at the feet of M. Duvaucel. It is but just to add that he mourned over the deed he had done.

The remains of a species of quadrumanous animal allied to *Semnopithecus* were found by Captain Cautley and Dr. Falconer amongst the fossils discovered by them in the tertiary strata of the Sewalik Hills in the north of Hindoostan. ('Geol. Proc.' 1838.)

SEMPERVIVUM, ('always living,' from 'semper' and 'vivo,' on account of their tenacity of life), a genus of Plants belonging to the natural order *Crossulaceae*. This genus is known by possessing a calyx 6-12-parted, and occasionally even 20-parted; petals 6-12 in number, seldom 20, more or less united at the base; 12-24 stamens or more, grown together at the base; scales at the base of the carpels, which are follicular, and equal in number to the petals. The genus is composed mostly of herbs, some of which are stemless, and have young plants growing from the axils. Others are caulescent, without young plants, or they may be shrubby and fleshy. The leaves are usually revolute, and their branches of cymose flowers are disposed in corymbs, or panicles. Their flowers are white, yellow, or purple. The species of *Semprevivum*, like the family to which they belong, have most of them thick fleshy leaves and small roots, and are adapted for growing in rocky, dry, barren places. The arrangement of their leaves is frequently very elegant, and many of the species are cultivated in our greenhouses and gardens. Some are used in the arts and medicine.

S. glutinosum, Clammy House-Leek. Stem frutescent; leaves wedge-shaped, viscid, rather scattered, fringed with cartilaginous cilia; petals 8-10. It is a native of Madeira. It has loose panicles of golden-yellow flowers, with a stem about two feet high. The fishermen of Madeira are in the habit of using this species to rub their nets, which are however previously steeped in an alkaline solution of some kind. They are said to endure as long as if they were tanned.

S. tectorum, Common House-Leek. Leaves ciliated; offsets spreading; petals 6-9, spreading; scales of flowers wedge-shaped, carunculate. It was originally a native of alpine and sub-alpine regions of central Europe, but it has now found its way to the tops of old walls and the thatched and tiled roofs of the houses of nearly all the countries of

Europe. It is known by many other names than that of House-Leek, as Jupiter's-Eye, Bullock's-Eye, and Jupiter's-Beard.

About 36 species of this genus are described. Those known in greenhouses are chiefly brought from the Canary Islands.

SENA/CIA, a small genus of Plants belonging to the natural order *Pittosporaceae*, named in honour of Jean Senac, a French physician. The species are natives of the West Indies, Mauritius, and of the Himalayas. The genus is characterised by its small 5-toothed calyx. Petals 5. Stamens 5, hypogynous. Younger capsules berry-formed, afterwards 2-valved, half 2-celled. Seeds 4-8. The species form smooth-branched shrubs, with feathery-veined entire leaves, and terminal corymbs of white flowers. This genus closely resembles *Celastrus*, but the hypogynous insertion of the stamens is a distinguishing character. The wood of *S. undulata* (the *Celastrus undulatus* of Lamarck), a native of the Mauritius, is well known, and esteemed for its hardness. It is thence called Bois de Joli Cœur by the French.

SENEBIERA (in honour of John De Senebier, of Geneva, a vegetable physiologist), a genus of Plants belonging to the natural order *Cruciferae*. The pouch is somewhat kidney-shaped, entire at the end, or notched above and below, and almost 2-lobed, not bursting. The cells 1-seeded.

S. coronopus, Common Wart-Cress, has an undivided uniform crested pouch with little sharp points, the pouches large in dense clusters. The leaves pinnate lobed. The stem much branched and prostrate. The sepals roundish, with white membranous margins. It is a native of Europe, North America, and England.

S. didyma, has a pouch notched by two wrinkled lobes, an extremely short style, and pinnatifid leaves. The stem is spreading, about a foot in length. The flowers small and white, in long lax clusters. It is found on waste ground near the sea in Great Britain.

S. Nilotica is eaten as a salad in Egypt. As these plants possess no beauty, they are not worth cultivating except in botanical gardens.

SENECA OIL. [NAPHTHA.]

SENE/CIO (from 'senex,' on account of its silvery capitate seed-down resembling the gray hairs of an old man), a genus of Plants belonging to the natural order *Compositae*. The species of this genus are very numerous, but are not remarkable for either beauty or utility. The Common Groundsel (*Senecio vulgaris*) is one of the most common of weeds. [GROUNDSEL.] The flower-buds and young tops are gathered as food for young birds, and especially for domestic Canary birds. *S. Saracenicus*, Broad-Leaved Groundsel, was used by the Saracens as an application to wounds. A few of the species are cultivated, the most pleasing of which are *S. hieracifolius*, the Hieracium-Leaved Groundsel; *S. pseudo-China*, the Chinese Groundsel; *S. hastatus*, the Spleenwort-Leaved Groundsel; *S. elegans*, the Elegant Groundsel.

SENEGA. [POLYGALA.]

SENNA. [CASSIA.]

SENSATION. [NERVOUS SYSTEM.]

SENSES. The senses are the faculties by which we become acquainted with some of the conditions of our own bodies, and with certain properties and states of external things, such as their colour, taste, odour, size, form, density, motion, &c. The senses are five in number, namely, sight, hearing, taste, smell, and touch; and each of them is exercised in the recognition of an impression conveyed along some nerve to the brain. [EYE; EAR; NOSE; TONGUE; SKIN; NERVOUS SYSTEM; MUSCLE.]

SENSIBILITY, an aptitude for receiving impressions of the senses. This is its physiological meaning, as designating that faculty of the senses whereby things external are made to act upon us. That peculiar fineness of organisation which renders a man alive to the impressions of physical objects, has, by a natural metaphor, become the expression of that peculiarity of mental organisation which renders the mind alive to impressions of moral objects, such as pity for the distress of others, admiration of heroic courage or patient endurance, &c.; and thus a person with a keen sense of grandeur, sublimity, nobility, beauty, or pathos, in nature or art, is said to possess great sensibility. It is this moral aspect of sensibility which in all people creates the love of poetry and fiction, and when possessed in a high degree, creates the poet himself.

SENSITIVE PLANTS is a term commonly applied to those species of plants that possess the property of visibly moving their leaves when they are touched or otherwise stimulated. This term is not applied generally to plants in which any movements can be observed; for the power of moving under the influence of certain external stimulants is a very general property of the tissues of plants, and especially of the flowers. [SLEEP OF PLANTS.]

There are a great number of species of plants of various families, that possess the power of moving their leaves under the influence of a slight touch; that which is best known is a plant belonging to the order *Leguminosae*, called *Mimosa pudica*. [MIMOSA.] It is a native of tropical climates in moist districts, where it is exposed to a temperature of between 70° and 80° Fahr. It is in its native districts where its excitability is seen to the greatest perfection. A knock upon the ground at a short distance from the plant is sufficient to produce an influence on the leaves; and Von Martius says, that at Rio Janeiro the falling of horses' feet by the way is sufficient to set whole masses of *Mimosa* in motion. When in this country, the motions of the plant are always best displayed in high temperatures.

The movements are not alone produced by mechanical irritants, for if various corrosive substances, as bichloride of mercury, sulphuric acid, caustic potash, &c., are applied to the knots of the joints, the same phenomena are observed. The removal of the plant to a higher temperature will produce the same result, as well as exposing it to a lower temperature or a draught of cold air. They are destroyed by the application of chloroform and other anæsthetic agents.

Besides the *Mimosa pudica* there are several other species belonging to this genus that possess the same property, though not in so remarkable a degree. Amongst them may be named *M. sensitiva*, *M. viva*, *M. casta*, *M. asperata*, *M. quadrivalvis*, *M. pernambucana*, *M. pigra*, *M. humilis*, *M. peltata*, *M. dormiens*. Species of other genera of the same natural order *Leguminosæ* exhibiting these movements are *Smithia sensitiva*, *Eschynomene indica*, *A. pumila*, and *Desmanthus stolonifer*. The locust-tree when its branches are roughly shaken closes up its leaves, and the same has been observed of *Gleditsia triacanth*, and it is probable that close observation during hot weather would prove that other leguminous plants possess this property.

Another family of plants that exhibit sensation when touched or stimulated is *Oxalidaceæ*. The *Oxalis sensitiva*, called by De Candolle on account of its sensitive properties *Biophytum*, has long been known to possess this property. *Averrhoa bilimbi* and *A. carambola* are both plants belonging to *Oxalidaceæ*, and have been described by travellers as possessing the property of folding their leaves on the application of a stimulus. But it is not only in these species that this property resides, for Professor Morren of Liège has observed it to occur more or less in all the species of the genus *Oxalis*. His observations were first made on the *Oxalis stricta*, which, if hit smartly on a warm day, will contract its leaves and assume a position as in the ordinary sleep of the leaves of these plants. He has also observed the same movements in *O. acetosella* and *O. corniculata*, and many extra-European species. The movements in these plants consist in the folding up of their leaves, so that the two halves of the leaf approach each other by their superior surface. The midrib is also slightly bent, so that its inferior surface presents a convexity; and the petioles of the leaflets bend downwards, so that the leaf, when irritated, becomes dependent. (Morren, 'Notes sur l'Excitabilité et le Mouvement des Feuilles chez les Oxalis,' in the 6th volume of the 'Bulletins de l'Académie Royale de Bruxelles.')

In the family *Droseraceæ*, or Sun-Dews, are some plants which exhibit a considerable amount of irritability. The leaves of *Dionaea muscipula*, or Venus's Fly-Trap [*DIONEÆ*], have the remarkable property of contracting upon insects that may happen to alight upon their surface. None of the Sun-Dews inclose insects in their leaves in this manner, but the surface of their leaves is covered with long hairs, which secrete a viscous matter. When any insect settles upon the leaf, it is entangled with the viscous secretion; and before it has time to escape, the hairs exhibit a considerable degree of irritability, and curving round, pin the animal down on the surface of the leaf.

Other instances of vegetable irritability occur in the *Berberis vulgaris*, *Mimulus*, and *Stylidium*. [BERBERIS; MIMULUS; STYLIDIUM; MOTIONS OF PLANTS; CYCLOSIS; SAP.]

SENSORIUM. [NERVOUS SYSTEM.]

SEPAL. [CALYX.]

SEPIA. [SEPIADÆ.]

SEPIADÆ (*Σηπία*), a family of Cephalopodous *Mollusca*, including the forms which are ordinarily known under the name of Cuttle-Fishes.

The genera comprehended under that term have been thus defined:—Animal in the form of a sac or purse, with or without fins; head large, very distinct, crowned with brachial appendages to the number of eight or ten; arms very unequal, always furnished with suckers on their internal surface, with or without hooks; branchiæ pyramidal; orifice of the organs of generation opening into the branchial pouch, which last communicates with the external surrounding medium by a sort of funnel, the tube of which opens under the neck. Shell monothalamous or rudimentary, sometimes horny or cellular, but never polythalamous. (Rang.)

Dr. Leach divided the group of Cuttles into two families, the Octopods and the Decapods. The forms belonging to the first division are described under the article OCTOPODA.

The *Decapoda* are thus defined:—Animal generally elongated, cylindriciform, having a thick sac, furnished with natatory expansions; head very distinct, crowned with ten arms, eight of which are sessile, shorter than in the Octopods, and furnished with acetabula or suckers along the whole length of their internal surface, and two much longer (tentacula), which are retractile, not situated on the same line with the arms, pediculated, and furnished with suckers, which are situated ordinarily on the enlarged and terminal portion only. No shell, but only a testaceous rudiment or support, which is either cartilaginous or calcareous in the interior of the back, in the greatest part of the genera.

Under this division are placed the *Teuthidæ*, or Calamaries, and the true *Sepiadæ*, or Cuttle-Fishes, properly so called.

Sepiola (Rondeletius, Leach).—Head of equal breadth with the body, owing to the magnitude of the eyes. Body scarcely ventricose, supported by a thin flexible transparent dorsal lamina, and with natatory organs extended from the sides of the body.

S. vulgaris, Grant; *S. Atlantica*, D'Orbigny. Dr. Grant, in a paper

on this species, describes the body or mantle of the specimens obtained on our coast as measuring generally about six lines in length, and as much in breadth, whilst the head measures only four lines in length, and, from the magnitude of the eyes, is equal in breadth with the body. The arms are of unequal lengths, the longest being about an inch long, and the shortest about a line less. The first or dorsal pair are the shortest, the second and fourth equal in length, and a little longer than the first pair; and the third pair the longest. This, Dr. Grant observes, is the order of the comparative lengths of the arms most common in the naked *Cephalopoda*. The third and fourth arms on each side are connected to each other by a musculo-membranous fold, which extends to about a third of their length, and is covered by the skin and subjacent coloured parts. The late Professor E. Forbes has observed that this species changes its colour according as it is exposed to light.

S. Rondeletii is a second British species, a single specimen of which was taken in Ireland by the late Mr. W. Thompson, and another in England by Mr. Joshua Alder.

S. stenodactyla is a species from the Mauritius, described by Dr. Grant in the 'Zoological Transactions.'

Three other species of *Sepiola* have been described. They are very generally distributed.

1, 2, *Sepiola stenodactyla*, back and front views (reduced); 3, *Sepiola vulgaris*, back view (natural size). (Grant, 'Zool. Trans.')

Rossia (Owen) has the body ventricose; two wide rounded sub-dorsal fins; anterior margin of the mantle free. Arms rather short, trihedral; the acetabula pedunculated; the peduncles very short, in two alternating rows at the base of the arms, aggregated in many rows at their point: order of the length of the equal arms, 1, 2, 4, 3. Tentacula equalling the body in length, furnished at the apex with many very small pedunculated acetabula. Gladius horny, 9 lines in length, a little dilated below.

S. palpebrosa.—Professor Owen, who established this genus upon a Cephalopod brought from the Arctic regions by Captain James Ross, R.N., and taken near the beach at Elwin Bay, Prince Regent's Inlet, on the 29th of August 1832, states that it differs from *Sepiola* and *Sepioteuthis* in the form, proportions, and position of its lateral fins, and in the extent of its horny dorsal style or gladius. In these respects, he observes, it bears a closer affinity to *Sepiola*, but differs from it generally in having the anterior margin of the mantle free in the whole of its circumference; its natural position is therefore, in his opinion, intermediate to *Sepiola* and *Sepioteuthis*, which it connects together, as well by its intermediate size as by the peculiarities of its structure.

The details of the anatomy of this animal will be found in the Appendix to Captain Sir John Ross's 'Second Voyage.' The ink-bag was situated between the liver and the muscles which surround the arms, close to which its duct entered the intestine. The ink was black, of the same tint as the China ink.

With reference to the remarkable development of the skin surrounding the eyeball (whence the trivial name *palpebrosa*), by means of

which this animal evidently possesses the power of defending the eye, as the pulmonated *Vertebrata* do by means of their more regularly-formed eyelids, Professor Owen observes that the utility of the provision, in seas abounding with fragments of ice, is obvious. Six species of this genus have been described. [ROSSIA.]

Rossia palpebrosa, dorsal aspect, showing the appearance of the eyes while the animal was alive.

Head and arms of *Rossia palpebrosa*, on the dorsal aspect, taken from the figure where it is laid open to show the internal structure. Here the eyelids (1, 1) are represented closed after death; *a*, the eight arms; *a'*, one of the brachial suckers, magnified; *b*, the two tentacles; *b'*, a tentacular sucker, magnified; *c*, ovisacs in the ovary, appended to filamentary pedicles; *d*, eggs. (Owen, 'Ross's Appendix'.)

Sepioteuthis (De Blainville). Animal elongated, bordered nearly throughout its length by a natatory membrane, which is narrow and lateral; arms sessile and pedunculated, as in the Calamaries, and less enlarged than in the Cuttles; acetabula as in the Calamaries.

Internal support or gladius comparatively wide, but horny and delicate.

S. sepiacea. This species is figured in the article CEPHALOPODA under the name of *Sepia officinalis*, to which however it bears a very close external resemblance, so close indeed that authors generally place it immediately before that species. Thirteen species of the genus *Sepioteuthis* have been described. They are inhabitants of the West Indies, the Cape, the Red Sea, Java, and Australia.

Cranchia (Leach).—Animal furnished with a bursaform sac, which is elongated and rounded posteriorly; aperture narrow; dorsal border not distinct; head less distinct from the body; arms sessile, unequal; tentacles pedunculated, longer, retractile, terminated in a club shape; peduncles without acetabula (?); caudal fins circular, touching each other at their origin.

C. scabra. Sao rough, with hard rough tubercles. (Appendix to Tuckey's 'Congo'.)

Cranchia scabra.

One other species has been described. They are both natives of the west coast of Africa.

Loligopsis (Lam.).—Body long and cylindrical, terminated by a pair of conjoined large round fins, forming generally a circular disc; superior border of the mantle adherent to the back part of the head for a small extent. Tentacula very long and slender (frequently mutilated). Gladius long, narrowest in the middle, dilated posteriorly. There are eight species of this genus found in the North Sea, Atlantic, Mediterranean, India, Japan, and the South Seas.

Onychoteuthis (Lichtenstein).—Body and fins as in the genus *Loligo*; ventro-lateral cartilages of the mantle long and narrow; horny hoops of the tentacular, and sometimes of the brachial, acetabula produced into the forms of hooks or claws. Gladius or internal support long, broadest in the middle.

Unclashed suckers of *Onychoteuthis*, from specimen in spirits in Mus. Coll. Chlr. (by permission).

O. Banksii. Professor Owen, after dwelling on Dr. Roget's accurate description of the mechanism by which the suckers of *Octopus* are worked, observes that still there are circumstances in which even this remarkable apparatus would be insufficient to enable the cephalopod to fulfil all the offices in the economy of nature for which it was created; and that in those species which have to contend with the agile, slippery, and mucus-clad fishes, more powerful organs of prehension are superadded to the suckers. Thus in the Calamary the base of the piston is, he remarks, inclosed by a horny hoop, the outer and anterior margin of which is developed into a series of sharp-pointed curved teeth. These, as he states, can be firmly pressed into the flesh of a struggling prey by the contraction of the surrounding transverse fibres, and can be withdrawn by the action of the retractor fibres of the piston. "Let the reader," adds the Professor, "picture to himself the projecting margin of the horny hoop developed into a long, curved, sharp-pointed claw, and these weapons clustered at the expanded terminations of the tentacles, and arranged in a double alternate series along the whole internal surface of the eight muscular feet, and he will have some idea of the formidable nature of the carnivorous *Onychoteuthis*."

"Banks and Solander," says Professor Owen in continuation, "in Cook's first voyage, found the dead carcass of a gigantic species of this kind floating in the sea, between Cape Horn and the Polynesian Islands, in 30° 44' S. lat., 110° 38' W. long. It was surrounded by aquatic birds, which were feeding on its remains. From the parts of this specimen which are still preserved in the Hunterian Collection, and which have always strongly excited the attention of naturalists, it must have measured at least six feet from the end of the tail to the end of the tentacles. The natives of the Polynesian Islands, who dive for shell-fish, have a well-founded dread and abhorrence of these

formidable Cephalopods, and one cannot feel surprised that their fears should have perhaps exaggerated their dimensions and destructive attributes."

Professor Owen then notices another structure, which adds greatly to the prehensile powers of the uncinated Calamaries:—"At the extremities of the long tentacles, besides the uncinated acetabula, a cluster of small, simple, unarmed suckers may be observed at the base of the expanded part. When these latter suckers are applied to one another, the tentacles are firmly locked together at that part, and the united strength of both the elongated peduncles can be applied to drag towards the mouth any resisting object which has been grappled by the terminal hooks. There is no mechanical contrivance which surpasses this structure: art has remotely imitated it in the fabrication of the obstetrical forceps, in which either blade can be used separately, or, by the interlocking of a temporary joint, be made to act in combination." ('Cyclopædia of Anatomy and Physiology,' vol. i.)

Onychoteuthis Banksii. a, gladius, or dorsal support.

There are five other species of *Onychoteuthis* found in the Atlantic, Indian, and Pacific oceans.

Loligo (Lam.).—The species of this genus are described under the article LOLIGO. We here subjoin an illustration of the *Loligo vulgaris*, the Common Calamary.

Common Calamary (*Loligo vulgaris*). a, its pen or internal support.

M. De Blainville gives *Loligo vulgaris* as the example of his genus *Pteroteuthis*. There are 21 species of this genus, of which three are British.

NAT. HIST. DIV. VOL. IV.

Sepia (Lam.).—Animal with an oblong depressed body, with two narrow lateral fins extending its whole length; mantle free at its anterior margin; the acetabula supported by horny hoops with the margin entire or very minutely denticulated.

Shell internal, lodged in a sac on the back part of the mantle, composed of an external calcareous apex or mucro, of a succession of calcareous laminae with intervening spaces filled with air, and supported by columns (but not perforated by a siphon), and an internal horny layer, corresponding to the anterior horny sheath in the Belemnites. (Owen.)

S. officinalis.—This is the Common Cuttle-Fish, so well known on our coasts, and whose shell is so often thrown up by the waves on the beach.

Internal shell of Common Cuttle-Fish (*Sepia officinalis*). a, view of back; b, side view; c, under side.

The ink (*nigra succus loliginis*) is common to this and other species of cephalopoda. This fluid is not only ejected as a defence to colour the water in order to favour the escape of the animal, as was well known to the ancients (Oppian, 'Halieut.' iii.; Pliny, 'Nat. Hist.' ix. 29), but as a direct means of annoyance. A gallant officer who was inconsiderately collecting shells in a pair of immaculate white trousers, came suddenly upon one of the naked cephalopods snugly harboured in a recess in the rock. They looked at each other, and the cuttle, who had his eyes about him, and knew well how to use them, upon seeing the enemy advance, took good aim, and shot so true that he covered the snowy inexpressibles with the contents of his ink-bag, and rendered them unrepresentable either in drawing-room or dining-room.

That the juico was used by the ancients as ink is evident from many passages: we content ourselves with a reference to that above given, and to the lines in the graphic description of the idler by Persius. ('Sat.' iii. lin. 10, et seq.)

The flesh of the naked cephalopods was rather esteemed of old, as it is indeed now in Italy and other countries. Aristotle declares that these animals are in the highest season when pregnant, and those who wish to taste a cuttle-fish sausage, will find a receipt for making that savoury viand in Athenæus. [CEPHALOPODA.]

Mr. F. D. Bennett states that the Fe, or Cuttle-Fish, is considered a luxury by all classes of the Sandwich Islanders, and that when fresh and well cooked it is an excellent food, and in consistence and flavour not unlike the flesh of a lobster's claw. ('Narrative of a Whaling Voyage round the Globe,' London, 1840.)

Independently of the swimming powers of the naked cephalopods, and their faculty of darting backwards in the water, they can, some of them at least, throw themselves out of the water, and take leaps analogous to flights. Thus Pliny says, and not without ground for the assertion, '*Loligo etiam volitat, extra aquam se efferens, quod et pectunculii faciunt sagittæ modo.*' ('Nat. Hist.' ix. 29.) It is not improbable that one of the species, *Loligo Sagitta*, may have received its name from the rapidity with which this leap or flight out of the water is executed.

Mr. F. D. Bennett, who describes the sea as peculiarly animated between 23° and 31° N. lat., 154° and 160° W. long., observes that the ship was constantly attended by such vast numbers of the Albacore, that, when swimming, as is their custom, on the surface of the water, they could be seen as a dense shoal extending several hundred yards on every side of the ship, about which sword-fishes (*Xiphias*) frequently came, "making destructive onslaughts" on the Albacores. More rarely he noticed the Barracuda, and transient shoals of Bonita. "Flying-Fish and (nearly allied to these in their movements) *Loligo* (*Loligo*) were also numerous. During a calm, in 30° N. lat., the Flying-Squid appeared in larger flights than

we had ever before witnessed. Persecuted probably by the Albacore (which select this tranquil time to descend deep in the water, and to rove far from the ship in quest of food), they rose from the sea in large flocks, leaping over its smooth surface, much in the same manner, and to the same height and distance, as the Flying-Fish. Many of them were captured by birds during their leaps; and one individual, in making a desperate effort to escape some aquatic pursuer, sprang to a considerable height above the bulwarks of the ship, and fell with violence upon the deck." In the appendix, the Flying-Squid is again noticed. "The head of this cephalopod," says the author, "is a plane circular disc, surrounded by long arms, furnished on their upper surface with many circular suckers, which hold with a tenacious grasp. The eyes are large, very perfectly formed, and lodged in specious cartilaginous orbits. The mouth, like that of most of the cuttle-fish tribe, is horny, and shaped like the beak of a parrot. A slender neck connects the head to the body, and is received into the latter as into a capacious sheath. The trunk is conical, tapering to a point at the tail, smooth, and composed of a dense white cartilaginous structure covered with a delicate membrane or skin, beneath which are deposited the brilliant colours this mollusc often displays. Near the tail is a broad fin-like appendage, which can either be expanded horizontally on either side, or folded neatly upon the abdomen. The interior of the back contains an elastic horny rod, or substitute for the sepia bone, that occupies the same part in some other tribes of the Cuttle-Fish. It extends the entire length of the body, and is flattened at its anterior extremity, whilst its caudal end is shaped like a cup; the whole bearing some resemblance to the instrument used for tasting wine from casks. This elastic structure and the membranous expansion on each side the tail are apparently the two principal agents employed by the animal in its protracted leaps through the air. Whether the fin-like appendage is also employed in swimming is very questionable." One kind of *Loligo*, captured in the Pacific Ocean, in 34° N. lat., which measured six inches in its entire length, must, from the description of its hooks, have been an *Onychoteuthis*. This individual leaped from the sea over the high bulwarks of the ship, and alighted on the deck at a time when vast flocks of the same species were seen leaping around, and often striking with violence against the bows of the vessel, the sea being comparatively smooth. It was much injured by the violence with which it struck the deck. Another species with its two long tentacles furnished at the extremities with rows of suckers (acetabula) instead of horny-hooked appendages, resembling the above in size and form, was obtained in the Pacific. The prevailing colours were silver-white and steel-blue, spread with red spots and tints of violet and purple, a brilliant and very beautiful spot of emerald-green being placed immediately above each eye. Mr. Bennett concludes by stating that they noticed examples of this family of *Cephalopoda* from the equator to 34° N. lat., and 16° S. lat. in the Pacific Ocean.

The size of the naked cephalopods varies greatly. Some are of very large dimensions, and others—the *Sepioidæ* for instance—very small. Mr. Swainson ('Malacology') remarks that he saw many caught on the shores of Sicily, and that two would be a good load, their arms being as thick as those of a man.

We must take with some grains of allowance the stories collected by Denys de Montfort: such as that of Dens, a northern navigator, who, according to Dr. Shaw, avowed that he lost in the African seas three of his men, while they were employed during a calm in scraping the sides of his vessel, by the attack of a monster of this kind, which suddenly appeared, seized them in its arms, and drew them under water in spite of every effort to save them, and that the thickness of one of the creature's arms, which was cut off in the contest, was that of a minzen-mast, whilst the suckers were of the size of pot-lids. Then again, another crew, it was alleged, were similarly attacked off the coast of Angola. A gigantic cuttle-fish suddenly threw its arms across the vessel, and was on the point of dragging it to the bottom, when the crew succeeded in cutting off its arms with swords and hatchets. When their danger was most imminent, they prayed to St. Thomas for aid, and, in gratitude for their deliverance, dedicated, on their return home, a picture representing their perilous encounter, to the saint in his chapel at St. Malo. Dr. Hamilton gives an engraving of this adventure in the volume on 'Amphibious Carnivora,' in the 'Naturalist's Library,' and beneath it is printed, "The Kraken, supposed a *Sepia*, or Cuttle-Fish (from Denys Montfort)." Dr. Shaw observes that the existence of some enormously large species of the cuttle-fish tribe can hardly be doubted; and that though some accounts may have been much exaggerated, there is sufficient cause for believing that such species may very far surpass all that are generally observed about the coasts of European seas. The last observation may be safely admitted; but the account given by Dr. Shaw of the narrative of Dens affords one of the many proofs that a story rarely loses anything in its progress. That narrative is sufficiently marvellous; but on turning to it as recorded by Denys de Montfort, we find that only two of Dens's men are stated to have been carried off; the third having been rescued, though he died delirious on the night following the encounter. The suckers are described as having been as large as ladles (cueiller à pot), and the arm, at its base, as big as a fore-yard (vergue d'un mât de misaine). In Shaw's lectures the yard is magnified to a mast, and the ladles are

promoted to pot-lids. The notion that the celebrated Kraken is not to be considered as a wild and groundless chimera, but as either identical with or nearly allied to a colossal cuttle-fish, is supported in Blackwood's 'Magazine,' vol. ii. A writer in the same work, vol. iii., attacks the opinion attempted to be sustained in vol. ii.

The other genera of *Sepiadae* are *Conatus*, Gray, with only one species; *Beloteuthis*, Münster, with six species; *Leptoteuthis*, Meyer, with one species; *Cheiroteuthis*, D'Orb., with two species; *Histroteuthis*, D'Orb., with two species; *Onychoteuthis*, Lichtenstein, with six species; *Enoplateuthis*, D'Orb., with ten species; *Ommastrephes*, D'Orb., with fourteen species. [CEPHALOPODA; OMMASTREPHES.]

SEPIOLA. [SEPIADÆ.]

SEPIOTEUTHIS. [SEPIADÆ.]

SEPS. [SEPSIDÆ; SCINCIDÆ.]

SEPSIDÆ, a family of Lizards. The type of this family is the genus *Seps*, of which the *Seps Chalcides* of Bonaparte and other naturalists may be taken as the type. [SCINCIDÆ.] The following is Dr. J. E. Gray's definition of this family:—Rostral plate rather large, square. Nostrils in the front edge of a small shield, in a notch at the hinder side of the rostral plate. Supranasal distinct, contiguous or united, frontonasal none (or small on the side of the face), frontoparietal often wanting, sometimes united, interparietal triangular. Tongue flat, scaly, nicked at the tip. Teeth conical, simple. Palate not toothed, with a deep central longitudinal groove behind. Eyes distinct, with connivent eyelids. Lower eyelid scaly, or with a transparent disc. Body fusiform or subcylindrical, elongate. Scales smooth. Toes simple, unequal, clawed. Tail conical, pointed.

In the 'Catalogue' of the specimens in the British Museum, Dr. Gray describes seven genera and seven species. They are as follows:—
a. Rostral rather produced, sharp-edged, with a large nasal notch. Head wedge-shaped.

1. *Sphanops*.—Legs 4. Mental shield small. Lower eyelid transparent.

S. sepsoides, the Sphenops; a native of Egypt.

2. *Scelotes*.—Legs 2, posterior. Mental shield large. Lower eyelid scaly.

S. bipes, the Bipes; from the Cape of Good Hope.

b. Rostral rounded, erect. Head pyramidal.

3. *Gongylus*.—Legs 4. Toes 5-5. Body subfusiform. Lower eyelid transparent. Frontoparietal shield none. Ears simple.

G. ocellatus, the Tiliguga; a native of Egypt.

4. *Thyrus*.—Legs 4. Toes 5-5. Body fusiform. Lower eyelid transparent. Frontoparietal shield distinct. Ears toothed in front.

T. Bogerii, the Thyrus; from Mauritius.

5. *Amphiglossus*.—Legs 4. Toes 5-5. Body elongate, cylindrical. Ears distinct. Lower eyelid scaly.

A. Astrolabi, the Keneux; a native of Madagascar.

6. *Seps*.—Legs 4. Toes 3-3. Body cylindrical, elongate. Ears distinct. Lower eyelid transparent.

S. tridactylus, the Cicigun; a native of Europe. [SCINCIDÆ.]

7. *Heteromelas*.—Legs 4. Toes 2-3. Body cylindrical, elongate. Ears indistinct. Lower eyelid transparent.

H. Mauritanicus, the Heteromele; from Algiers.

SEPTARIA, a genus of Acepulose *Mollusca*, belonging to the family Tubicolæ. It has the tube testaceous, very long, gently attenuated posteriorly, and divided internally by arched incomplete partitions. Anterior extremity terminated by two slender tubes, which are not chambered in the interior.

S. arenaria is described and figured by Sir Everard Home in the 'Philosophical Transactions' for 1806, under the name of *Teredo gigantea*. It lives in sand in the Indian seas.

SERGESTES. [PELONIDÆ.]

SERIALARIA. [POLYZOA.]

SERIA'NA, an entirely tropical South American and West Indian genus of Plants belonging to the natural order *Sapindaceæ*, named by Schumacher after Serjeant, a French friar and botanist, but the genus is also and more commonly written *Serjania*. The species consist of climbing or twining shrubs. *S. triernata* is acrid and narcotic, and employed for the purpose of stupefying fish.

SERIATOPORA. [MADREPORÆA.]

SERICA. [MELOLONTIDÆ.]

SERICOSTOMA. [NEUROPTERA.]

SERICULUS. [MERULIDÆ.]

SERISOMUS. [CUCULIDÆ.]

SEROLIS. [ISOPODA.]

SEROUS MEMBRANES. [MEMBRANE.]

SERPENTARIA. [ARISTOLOCHIACEÆ.]

SERPENTINE, a rock regarding whose origin geologists have differed. It is described as an irregularly overlying mass in the Lizard district of Cornwall, as a dyke at Portsoy, and as nodular aggregations in the granite of Aberdeenshire. The relation in which it stands to Diallage Rock (a compound of diallage and felspar) is very intimate, both in the Alps, in the Shetland Isles, and in Cornwall. In fact the composition of these rocks is scarcely more different than may be seen between largely crystallised and fine-grained greenstone. Veins

and masses of trap on passing through or being in contact with limestone not unfrequently change the nature of that rock near the junction, and either fill it with serpentinous lines or masses, or produce therein asbestic or steatitic admixtures. It is a very common circumstance among the primary limestones to find light-green veins and strings of serpentine, and in the Pyrenees calcareous rocks comparatively of very recent date are similarly altered.

As a mineral Serpentine occurs, although rarely, in right rectangular prisms. It is usually massive and compact in texture, and of a dark-green or blackish-green colour. It also occurs in fibrous and lamellar varieties. Its hardness is 2·5 to 4, and it may be cut with a knife. Its specific gravity is 2·5 to 2·6. It becomes yellowish-gray on exposure, and feels sometimes a little unctuous. The following varieties are recognised:—

Precious Serpentine.—Purer specimens of a rich oil-green colour, and translucent, breaking with a splintery fracture. It is a beautiful stone when polished. It has the following composition:—

Silica	42·3
Magnesia	44·2
Protoxide of Iron	0·2
Carbonic Acid	0·9
Water	12·4
	—100·0

It gives off water when heated; becomes brownish-red before the blow-pipe, but fuses only on the edges.

Common Serpentine.—Opaque, of dark-green shades of colour.

Pierolite, Schiller Asbestos.—A Fibrous Serpentine, of an olive-green colour, constituting seams in Serpentine. The fibres are coarse or fine, and brittle. It resembles some forms of asbestos, but differs in its difficult fusibility. Thomson's *Baltimorite* belongs here.

Marmolite.—A Foliated Serpentine, of greenish-white and light green shades of colour, and pearly lustre, consisting of thin folia rather easily separable. The folia are brittle, and the variety is thus distinguished from tale and hrucite. It has the following composition:—

Silica	40·1
Magnesia	41·4
Protoxide of Iron	2·7
Water	15·7
	—99·9

Kerolite.—Near Marmolite, but folia not separable.

Serpentine is a very handsome stone when polished. Beautiful specimens from Cornwall, and other parts of England and Ireland, may be seen in the Museum of Economic Geology, London. When mixed with limestone it constitutes the Verd-Antique Marble. It does not wear well, although at first it receives a fine polish. Chromic iron is usually found disseminated through it. Dr. Jackson of America has shown that Epsom salts or sulphate of magnesia may be profitably manufactured from Serpentine.

(Dana, *Mineralogy*.)

SERPENTS. [OPHIDIA.]

SERPICULA (from 'serpo,' to creep, on account of the creeping habits of the species), a small African and Indian genus of Plants belonging to the natural order *Haloragaceæ*. The genus is characterised by being monœceous. The male flowers have the calyx small, quadripartite. Petals 4. Stamens 4 to 8. Styles 4, sterile. The female flowers have the calyx-tube adnate to the ovary, limb small, quadripartite. Petals and stamens wanting. Ovary 4-celled. Ovules and styles 4. Nuts brittle, 1-celled, 1-seeded. The species form herbaceous creeping branched plants, with axillary flowers, the males being pedicellate, and the female aggregated and almost sessile, though they are but little known. The plants of this genus are not possessed of any remarkable properties, but they must not be confounded with the *Serpicula* now *Hydrilla verticillata* of Roxburgh, which belongs to the natural family of *Hydrocharidaceæ*, and which is used in India in refining sugar, in the same way that clay is employed in other countries. A layer of the plant being spread upon the surface of the sugar, water is allowed slowly to percolate through the mass.

SERPULA. [ANNELIDA.]

SERPULITES, a genus of Fossil *Annclida*. [ANNELIDA.]

SERRAFALCUS, a genus of Plants belonging to the natural order of Grasses and the tribe *Festucineæ*. It has unequal herbaceous many-flowered glumes, the lower are from 3- to 5-nerved, the upper 7 to 9. The flower is oblong and trifid. The outer palea with a short seta founded on three nerves from below the tip. The styles lateral, below the summit of the fruit. The spikelets narrow at the top.

S. scabellus has a loose panicle slightly compound, the simple peduncles about equalling the oblong glabrous spikelets, the flowers at first loosely imbricated, afterwards distinct, about as long as the straight awn, the outer palea not overlapping the next flower. The flower is large and downy, the leaves hairy with nearly smooth sheaths. It is a native of Great Britain.

S. racemosus has a close or elongated erect panicle usually simple, the spikelets glabrous ovate and somewhat compressed. The midrib of the glumes and palea scabrous towards the top, the leaves and sheaths slightly hairy. It is a common species in sandy places in the south of Great Britain.

(Babington, *Manual of British Botany*.)

SERRANUS, a genus of Fishes belonging to the family *Percide*.

It has a single elongated dorsal fin, the rays of the anterior portion spinous, the others flexible; branchiostegous rays 7; small teeth in both jaws on the palatine bones and the vomer, some elongated teeth among the smaller ones; cheeks and operculum covered with small scales; preoperculum serrated; operculum ending in two or three flattened points projecting backwards.

Two species of this genus have been found on the British coasts, which may be given as examples of the genus.

S. cabrilla, the Smooth Serranus, is the *Perca cabrilla* of Linnæus, the *Perca channus* of Mr. Couch. It is abundant in the Mediterranean, and not uncommon on the Cornish coast.

S. gigas, the Dusky Serranus, is the *Perca robusta* of Couch. It is abundant in the Mediterranean, where it sometimes attains the weight of 60 lbs. It has been taken off the coast of Cornwall.

(Yarrell, *History of British Fishes*.)

SERRATULA, a genus of Compositous Plants of the order *Cynaraceæ*, and the section *Serratuleæ*. The heads of flowers are dioecious by abortion; the involucre is imbricated, sharp, and unawed; the scales of the receptacle split longitudinally into linear bristles; fruit compressed, not beaked, basal areola oblique; the pappus persistent. There is but one British species of this genus, *S. tinctoria*, the Saw-Work. (Babington, *Manual of British Botany*.)

SERRICORNES, the third family of Pentamerous *Coleoptera*. They have four palpi; elytra which cover the abdomen; and antennæ which are for the most part equal throughout, or smaller at the extremity. The Linnæan genera *Buprestis*, *Elater*, *Lampyrus*, and *Ptinus* belong to this family, as also do *Melyris*, *Clerus*, and *Cebrio*. The *Ptinus fur* is the little beetle whose larvæ do so much damage among collections of natural history.

SERTULARIA, a Linnæan genus of *Polypifera*.

SERTULARIADÆ, the name of a family of *Polypifera*, including the genus *Sertularia* of Linnæus. [HYDROIDA.]

SERTULARIÆA, De Blainville's name for the family of *Polypiriæa*, founded on the Linnæan genus *Sertularia*.

SERUM, the name given to the fluid part of the blood, also to the fluid poured upon the surface of serous membranes. [BLOOD; MEMBRANE.]

SERVAL. [FELIDÆ.]

SERVICE-TREE. [PYRUS.]

SESAMUM (*Σησαμύον*), a genus of Plants belonging to the natural order *Sesamaceæ*, sometimes called *Pedalineæ*, containing only few genera and species. It is distinguished by having a 5-parted calyx; corolla with a short tube; bell-shaped throat; and the limb quinquefid, somewhat bilabiate. Stamens 4, didynamous, with the rudiments of a fifth stamen; stigma hilamellate; capsule oblong, 4-celled, 2-valved; seeds numerous.

The species, though now cultivated in many countries, are supposed to have been originally natives of India. They form annual plants; with opposite and alternate leaves, and axillary solitary flowers. The species are by some considered to be five in number, that is, *S. orientale*, *S. Indicum*, *S. luteum*, *S. laciniatum*, with *S. radiatum*, said to be a native of Guinea. Others consider them all to be varieties of one species. These are cultivated in various countries, but especially in India, Egypt, and Syria. They have also been taken to the West Indies, where the plant is called Banglo and Oil-P'laut. *Sesamum* seeds are sometimes added to hroths, frequently to cakes by the Jews, and likewise in the East.

SESARMA. [GRAPSIDÆ.]

SESBANIA, a genus of Plants belonging to the natural order *Leguminosæ*, which is so named from the Arabic name of the species, which is indigenous in Egypt. The rest are found in the equinoctial parts of the world, but the most remarkable in India. The genus is characterised by having a 5-lobed or 5-toothed calyx; the standard of the corolla roundish, larger than the keel, which is obtuse, 2-edged at the base; stamens diadelphous (9 and 1), with the sheath auricled at the base; legume elongated, slender, torulose, many-seeded. The species form shrubs or herbs with abruptly pinnate leaves, many pairs of leaflets, cauline stipules lanceolate, and the petiole ending in a bristle point. Flowers axillary, racemose, usually yellow.

S. Aegyptiaca, the Egyptian species, found also in India, forms a small and very elegant tree; its wood is employed in making the best charcoal for gunpowder.

S. cannabina, the Dhanchi of Bengal, is not found wild. It is cultivated on account of the fibres of its bark, which are coarse, but more durable than some other substitutes for hemp, especially when exposed to wet, and are therefore generally employed for the drag-ropes and other cordage about fishing-nets.

SESLERIA, a genus of Plants belonging to the natural order of Grasses and the tribe *Seslericeæ*. It has a spiked panicle, sessile spikelets tiled all round; the glumes are from 2- to 6-flowered, nearly as long as the spikelet; the outer palea keeled and membranous, with a scarious margin ending in 3 or 5 points; the dorsal rib evanescent.

S. cerulea has an ovate slightly one-sided spike, the outer palea terminating in 4 teeth, the dorsal rib rough, with a short excurrent point, the leaves abrupt, with a minute rough point; the roots are tufted, the stem from 6 to 12 inches high; the spike about half an inch long, and of a bluish-purple colour. This is the only British species. It is found chiefly on mountains.

S. Quitensis is the *Festuca quadridentata* of Humboldt and others. Humboldt tells us that it is very poisonous.

(Lindley, *Flora Medica*; Babington, *Manual of British Botany*.)

SETARIA, a genus of Grasses containing a few species cultivated as corn-grains in some countries. The genus is named from 'seta,' a bristle, on account of the bristly nature of the involucre. The species are found in both the hot and temperate parts of the world. The genus nearly corresponds in character with *Panicum*, under which it is sometimes included, but it is also combined with *Pennisetum*. It is characterized by having the spikelets 2-flowered, supported by two or more bristles; the lower valve is the smallest; the lower flower is neuter or male, with the valves of the corolla coriaceous and indurated, awnless, the lower one embracing the other; petaloid scales very obtuse and subfalcate; germs emergent; seed included within the persistent glumella. The species are found both in the hot and temperate parts of the world.

S. verticillata, Bristle-Grass, has a panicle spiked, lobed below; branches whorled; bristles of the involucre rough, with reversed teeth, outer glumella of the fruit nearly even; lower floret united with one glumella. It is found in cultivated fields in England.

S. viridis, Green Bristle-Grass, has a panicle spiked, continuous; bristles of the involucre rough, with erect teeth; outer glumella of the fruit nearly even; lower floret neuter, with one glumella. This species is also British.

S. glauca, Glaucous Bristle-Grass, has a panicle spiked, continuous; bristles of the involucre rough, with erect teeth; outer glumella of the fruit conspicuously wavy, wrinkled transversely; lower floret triandrous with two glummels. It is found in Hertfordshire and other parts of England. The first two species are found in America and India. *S. Germanica* and *S. Italica* are cultivated as articles of diet in Europe.

SETTER, the name for that variety of the Dog which partakes of the characters of the POINTER and SPANIEL, *Canis familiaris* Index of Cains.

The Setter is less liable to be foot-sore than the Pointer; but is generally considered more difficult to break. When however a well-broken well-bred Setter is hunted frequently, no dog trained to the gun does his work better, or is more staunch. The breed originated, in all probability, between the large English spaniel and the Spanish pointer.

This variety possesses a high degree of intelligence, and is capable of the strongest attachment. Mr. Bell's account of a favourite of this breed is so interesting that we give it in his own words:—

"By far the most interesting, and, if I may so employ the term, amiable animal I have ever known, was a bitch of this kind, formerly belonging to my father, which he had from a puppy, and which, although never regularly broke, was the best dog in the field that he ever possessed. The very expression of poor Juno's countenance was full of sensibility and affection. She appeared to be always on the watch to evince her love and gratitude to those who were kind to her; and the instinct of attachment was in her so powerful that it showed itself in her conduct to other animals as well as to her human friends. A kitten which had been lately taken from its mother was sent to us, and on Juno's approach showed the usual horror of the cat towards dogs; but Juno seemed determined to conquer the antipathy, and, by the most winning and persevering kindness and forbearance, advancing or receding as she found the waywardness of her new friend's temper required, she completely attached the kitten to her; and as she had lately lost her puppies, and still had some milk left, I have often seen them lying together before the fire, the kitten sucking her kind foster-mother, who was licking and caressing her as her own offspring. She would also play with great gentleness with some tame rabbits of mine, and would entice them to familiarity by the kindness of her manner; and so fond was she of caressing the young of her own species, that when a spaniel bitch of my father's had puppies, of which all excepting one were destroyed, Juno would take every opportunity to steal the remaining one from its mother's nest and carry it to her own, where she would lick and fondle it with the greatest tenderness. I poor Busy, the mother, also a good-tempered creature, as soon as she had discovered the theft, hastened of course to bring back her little one, which was again to be stolen on the first favourable opportunity, until at length the two bitches killed the poor puppy between them, as they were endeavouring each to pull it from the other; and all this with the most perfect mutual good understanding. Juno lived to a good old age, an unspoiled pet, after her master had shot to her for fourteen seasons." (*British Quadrupeds*.)

SEVERITE, a Mineral occurring massive, in pieces from two to five inches in diameter. Its fracture is uneven; the fractured surfaces dull. Hardness 1 to 1.5; it yields easily to the knife. Brittle. It polishes by friction. It adheres strongly to the tongue, but emits no argillaceous odour when breathed on. Colour white. Streak shining. Dull. Slightly translucent. It is found near St. Sever, in France, in a gravelly soil. *Severite*, as shown by the annexed analysis by Pelletier, is a hydrated silicate of alumina:—

Silica	50
Alumina	22
Water	26
Loss	2

SEXES OF PLANTS. [REPRODUCTION IN PLANTS AND ANIMALS.]

SEXUAL SYSTEM. [REPRODUCTION IN PLANTS AND ANIMALS.]

SEYBETITE. [CLINTONITE.]

SEYCHELLE COCOA-NUT is the fruit of one of the Palms (*Lodoicea Sechellarum*), respecting which many fabulous accounts were formerly related, such as, that it was produced at the bottom of the sea, the nuts being only found thrown up on the coasts of the Maldivé Islands. They were called Coco de Maldivia, or Coco de Salomon, by the early Portuguese navigators. Many marvellous medical virtues were ascribed to these nuts by the physicians of the age, both Asiatic and European, and they were consequently sold at a high price. At present they form only objects of curiosity, and are well known under the name of Double Cocoa-Nuts. The tree yielding them was first discovered by Barré, a French officer of engineers, in 1769, then described by Sonnerat, but for the first time accurately described by Labillardière, 'Ann. Mus., Paris, ix. p. 140, t. 13. A very full description and illustrative plates have been given by Dr. Hooker, in the 'Botanical Magazine,' N. S., Nos. iv., v., and vi., 1827; and a paper on the subject was read at the Royal Asiatic Society by a resident of the Seychelle Islands. To the inhabitants the tree is useful for its timber, which is hard externally, and employed in building their huts and for posts; the leaves and their footstalks are used for the roof, walls, and partitions, and for many other domestic purposes. The nuts weigh from 20 to 25 pounds each, and when fresh contain a white, transparent, and jelly-like substance, which is edible. The shells are employed in making vessels and dishes of various kinds, and the entire nuts form articles of commerce, as they are esteemed in other countries both for their fabled virtues and as curiosities.

SHAD. [CLUPEIDÆ.]

SHADDOCK. [CITRUS.]

SHAG. [PELECANIDÆ.]

SHALE. Any argillaceous deposit, naturally divided into laminae parallel to the plane of deposition, is rightly so called by geologists. These are sandy, calcareous, purely argillaceous, and carbonaceous shales. Geologists sometimes, very inconveniently, call fine-grained very laminated shales by the title of Slates. A synonym in the north of England mining-districts is Plate. [COAL FORMATION.]

SHALLOTT. [ALLIUM.]

SHALLOW, a name for the Rudd. [LEUCISCUS.]

SHELL. The hard calcareous substance which protects either partially or entirely the Testaceous Molluscs externally, or supports certain of them internally, is termed Shell.

This substance, when external, may be considered as the exoskeleton of the animal; when internal, as its endo-skeleton.

The Common or Waved Wink of our shores (*Buccinum undatum*) and the Common Oyster (*Ostrea edulis*), may be taken as examples of external shells; and the internal support, or cuttle-bone, as it is generally called, of the Common Cuttle-Fish (*Sepia vulgaris*) [SEPIADÆ], affords an example of an internal shell.

At one time it was supposed that the shells of the various forms of *Mollusca*, as well as those of Crabs, Lobsters, and other *Crustacea*, were merely exudations of inorganic matter from the internal structure of the animal. It has however been recently shown by the microscopic and physiological researches of Dr. Carpenter, and the observations of Mr. Bowerbank and others, that this view is entirely erroneous, and that shell, like other organic products, is the result of the regular growth of cells.

Although the forms and mode of development of these cells are very numerous, and differ in almost each particular species, a sufficient number of observations have been made to lead to the conclusion, that the growth of shells depends on the same general laws as are observed in bone, teeth, scales, horns, and other hard parts of animals. Wherever hardness and solidity is required in the animal body, there phosphate of lime and carbonate of lime are deposited, and the mode of their deposit is strikingly similar in all cases.

In a report made to the British Association, 1844, Dr. Carpenter has given the result of his researches on the structure of a large number of shells, and all observations have since tended to confirm his accuracy. He finds that certain forms of shell-structure are so constant that he proposes them, if not as a means of distinguishing species, at least of recognising groups. "My inquiries," he says, "so far as they have yet proceeded, tend to establish this position, that where a recognisable and constant diversity presents itself in the elementary structure of the shell among different groups, that diversity affords characters, which are to a very high degree indicative of the natural affinities of those groups. It is not always that peculiarities sufficiently distinct present themselves, even between

what are regarded zoologically as distinct families; but where a marked diversity does exist, I believe that it will always be indicative of the affinities of the animal. Thus the conformity in structure between all the shells of one natural family is usually so close, that any strongly marked difference in a particular genus would make me hesitate in admitting it into the group." Dr. Carpenter further adds that although the characters derived from the structure of the shell are not likely to serve for the distinction of species from each other or even genera, for the distinction of some families they furnish the best natural characters at present possessed by the naturalist.

In examining the structure of shells, very thin sections of the shell must be obtained, and on these being placed under the microscope, it will be found that they are translucent, and permit of the passage of the rays of light. This is the case with all shells, and is indicative of their crystalline character. This shows that the distinction of shells into crystalline and granular or concretionary, as proposed by Dr. J. E. Gray, is not founded on a knowledge of the microscopic structure of the shell, although for practical purposes it serves to distinguish between certain forms of shell. When it is wished to examine the animal matter of shells independent of their inorganic constituents, the shell should be immersed in dilute hydrochloric acid, which leaves the animal matter and takes away the calcareous. This process Dr. Carpenter calls 'decalcifying.'

The animal matter of the shell exhibits itself more particularly in two forms, the Cellular and the Membranous. In most cases amongst the *Mollusca* the cellular structure assumes a prismatic form. "If," says Dr. Carpenter, "a small portion be broken away from the thin margin of the shell of any species of *Pinna* and it be placed without any preparation under a low magnifying power, it presents on each of its surfaces, when viewed by transmitted light, very much the aspect of a honeycomb; whilst at the broken edge it exhibits an appearance which is evidently fibrous to the eye, but when examined under the microscope with reflected light, resembles that of an assemblage of basaltic columns. The shell is thus seen to be composed of a vast multitude of prisms, having for the most part a tolerably regular hexagonal shape and nearly uniform size. These are arranged perpendicularly to the surface of each lamina, so that its thickness is formed by their length, and its two surfaces by their extremities." The substance forming these prisms is generally transparent, but here and there is found a dark spot. This arises from the fact that the prisms are found to be composed of a series of cells laid one on the top of the other. In the majority of the cells the calcareous matter is deposited in a crystalline form, so as to give it a translucent character, but occasionally this object is not effected, and the cell is filled with air, and presents the dark appearance known to be produced under the microscope by transparent vessels containing air. This prismatic cellular substance is formed upon the external surface of the mantle or skin of the animal, and may be regarded as homologous with the epithelial cells, which constitute the epidermis of the higher animals, and is called by Dr. Carpenter a 'calicified epithelium.' That these cells are deposited by successive layers appears from the fact that, when the decalcified layers are examined they exhibit a series of transverse lines not unlike the transverse striæ of muscular fibre.

In the shells which do not present the prismatic cellular tissue there is seen a layer of membranous shell-substance. In this layer no cells can for the most part be discovered. In no shell is there an entire absence of this organic basis, and Dr. Carpenter suggests that at one time this membrane was a constituent part of the mantle of the Mollusc. It appears to be homologous with the 'basement membrane' found in the mucous membranes and the skin. This membranous substance presents a variety of appearances; sometimes it is single, as if the shelly matter had been uniformly diffused over a plane surface. It is more frequently uneven, sometimes amounting simply to a corrugation or wrinkling, at other times the wrinkles are so strongly marked that they give the appearance of a series of fusiform cells, as is well seen in the shell of the common *Patella*.

What is called the Nacre in shells, and which is more especially observed in their interior, and which is distinguished by the iridescence produced by the action of light, is found to consist of layers or folds of this membranous shell-substance. When examined under the microscope, this substance exhibits a series of layers, and it has been supposed that these are alternately layers of membranous and calcareous matter; but Dr. Carpenter has shown that when these layers are decalcified they exhibit the iridescence, but that when the corrugations are removed by stretching, the membrane no longer exhibits its beautiful hues.

The membranous shell-structure is often traversed by tubes which vary from the $\frac{1}{100}$ inch to the $\frac{1}{2}$ inch in diameter. Their direction and distribution is exceedingly various, but in general they form a kind of network, which spreads itself out in each layer. At other times these tubes are quite straight. They have been regarded as perforations; but Mr. Bowerbank and Dr. Carpenter have both seen in them indications of a cellular structure, and regard them as originating in the coalescence of a series of cells. This structure is not often observed in the nacreous substance.

A structure of the shell-substance occurs in *Ruditapes* which Dr. Carpenter calls 'cancellated structure.' It resembles the prismatic

cellular substance, but the cells are hollow instead of being filled up. Dr. Carpenter says he has not met with this structure in a decided form amongst recent shells.

The Pearls found in the interior of the shells of many species of *Mollusca* seem to result from the deposit of the nacreous substance around some nucleus mostly of foreign origin. They are probably always formed between the mantle and the shell, although sometimes found in the muscles or viscera of the animal. The *Avicula margaritifera* is called the Pearl Oyster, on account of the frequency with which pearls are found in its interior. [AVICULA.] Pearls are not unfrequently found in the common oyster, and most fishmougers possess specimens which they have obtained from oysters they have opened. Many of the fresh-water *Conchifera* of our own rivers contain them. The *Unio margaritifera* yields them. It is said that the reputation of British pearls excited the cupidity of Julius Caesar, and that he presented a buckler covered with them to Venus Genetrix, which was suspended in her temple. Pliny speaks of British pearls disparagingly. Those obtained from the *Unio* are generally very good; but many are procured from the *Mytilus edulis*, and these are not so valuable. (Forbes and Hauley, 'British Mollusca.')

With regard to the growth of shells, although it is true, generally speaking, that shells cover the embryo of the testaceous mollusc in the egg, as observed by Swammerdam, Pfeiffer, and others, such is not its condition in all cases. In *Argonauta*, for instance, the shell is not coeval with the first formation of the animal. [OCTOPODA.]

Dr. J. E. Gray, who states that the shells of *Mollusca* appear to be coeval with the first formation of the animal, observes that the Cephalopodous *Mollusca* form no exception; their bone, composed of two or three calcareous plates, being found fully developed in the cuttle-fish some time before the young animal is hatched. These observations, he adds, are directly at variance with the theory maintained by Sir Everard Home ('Phil. Trans.' 1817), namely, that the shell is formed after the animal has quitted the egg; and, as regards the cuttle-fish, they are opposed to the remark made by Baron Cuvier, that the young cuttle-fish, when first hatched, has only a cartilaginous plate like the *Loligo*.

The shell, when first observed on the embryo (even of the animals of spiral shells), forms, Dr. Gray observes, a short blunt more or less curved sub-cylindrical cone, covering the hinder part of its body. As the organisation of the embryo becomes developed, and the hinder part of the body extended, the shell, he remarks, increases in size, till the body and shell together occupy nearly the whole of the egg. "While in the egg," says Dr. Gray in continuation, "the embryo shells are generally of a pale horn colour, and destitute of markings; when therefore they remain attached to the apex of the spire of adult shells, they may be easily distinguished by their appearance from the part formed after their exclusion; and as in such cases they offer some characters of importance, it has been proposed to designate them by the name of the nucleus of the shell. The effect of the atmosphere on the shell is almost instantaneous. In some young *Helices*, and in a species of *Voluta*, in my collection, the very first line of calcareous matter deposited after their exclusion from the egg is marked nearly as the adult shells of the species."

The same author remarks that the nucleus which forms the original apex in all shells, and frequently remains attached to them during all the periods of their growth, is largest in those shells the animals of which are viviparous, and is consequently very distinct in *Voluta*, *Paludina*, and *Cyclades*. In the oviparous species, he observes, it agrees in size with the egg of the animal; thus *Achatina octona*, which has an egg nearly equal in dimensions to the month of the shell, and *Bulinus ovatus* and *B. bicarinatus*, which lay large eggs, have large nuclei, the magnitude of the nucleus in general rendering the top of the spire blunt. Some, on the contrary, as *Stylina* generally, and *Pupa purpurea*, have, he adds, a very long slender acute turret-nucleus. The form and size of the eggs of these molluscs do not appear to be known.

The nucleus consists of two coats or parts: the external coat or layer, Epidermis and Periostacum of authors, is of a somewhat horny or membranous character; the inner layer constitutes the true shell. This epidermis is thinnest in such shells as are enveloped in the mantles of their animals. The gradual growth of the shell so constituted is effected by the secretion from the mantle. The preparation No. 93 A, in the Museum of the College of Surgeons in London, exhibits a *Cypræa Tigris* with the soft parts. One of the lobes of the mantle, the secreting organ of the shell, is protruded. There are glands at intervals in the mantle of those shells that are ornamented with coloured patterns in the form of necklaces or stripes, which produce those patterns in many cases with all the correctness of a design. But though the mantle is the ordinary secreting organ, the vitreous external coat giving the highly glazed appearance to which the olives owe so much of their beauty is secreted by the foot, and not by the mantle.

The plates which form the rhombic crystalline shells are, Dr. Gray observes, deposited in succession, each gradually increasing in thickness as the shell enlarges. As the animal waxes in size, the lip gradually shelves, becoming thinner from the inner to the outer edge, the innermost part being formed of three layers, the next of two, and the outer and thinnest part (that which is first formed) of only a single layer. At the approach of the periodical stoppage of the

growth of the animal, the second layer of shell, and afterwards the innermost layer, is deposited up to the edge of the mouth, which is thus completed. By this process a spiral shell, a cone for instance, becomes as it were rolled on itself.

But besides this gradual onward increase, another process is called into action in certain cases, in order to the symmetrical growth of the spiral shell. Take a *Triton* or a *Murex* for instance: the intervals of growth are marked by the elevated varices. In the direction in which the shell is, so to speak, to be rolled on itself, there will be found a thickened spreading inner lip, into which a varix descends. Now both these must be removed, in order to insure the uninterrupted progress of the shell; for if these shells be examined internally, they will be found to be smooth and uninterrupted, and what is now inside was once outside. The power of absorption then must be great to remove the masses of shell which are contained in the highly-elevated and wrought varices, for such in many shells they are, to say nothing of the thickened and patulous lip.

In the smooth shells, cones for instance, where the animal has no obstacle to remove in the enlargement of the shell, the internal volutions are often so much absorbed as to be as thin as paper, and not unfrequently have vanished altogether. In both these cases, may not the animal derive from its own shell the means of increasing it?

The Operculum would in itself almost justify a treatise, which our limits forbid. It is a horny or shelly plate, which closes more or less completely the aperture of the spiral shell; so that those spiral shells which are so furnished are in fact bivalves. They are developed with the embryo in the egg. We must refer our readers for details to the interesting papers of Dr. Gray, who has for some years past paid great attention to this subject. In the 'Medical Repository' for 1821 he first urged the importance of this adjunct as a generic and family distinction, and he pursues the subject in the memoir from which we have quoted in this article; nor has the study of this interesting part of the conformation of many testaceous molluscs been neglected by M. De Blainville and other French zoologists, who have followed it out with great assiduity.

The nucleus, spire, and indeed the upper whorls of many shells, of the Volutes for instance, and most especially of *Magilus*, become, as they advance in growth, filled more or less by a transparent calcareous secretion; and Dr. Gray remarks that the distinction between such shells and those which are decollated, such as *Bulinus decollatus*, *Carithium decollatum*, &c., is, that in the latter the animal, instead of lining the upper whorls with an internal coat, suddenly withdraws its body from them, and forms behind its extremity a concave septum: the vital communication between the body and the apex of the shell being thus cut off, the latter part, he observes, decays in the manner of a dead shell, and falls off in particles; but M. De Blainville refers the decollation of the spire to the filling up of the inner surface of the cavity of the shell with a very brittle vitreous deposit.

Dr. Gray remarks that in many fresh-water bivalves there is deposited between the layers of the shell a lamina of animal matter, similar to the periostacum; and that in the genera *Ethieria* and *Mulleria* such a coat is deposited between nearly all the layers, giving them a very peculiar olive-green colour, and having minute dots on its surface. The erosion of these shells must be familiar to all who are conversant with the subject; and Dr. Gray states that these successive depositions of animal matter enable them to offer a new layer of periostacum for the protection of each succeeding plate, as the plate above it yields to the destructive influence of the medium in which the animal resides. A similar deposit of animal matter is also found, he adds, forming green stains in the pearly inner coat of the various species of *Uniona*, and protects from the action of the water the inner part of the umbones of shells which have been eroded. Dr. Gray has observed the thick inner layer in the upper valve of *Ostrea Cornucopia* to be prismatic, and the outer part of the lamina to be separated by layers of periostacum.

The disintegrated thin, lamellar, pearly gray, silvery scales of iridescent shells, when reduced to powder, may be used as a pigment to imitate the silvery appearance of fishes, &c., and indeed the disintegrated and powdered scales of the *Placuna* (Moon-Shells, Chinese-Window Oysters, as they are called by collectors), are so used by the Chinese in their water-colour drawings.

The term Shell is also commonly applied to the covering of crustaceous animals and the crusts of *Echini*: thus people familiarly talk of the shell of a lobster or crab and of the shell of a sea-egg. Mr. Hatchett remarks that there is reason to conclude that phosphate of lime mingled with the carbonate is a chemical characteristic which distinguishes the crustaceous from the testaceous substance; and that the principal difference of the qualities of each, when complete, is caused by the proportion of the hardening substances, relative to the gluten by which they are cemented; or by the abundance and consistency of gelatinous, membranaceous, or cartilaginous substance, in and on which the carbonate of lime, or the mixture of carbonate and phosphate of lime, has been secreted and deposited. Thus the presence of phosphate of lime mingled with carbonate appears to be a chemical character of Crustaceans and *Echini*.

SHELL-INSECTS. [ENTOMOTRACA.]

SHE-OAK. [CARUARINACEÆ.]

SHEPHERDITE. [MAGNESIA.]

SHEPHERD'S NEEDLE. [SCANDIX.]

SHEPHERD'S PULSE. [CAESSELLA.]

SHERARDIA (so named by Dillenius after his patron William Sherard, LL.D., consul at Smyrna), a genus of Plants belonging to the natural order *Rubiaceæ*. It has a funnel-shaped corolla, a dry fruit, crowned with the limb of the calyx, which is 6-toothed.

S. arvensis, Corn-Field Madder, is the only species. The stem is mostly decumbent, branched, square, and leafy; the whole plant is rough and hairy; the leaves are six in a whorl, acute, and obovate lanceolate; the flower is blue, in a small sessile terminal umbel. It is found on sandy soils, in Great Britain, Europe, and the Crimea.

(Babington, *Manual of British Botany*.)

SHOREA, a small Indian genus of Plants, belonging to the natural order *Dipterocarpaceæ*, named in compliment to Sir J. Shore, afterwards Lord Teignmouth, then governor-general of Bengal. The genus is found as far south as the line; and *S. robusta*, the best known and most useful species, as far north as 30° N. lat., in many parts forming the forests which skirt the south-western base of the Himalaya Mountains.

The genus is characterised by having a calyx of 5 sepals enlarging into 5 long wings; petals 5; stamens 25 to 30; fruit 1-celled, 3-valved, and 1-seeded.

The family to which the *Shorea* belongs is remarkable for the number of useful products yielded by its different species, as the camphor of Sumatra, resin, wood-oil, and valuable timber. *S. robusta* is remarkable on all these accounts, as it is a lofty and ornamental tree with showy inflorescence. It is well known as a timber-tree by the name of 'Saul,' or 'Sal,' and chiefly employed in the north-western provinces of India in all government works, house-timbers, gun-carriages, &c. The wood is of a uniform light-brown colour, close-grained and strong. The tree exudes a resin which by the natives is called 'ral,' and by the Europeans one of the kinds of Dammer, being used for the same purposes as many other resins, and in Bengal very frequently as a substitute for pitch in the dockyards. It is also sometimes used by the Hindoos as an incense.

SHRIKES. [LANIADÆ.]

SHRIMPS. [CRANGONIDÆ.]

SHRIMPS, FRESH-WATER. [GAMMARUS.]

SHRUB ('Frutex'). All plants are divided into herbs, shrubs, and trees. A shrub is a plant with a woody stem, which approaches the tree in its duration and consistence, but never attains the height of a tree, and is generally taller than the herb. It varies in height from about four to twelve feet. Linnaeus attempted to distinguish trees from shrubs by the former having huds and the latter having none. But this distinction is of no avail, as plants like the willow, generally called shrubs, possess huds, whilst most trees in hot countries are without them.

In horticulture shrubs are too well known to need a definition. For practical purposes they are divided into the deciduous and evergreen kinds, and each of these kinds may be further divided, according to their hardy or tender habits, their form, size, mode of growth, colour, &c. The most ornamental flowering shrubs are those belonging to the genera *Rosa*, *Rhododendron*, *Azalea*, *Kalmia*, *Andromeda*, *Vaccinium*, &c. Among the evergreen shrubs are the Holly, the Ivy, the Jasmine, the Box, various Heaths, &c.

Shrubs are often planted together, forming what are called shrubberies, and when the kinds are judiciously selected and arranged, these collections add greatly to the beauty of the gardens and pleasure-grounds where they are introduced.

SIEBALDIA (in honour of Robert Siebold, formerly Professor of Physic at Edinburgh), a genus of Alpine Plants, belonging to the natural order *Rosaceæ*. It has a concave 10-parted calyx, the 5 outer segments accessory; it has 5 yellow or white petals, 5 sepals, and a lateral style; the fruit consists of from 5 to 10 small nuts seated on a dry receptacle.

S. procumbens has trifoliate leaves, wedge-shaped leaflets, with three teeth at the apex, rather pilose, the flowers corymbose; petals yellow, small, shorter than the calyx. It is found on dry mountains in Scotland, in Europe, Siberia, and North America.

S. parviflora is a native of Cappadocia. It has trifoliate leaves, the leaflets bect with strigose pili on both surfaces, the flowers in glomerate heads, the petals obovate, one-half shorter than the calyx.

(Babington, *Manual of British Botany*.)

SIBTHORPIA, a genus of Plants named after Dr. Sibthorp, professor of botany at Oxford, the successor of Dillenius, and the father of Dr. John Sibthorp, the traveller. This genus consists of small creeping, rooting, tufted herbs with small alternate uniform leaves, a 5-parted calyx, 5-lobed subrotate corolla, 4-5 nearly equal stamens, a capitate stigma, and a suborbicular capsule dehiscing at the top. The flowers are axillary, solitary, and inconspicuous. One of the species, *S. Europæa*, is a native of Europe, and is found in Portugal, Spain, and France, and in Devonshire and Cornwall in England. This genus is referred by most botanists to the order *Scrophulariaceæ*; but it differs from this order in its globose placenta and regular flowers. It differs from *Primulaceæ* in its stamens, being alternate with the lobes of the corolla, and in its capsule being 2-celled; hence Don has proposed to place this and some other doubtful genera in a new order, *Sibthorpiaceæ*, which possesses characters intermediates between those of *Scrophulariaceæ* and *Primulaceæ*.

SICYONIA. [PALEMONIDÆ.]

SIDA, a genus of Plants belonging to the natural order *Malvaceæ*, containing nearly 200 species, which are very extensively distributed throughout the warm parts of the world, and abound in the peninsula and plains of India. The name was originally applied by Theophrastus to a plant growing in moist situations, which is believed to have been an *Althæa*, also belonging to the family of *Malvaceæ*, and was adopted by Linæus for this genus.

Sida is characterised by having a naked quinquifid calyx with valvate segments. Corolla with 5 petals, which are obovate, with the claws often united into a tube, and joined to the bottom of the stamen tube. The stamens numerous, with their filaments connected into a columnar tube at their base, and free at the apex, bearing the reniform anthers. The styles are numerous, but more or less united at the base. Capsule 5- or many-celled. Cocci single-seeded; seeds suspended, roundish, and flattened.

The species of this genus vary much in habit, as well as in the structure of their fruit and seeds, but they resemble each other, as indeed do all Malvaceous plants, in abounding in mucilage, and in some of them having tough ligneous fibres, which are employed for the purposes of cordage in different countries. From their mucilaginous nature several are employed as demulcents in India, such as *Sida Indica*, *S. Asiatica*, and *S. populifolia*, in the same way that the Mallow and the Marsh-Mallow are in Europe. The leaves of *S. carpinifolia* (a native of Brazil and the Canary Islands) are chewed by the Brazilians, and applied with success to the stings of wasps and bees. *S. rhomboidea* and *S. rhombifolia* abound in very delicate flax-like fibres, which may be used for many of the same purposes as hemp and flax; but when the plants are grown for the sake of their fibres, they ought to be sown thick, under which circumstances, like other plants similarly sown, they grow tall and slender without branches. So *S. periplocifolia*, a native of the Malay Islands, which succeeds well in India, may be cultivated for the same object, especially as when cut near the earth it quickly shoots into long simple twigs which abound in flax-like fibres. A species, *S. tiliafolia*, is actually cultivated for this purpose in China. Seeds of this species were received at the Calcutta Botanic Garden under the name of King-ma from Pekin, in the neighbourhood of which the plant was said to be cultivated as a substitute for hemp and flax. At Rio Janeiro the straight shoots of *S. macrantha* are employed as rocket-sticks.

SIDERASTRÆA. [MADREPHYLLIÆA.]

SIDERITE. [QUARTZ.]

SIDERITIS (from *σίδηρος*, iron), the name of a genus of Plants belonging to the natural order *Lamiaceæ*. The species of this genus are numerous, and are inhabitants of Europe and the northern parts of Asia. Dioscorides mentions three species of *Sideritis*, which were celebrated for stanching blood and healing wounds.

The genus consists of herbs and shrubs, with small yellowish flowers arranged in whorls; a tubular 5-cleft calyx; a ringent corolla, with upper lip 2-parted, the lower lip spreading, and deeply 3-cleft; four didynamous stamens, the upper short, bearing 2-celled anthers, the lower ones longer, and bearing irregular empty anthers; an inclosed style, bifid at the top, with one of the stigmas shorter and embracing the other.

S. Romana, Roman Iron-Wort, is an annual, clothed with soft rather woolly hairs, with oblong-ovate leaves; a nearly glabrous calyx, with long mucronate teeth, the upper tooth large and ovate, the lower teeth lanceolate. This plant is a native of the Mediterranean. It was found by Dr. Sibthorp in Greece and the isles of the Archipelago; and Sir J. E. Smith believes it to be identical with the *Sideritis* of Dioscorides. It flowers from June to August, and attains a height of about six inches.

SIDEROPORA. [MADREPORÆA.]

SIDEROSCHISOLITE. [IRON.]

SIDEROXYLON (from *σίδηρος* and *ξύλον*), a genus of Plants belonging to the natural order *Sapotaceæ*. The species of this genus are natives of Africa, America, the East Indies, and Australia. They are evergreen trees, with axillary and lateral fascicles of flowers. They are remarkable for the hardness and weight of their wood, which sinks in water, and the genus has hence derived the name of Iron-Wood. The *S. incense* (Smooth Iron-Wood) is a native of the Cape of Good Hope, and has long been cultivated in the greenhouses of Europe. None of the species however are at all remarkable for beauty.

SIEBOLDIA. [AMPHIBIA.]

SIENITE. A compound of quartz, felspar, and mica, being called Granite, we find in many instances hornblende instead of mica, and the rock is then called Sienite, or Syenite (from Syene in Egypt, where such a rock is well known). If we imagine (what is of common occurrence) the diminution of the quartz, and the partial obscuration of the crystalline structure, the rock becomes greenstone. If in place of hornblende we find hypersthene or epidote, the rock may be called Hypersthene, or Epidotic Sienite, as in the Val di Fassa and Shetland. Definition fails in respect of Sienite, as it does in regard to other rocks of igneous origin.

Dr. McCulloch ('Treatise on Rocks') ranks two rocks usually called Sienite (one composed of quartz, felspar, and hornblende, and the other of quartz, felspar, hornblende, and mica) as Granite. Mount Sorrel in Leicestershire, the Malvern Hills, and Criffel in Galloway, afford abundant and characteristic sienites.

SIGARETUS. [CHISMOBRANCHIATA.]

SIGHT. [EYE.]

SIGILLARIA, the name of an extinct genus of Plants. It is known by possessing a conical stem deeply furrowed but not jointed; with oblong discoid or nearly rounded cicatrices or scars, not arranged in a distinctly spiral manner, with frequently three smaller vascular cicatrices in the centre of the larger scars. This genus includes the *Rhytidolepis*, *Alveolaria*, *Syringodendron*, *Catenaria*, and the *Lepidodendron punctatum* and *L. appendiculatum* of various authors. The largest specimens of these plants occur in the coal-formation and in beds of the mountain-limestone series.

A variety of opinions have been entertained by geological botanists as to the affinities of these plants. Artis thinks them related to *Euphorbiaceæ*; Schlotheim refers them to Palms, and Von Martius to *Cactaceæ*. Brongniart at one time thought them a family sui generis, but has since referred them, with Count Sternberg, to the family of Arborescent Ferns. Lindley and Hutton think that "the weight of evidence seems to incline in favour of both *Sigillaria* and *Stigmaria* having been Dicotyledonous Plants, and of the highest degree of organisation, such as *Cactaceæ* or *Euphorbiaceæ*, or even *Asclepiadaceæ*." To these families they seem to approach, particularly in their soft texture, in their deeply channelled stems, and especially in their scars being placed in perpendicular rows between the furrows. These writers however add that "in the total absence of all knowledge of the leaves and flowers of these ancient trees, we think it better to place the genus among other species the affinity of which is altogether doubtful."

Brongniart, in his 'Histoire des Végétaux Fossiles,' enumerates 59 species of *Sigillaria*, and Lindley and Hutton, in the 'Fossil Flora,' have figured eight species found in Great Britain. [COAL-PLANTS.]

The circumstances under which *Sigillaria* occur in the strata associated with coal are remarkable, and probably may be interpreted so as to reveal some of the conditions which were necessary for the production of the vegetable mass of coal. The first thing which strikes us is the hitherto almost universal absence of leaves, top, roots, and interior structure; we generally find large fragments, or perhaps almost the whole of the stems, furrowed, and marked by the bases of leaves, but in other respects deficient, truncate at top, and abruptly ending toward the bottom. If the plant lies in laminated shale above a bed of coal, it is generally compressed flat, having the exterior converted to coal, and the opposite sides nearly or quite in contact, to the exclusion of the central (perhaps cellular) portions. If in gritstone above a bed of coal, we find it more or less transverse to the strata, as if in attitude of growth, its top broken off, its lower part enlarged and tumid, and nearly touching the coal-bed, but apparently rootless; the interior full of saudy laminae or irregular accumulations of sand, fragments of other plants, lumps of ironstone, &c. The tree was certainly hollow when the sandstone was formed; but whether through decay of the internal cellular substance, or a general wasting and consumption of vascular and cellular structure, as suggested by Mr. Hawkshaw from observations of hollowed dicotyledonous trees in South America, is still doubtful. Whether the leafless and apparently rootless trees, which in other respects are in the attitude and have the aspect of growth, did really grow where they appear, and have lost their roots by absorption and conversion into the coal mass below, or were deposited by drifting with their roots more or less deficient, is a question of great importance, on which some of the excavations on the line of the Bolton railway, a few miles north of Manchester, have thrown much light. Here, above a thin (6-inch) coal-bed, in shaly strata much inclined, are seen several furrowed stems of trees, also inclined so as to stand at right angles to the stratification, most of them evidently rooted, by dichotomising root-branches, in the clay over the coal. The extremities of the roots are not seen; perhaps they entered the vegetable mass which is now coal, and were carbonised with the other plants. The stems are furrowed, but less regularly than is usual in *Sigillaria*, and marked less plainly than is usual with the cicatrices of leaves. The 'hark,' as it is called, is coal, showing vegetable structure; the interior is sedimentary rock. These plants are commonly imagined to be *Sigillaria*; at all events some of them are likely to prove so (those in which the roots are least obvious, and the base is tumid); others appear to us to be as much allied to *Lepidodendron*. We have seen specimens, in different coal-districts, certainly congeneric, and presenting the same intermediate characters between *Sigillaria* and *Lepidodendron*. Around the bases Mr. Bowman collected abundance of *Lepidostrobi*, which are usually referred to *Lepidodendron*.

Upon the whole, it is clear that here trees analogous to *Sigillaria* and *Lepidodendron* remain in the place, attitude, and circumstances of growth; their roots entered a sort of vegetable magma, partly the fallen accumulation of leaves and fruits of the forests; over this mass and around these stems water left its sediments horizontally; these horizontal strata have been upheaved, and the once vertical stems made to slope in accordance with the movement. These interesting trees have been carefully preserved in situ, by the care of Mr. Hawkshaw, and models have also been made of them.

SILANE. [DRACONINA.]

SILAUS, a genus of Plants belonging to the natural order *Umbelliferae*, and the tribe *Scaselineæ*. The calyx is obsolete; the petals

ovate-oblong, entire, or slightly emarginate, with an inflexed lobe, sessile, truncate, or appendaged at the base.

S. pratensis, Meadow Pepper-Saxifrage, has an angular stem, supra-decompound leaves, pinnate leaflets with the segments rather remote. It is a smooth dark-green herb. The umbels consist of several unequal rays. The flowers are yellowish or greenish white. The fruit is roundish and ovate. It is found in damp and moist places in England, Europe, and Siberia. The whole plant has an unpleasant smell when bruised, and is said in some parts of Norfolk to give a bad flavour to the milk of cows feeding on it, and it is generally found that cattle avoid it in pastures. The species of this genus are not numerous.

(Babington, *Manual of British Botany*.)

SILENACEÆ, a natural order of Plants, belonging to the syncarpous group of the Polypetalous sub-class of Exogens. This order is a part of the larger order *Caryophyllæ* [CARYOPHYLLACEÆ] of Jussieu, and was originally separated by De Candolle. It has since been adopted by Bartling and Lindley in their systematic works. It differs from the remaining portion of the order *Caryophyllaceæ*, which are now called *Alsinaceæ*, in the possession of a tubular calyx, and petals with claws.

SILENE, a genus of Plants belonging to the natural order *Caryophyllaceæ*. It is known by its having a tubular naked 5-toothed calyx; 5 bifid unguiculate petals, which are usually crowded in the throat with 5 bifid scales; 10 stamens; 3 styles; capsules 3-celled at the base, ending in 6 teeth at the apex. The species are in general herbaceous, many of them annual, very few shrubby. Their stems are leafy, jointed, branched, and frequently glutinous below each joint. The calyx and leafstalks are also frequently viscons. The leaves are opposite, simple, and entire; the petals are mostly red and white, sometimes greenish or yellowish. Some of them give off a delicious perfume, especially at night. The extent of this genus is very great, and constant additions are being made to it by the collections of travellers. The greatest proportion are inhabitants of the south of Europe and north of Africa. Don, in Miller's Dictionary, enumerates 256 species of this genus; of these we shall give a few examples of the more common and interesting forms:—

S. acaulis, Stemless Catchfly, or Moss Campion. Whole plant glabrous, caespitose; leaves linear, ciliated at the base; peduncles solitary, 1-flowered; petals crowned, slightly notched. It is a native of Europe, and is found abundantly on the Alps. It is found on nearly all the Scotch mountains, and also on Snowdon, and the highest hills of Devonshire. Chmisseo also gathered it on the islands of the western coast of North America. The flowers are of a beautiful purple colour, and it forms one of the greatest ornaments of our alpine flora. Several varieties of this plant have been recorded, varying chiefly in the form and existence of parts of the flower.

S. inflata, Bladder-Campion or Catchfly. Stems branched; flowers numerous, panicled; calyx inflated, netted; petals deeply cloven, scarcely any crown; leaves ovate-lanceolate. This is a very common plant throughout Europe, and is met with in almost every field and wayside in Great Britain. Like most plants that are widely and largely diffused, many varieties of it have been recorded. This plant has been recommended to be cultivated in the garden on account of its edible properties.

S. noctiflora, Night-Flowering Catchfly. Panicles forked; petals bifid; calyx with long teeth, oblong in fruit, with 10 connected ribs; leaves lanceolate, lower ones spatulate; whole plant clammy, pubescent. It is a native of Sweden, Germany, and Great Britain. It resembles very much the common red and white campion (*Lychnis dioica*). It is not a common plant, and is remarkable for opening its flowers at night only, and in warm weather, when they exhale a powerful and delicious scent.

S. quinquevulnerata, Five-Wounded Catchfly.

S. muscipula, Spanish or Fly-Trap Catchfly.

S. fruticosa, Shrubby Catchfly.

S. compacta, Close-Flowered Catchfly.

S. maritima, *S. Otites*, *S. Anglica*, *S. nutans*, *S. Italica*, *S. conica*, and *S. Armeria*, are all British plants.

SILEX. [SILICA.]

SILICA, a compound of oxygen, and the base known to chemists by the names of Silicium and Silicon. By some chemists Silicon is regarded as a metal, and hence the termination of its name in 'um,' while others consider it as non-metallic, but more allied to boron, and these adopt the term Silicium.

Sir H. Davy, by acting upon Silica with potassium, arrived at the conclusion that it was an oxide, containing a peculiar inflammable base, to which he gave the name of Silicium; the accuracy of this determination has since been demonstrated by Berzelius.

In Davy's experiments the Silica yielded its oxygen directly to the potassium.

The properties of Silicon are, that it has a dark-brown colour, no lustre, and is a non-conductor of electricity: it is this latter circumstance which has induced many chemists to question or deny the property of classing it with the metals. It is insoluble in water, and incombustible in air or in oxygen gas; it neither fuses nor undergoes any other change when heated in the flame of the blow-pipe. Neither the nitric, hydrochloric, sulphuric, nor hydrofluoric acid oxidizes or dissolves it; but a mixture of nitric and hydrofluoric acid dissolves it

readily, even cold. When ignited with chlorate of potash, silicon is not acted upon; but if deflagrated with nitrate of potash, the silicon combines with the oxygen of the decomposed acid, and is converted into silica, or silicic acid; and this uniting with the potash of the decomposed nitrate, silicate of potash is formed.

Oxygen and Silicon form only one compound, namely, silica, or silicic acid. It may be obtained artificially, but very inconveniently, by deflagrating silicon with nitrate of potash. Silica exists very largely in nature; it is indeed probably the most abundant of all substances whatever. [QUARTZ; OPAL; AGATE; FLINT.] Rock crystal is silica, nearly or quite pure, and flints or white sand are but slightly intermixed with other bodies. It is artificially obtained in a pure form by fusing crystal, sand, or flints, with about four times their weight of carbonate of soda or carbonate of potash; the resulting fused mass is either silicate of soda or silicate of potash; the latter is a deliquescent substance, and when it has become fluid by exposure to the air, has been long known by the name of Liqueur of Flints: when either of these silicates is treated with hydrochloric acid diluted with water, it combines with the alkali, and with any impurity which the sand or flint might contain, such as lime, alumina, or oxide of iron, and precipitates the silica as a hydrate in the state of a colourless gelatinous mass. It possesses the following properties:—

When recently precipitated, and while it retains the state of moist hydrate, it is to a certain extent soluble in water, and still more so in acids, and also in solution of potash or soda. When it has been dried, it is an opaque white powder, inodorous, insipid, and gritty, and then with more difficulty soluble in the alkaline solutions, and scarcely at all so in any other acid than the hydrofluoric. It is infusible by the heat of ordinary furnaces, but by the oxy-hydrogen blow-pipe it is more readily fused than lime or magnesia. Its specific gravity is about 2.7. It consists of 3 parts of oxygen, 24; and 1 of silicon, 20; so that the larger proportion, by weight, of this substance is oxygen.

Although it is tasteless, and does not change vegetable blue colours red, and is insoluble in water, except under the peculiar circumstances mentioned, it is nevertheless by many chemists considered as and classed with acids, under the name of Silicic Acid; and the various compounds which it makes with alkalies and earths, to form glass, are considered as salts. Thus with potash it forms silicate of potash; with soda, silicate of soda; and with oxide of lead, silicate of lead; and these are all constituents of glass. China and porcelain, on the other hand, may be regarded as silicates of alumina and magnesia, and mortar is probably a silicate of lime.

It is from a knowledge of the chemical properties of silicic acid that the mineralogist and geologist are enabled to account for its presence in so many forms in nature. It is in fact one of the most generally diffused substances in nature. The circumstances of its deposit in the form of Agates, Chert, Flint, and other minerals have produced much discussion. In all these cases it is maintained by Mr. Bowerbank, that the silica has been deposited upon some kind of siliceous matter at the bottom of the sea. In the case of flints the spicules of Sponges and the skeletons of *Diatomaceæ* have been found in the midst of the silica of which they are composed. It is argued that it would be quite impossible that these bodies should be found diffused through the substances of the flint if the silica had been deposited in a mould already formed, and that the only explanation of this circumstance is to be found in the supposition that the spicules exist in the meshes of the sponge, and that the other creatures found in the midst of the sponge have been caught in its meshes. This explanation also applies to the occurrence of the casts of molluscous shells, fish-teeth, and other organic remains found in the interior of flints. *Echini* and *Mollusca* are often found converted into flint with no siliceous matter surrounding them. These Mr. Bowerbank maintains were first taken possession of by sponges, and that the silica has been deposited in them in virtue of this condition. It is only right to say here, that Mr. Bowerbank has in his collection specimens which support his theory in every respect. He has several recent shells which are entirely filled with sponges. If this is really the case with flints it seems equally applicable to the explanation of the formation of agates and other forms of siliceous stones. We ought to add here that with increased attention to the examination of agates and other stones, there is no reason to believe that any of them possess in their interior the remains of Mosses, *Conferæ*, or other plants, as was at one time supposed. [AGATE.]

Silicic acid combines with the earths and metals and forms a large series of the most common as well as the rarest minerals known. With lime it forms *Tabular Spar*. With boracic acid and lime, *Dalholite*. With magnesia and water it forms *Talc*, *Serpentine*, *Nephrite*, *Schiller Spar*, and a large number of less-known minerals. Without water, silica and magnesia form *Pyroxene*, *Hornblende*, *Chrysotile*, *Chondrodite*, and many others. Silica, alumina, and water form *Hyalosilite*, *Pinite*, *Chlorophyllite*, and the *Zeolite* family. The *Zeolites* are *Heulandite*, *Apophyllite*, *Laumontite*, *Natrolite*, *Thomsonite*, *Harmotome*, *Analcime*, and *Chabasite*. Silica, lime, and alumina form *Prehnite*. The anhydrous silicates of alumina are *Sillimanite*, *Kyanite*, *Andalusite*, *Staurolite*, *Leucite*, and the *Felspar* family, which includes *Albite*, *Labradorite*, *Nepheline*, and many minor forms of these.

Scapolite is a silicate of alumina and lime. *Spodumene* and *Petalite*

are silicates of alumina and lithia. *Epidote* and *Idocrase* are silicates of alumina, lime, and iron. *Garnet* is a silicate of alumina, iron, and manganese.

Tourmaline is a compound of silica, alumina, lime, iron, soda, and boric acid. *Axinite* is the same, with magnesia, instead of lime. *Ilolite* is a silicate of alumina, magnesia, iron, and manganese.

Mica consists of silica, alumina, potash, iron, fluoric-acid, and water. The *Topaz* is a silicate and fluoride of alumina. *Lapis Lazuli* is a silicate and sulphate of alumina, soda, lime, and iron. *Sodalite* is a silicate of alumina, with chloride of sodium.

The *Beryl*, *Euclase*, and *Chrysoberyl*, consist of silica, alumina, and glucina. The most important of these minerals are described under their proper names in this work.

SILICULA, a kind of Fruit. [FRUIT.]

SILICULA, a genus of *Mollusca*. [PYLORIDIA.]

SILICUA, a kind of Fruit. It is characterised by having one or two cells, with many seeds, dehiscing by two valves, which separate from a central portion called the Replum. It is linear in form, and is always superior to the calyx and corolla. The seeds are attached to two placeute, which adhere to the replum, and are opposite to the lobes of the stigma. This position of the seeds, being abnormal, can only be explained in two ways: either this fruit is in reality composed of four carpels, two of which have, during the growth of the pistil, become abortive; or the stigmas must be looked upon as the fusion of two halves, one from each side. The dissement of the fruit in this case is most probably a spurious one formed by the projecting placeutæ. It is sometimes found incomplete, from the edges of the placeutæ not meeting; it is then said to be 'fenestrate.' This kind of seed-vessel is possessed by a large number of plants belonging to the order *Crucifera*, and examples may be seen in the Stock or Wall-Flower (*Cheiranthus*), in the Ladies' Smock (*Cardamine*), and in the Cabbage, Turnip, and Mustard. The Linnæan class *Tetradynamia* is divided into two orders, according to the form of its fruit: those plants of the class having a silique are comprised under the order *Siliquosa*; those having a silicle, under the order *Siliculosa*.

SILK-COTTON. [BOMBAX.]

SILK-WORM. [BOMBYCIDÆ.]

SILLIMANITE, a Mineral—a crystallised Silicate of Alumina. It occurs in rhombic prisms imbedded in quartz. Cleavage parallel to the long diagonal. Its colour is dark brownish-gray or clove-brown. Fracture uneven, splintery. Specific gravity 3·41. Its lustre is vitreous, nearly adamantine on the face of cleavage. Nearly opaque. Hardness 8·0 to 8·5. It is brittle, and easily reduced to powder.

It is met with at Saybrook, Connecticut, North America. It was at one time considered to be a variety of *Anthophyllite*, but it is much harder than this mineral, and contains more alumina and less silica and oxide of iron. It more nearly resembles *Sienite*, both in form and composition.

It yielded by the analysis of Bowen—

Silica	42·67
Alumina	54·11
Oxide of Iron	2·00
Water	0·51
	—99·29

SILLOCK. [MERLANGUS.]

SILPHIUM (Σίλφιον). Ancient authors mention this plant and its juice. Two kinds of this substance are described: one, from Cyrene, was probably yielded by *Thapsia Silphium* [LASER]; and the other was most likely *asafoetida*, which has been employed medicinally by Asiatics from very early times, though it has been known by this name in comparatively modern times.

Silphium was however remarkable for other properties, and hence has attracted the attention of modern travellers who have recently visited the countries where the *Silphium* is described as growing by the ancients. The army of Alexander, in crossing the mountain range which Arrian calls Caucasus (iii. 28, 10), and which is the same range that he afterwards mentions under the name of Paropamisus (v. 5, 3), met with the *Silphium*. Arrian says, on the authority of Aristobolus, "In this part of the Caucasus nothing grows except pines and *Silphium*, but this country was populous and fed many sheep and cattle, for the sheep are very fond of the *Silphium*. If a sheep should perceive the *Silphium* from a distance, it runs to it, and feeds on the flower, and digs up the root and eats that also. For this reason, in Cyrene, they drive the sheep as far as possible from the spots where the *Silphium* grows, and some even fence in such places to prevent the sheep from entering them if they should approach; for the *Silphium* is worth a good deal to the Cyrenæans." Burnes, in crossing the Hindu Koosh, and seeing both the men and cattle eating the young parts of the *asafoetida* plant, supposed that it must be the *Silphium* of Arrian. But as this author describes the country where the *Silphium* grows as abounding in cattle, Dr. Royle had concluded that the *Prangos* of Mr. Moorcroft was the *Silphium* alluded to, and which is much fed on by sheep and cattle in the present day in Tibet. Mr. Vigne, when travelling in these regions, came to the same conclusion. It is probable therefore that both plants, being umbelliferous, and employed for the same purposes in nearly the same regions, may have contributed to form the accounts which are so brief in ancient authors. [LASER; PRANGOS.]

NAT. HIST. DIV. VOL. IV.

SILURIAN SYSTEM. A considerable group of the Fossiliferous Primary Strata, occurring in remarkable perfection in Wales, especially in the eastern and some of the southern districts, and in some of the adjoining English counties, is thus named by Sir Roderick Impey Murchison.

When Sir Roderick commenced his researches in Shropshire and Wales (1831), the principal knowledge we possessed of the succession of the older stratified rocks of Great Britain, then commonly called Grauwacke and Transition Formations, was based on the still incompletely published labours of Sedgwick in Wales and the district of the English lakes; and so little was known of their fossil contents, that it is believed that the first definite notice of this kind was contained in Professor Phillips's description of a group of slate-rocks in the vicinity of Kirby Lonsdale. ('Geol. Trans.,' 1827.) Now, in consequence principally of the development given to this subject by the appearance of the Silurian researches of Sir Roderick Murchison, and other works to which it has led, we are able to trace in one consecutive history nearly the whole series of mineral depositions and organic combinations of which the ocean was anciently the theatre, from the period of the Mica Schists to the termination of the Carboniferous era.

In this survey, the Silurian Strata form a very conspicuous and interesting portion, and in the district from which the type was originally drawn they appear within distinct and definite limits, which seem to insulate them from the older and new rocks, and to justify their claim to the rank of a peculiar system; but in other districts phenomena appear which show that the order of physical changes and organic combinations which characterise the Silurian System, was in operation both before and after the period included in the ages of the four Silurian groups of Llandeilo, Caradoc, Wenlock, and Ludlow; while in other districts these characteristic assemblages do not all clearly appear; and thus we are naturally conducted to a more comprehensive view of the whole of the ancient (Palæozoic) formations.

Whatever be the true theory of the origin of the Granitoid Strata of gneiss and mica schist (with their many and various quartzose, chloritic, and calcareous accompaniments), it is at least certain, as a general rule, that rocks of this general type are prevalent among the very deepest and oldest deposits from water which retain proof of their watery aggregation, and that they are in this position devoid of the traces of ancient life.

Equally certain is the character of the great series of Neptunian rocks which lies upon the mica schist; it is a vast and various mass of strata (principally argillaceous, locally arenaceous or conglomeritic, rarely yielding limestone), in which, though unequally, and in degrees varying with locality, slaty cleavage tends to be developed. Organic life has left traces in this series of muddy sediments both of vegetable and animal origin; in the lower and older parts very sparingly, in the upper parts abundantly. If, with Professor Sedgwick and Sir Roderick Murchison, we take the series of these rocks as they appear in Wales and Cumberland, namely—

Silurian, or Upper group;
Cambrian, or Middle group;
Cumbrian, or Lower group;

we shall find in the mineral characters of these groups, in the countries named, some diagnostic marks of importance, but they vanish or become equivocal in other regions. In like manner, the organic contents seem, in the countries named, to be definitely arranged in zones, so as to mark successive periods there. No organic remains are known in the Cumbrian rocks; they are rare, and confined to a few layers, in the Cambrian deposits; and are very plentiful and general in the Silurian group. The districts in which these peculiarities occur are probably more wide and scattered farther asunder than those in which the original types of mineral structure prevail; but yet it is evident that they are limited in respect of geographical area, and variable in regard to the distinctness and completeness of the terms, even in districts not far removed from the centre of investigation. Let any one who may desire proof of this compare the argillaceous series of Ayrshire, Westmoreland, Pembrokeshire, Tyrone, or Waterford, in which Silurian fossils occur, with the full and varied series of Shropshire, the Berwyn, and Snowdon.

Under these circumstances of difficulty in regard to the right general view of the ancient fossiliferous strata, we must consider the series of Silurian rocks and fossils not as the type of this enormous sequence of mineral and organic phenomena, but as one, and perhaps the richest, of all the local physical combinations of that ancient period, and employ it as a general term of comparison for reducing to order and place many detached and difficult districts in which the strata have local, peculiar, and perhaps exceptional aspects.

Sir Roderick Murchison arranges the Silurian Strata in groups, as follows, in a descending order:—

	Formations.	Divisions.	Thickness in feet.
Upper Silurians	Ludlow rocks	Upper Ludlow rocks	1500
		Aymestry limestone	
	Lower Ludlow rocks	Lower Ludlow rocks	
Lower Silurians	Wenlock rocks	Wenlock limestone	1000
		Wenlock shale	
	Caradoc rocks	Caradoc rocks	very variable.
	Llandeilo rocks	Llandeilo rocks	

Pyrogeous rocks are associated with the Silurian Strata in many

situations, as the Caradoc Hills, where compact felspar predominates; the Wrekin and Lilleshall Hill, characterised by sienitic rocks; Corndon, full of greenstone. Alterations of stratified rocks by the contact of igneous rocks are common in the Caradoc, Stiperstones, &c. The trap rocks near Welshpool are in places columnar; the Breiddyn Hills are mostly greenstone, and yield elongated dykes in a north-east direction, which traverse the new red-sandstone. Mineral veins (yielding lead-ore) are plentiful in Lower Silurian rocks, in the Shelve district, adjacent to the trap rocks of Corndon and the altered sandstones of the Stiperstones. "In a plan of Mr. More's of Linley Hall, the chief proprietor of this district, upwards of 24 are laid down in the district of Shelve alone, excluding the tracts around the Bog and Penally; so that, comprehending the principal portion of the mining-ground, we may say that it contains upwards of 30 metalliferous veins which have been profitably worked." (Murchison, 'Silurian System,' p. 282.)

Volcanic grits, composed of materials derived from igneous action, and subsequently arranged in water, are mentioned by Sir Roderick Murchison rather frequently. In the Shelve district they are traversed by lead veins; in the Caradoc Hills they abound, and were noticed as 'allied to greenstone' in the Wrekin by Mr. A. Aikin. They contain organic remains in several places, as near the Corndon Hills.

On reviewing the series of strata comprised in the Silurian System in the vicinity of Ludlow, Usk, Llandello, or Denbighshire, we see them to form in reality one closely-associated sequence of oceanic deposits—apparently accumulated with little local disturbance and very slight admixture of organic exuvium from the land. Volcanic eruptions appear to have rather varied than greatly disturbed this system of operations, though it is evident they contributed no small part of the granular materials of the principally sedimentary strata. The formation of limestone is local: where coral prevailed, we find the Aymestry and Wenlock limestones, and even the calcareous parts of the Llandello rocks, to be in a great degree filled with coral. The Brachiopod shell *Pentamerus* fills some whole beds of limestone (near Aymestry), and where it is deficient the limestone also fails, as in the district of Usk. In their course from Shropshire northward to Denbighshire, Mr. Bowman ('Reports of the British Association for 1840-41') has found the general type of the Silurian rocks to vary,

The following analysis from Professor Phillips's 'Manual of Geology,' gives a more extended view of these rocks:—

Collective Titles.	Formations.	Name.	Prevalent Mineral Typc.		
LOWER PALÆOZOIC.	SILURIAN.	Upper.	Fossils abundant.	Tilestone	Arenaceous.
				Upper Ludlow	Argillo-Arenaceous.

		Llanberris Slates and Grits	Argillo-Arenaceous.		
		Longmynd Slates	Argillo-Arenaceous.		

On considering the distribution of organic remains in the successive stages of the Silurian rocks, it is evident that the greatest variety of species occurs in the lower part of the Upper and towards the upper part of the Lower Silurian rocks. In other words, the conditions favourable to organic life in the sea were in the earliest period considerable; they arrived at a maximum in the middle part of the period in the Caradoc sandstone, the Wenlock shale, and the Wenlock limestone, and still continued considerable till the Silurian depositions ceased, and were replaced by old red-sandstone nearly devoid of organic remains. *Polyparia*, *Crinoidea*, and *Crustacea* are most numerous in the principal calcareous rock, Wenlock limestone; *Brachiopoda* are most plentiful in Caradoc sandstone; *Cephalopoda* in the Wenlock shale; fishes in the upper Ludlow rock.

The following list of fossils is given by Professor Phillips:—

AMORPHOZOA.	
Species.	Species.
<i>Acanthospongia</i> (!) 1	<i>Chemidium</i> 1
<i>Choria</i> 2	
FORAMINIFERA.	
<i>Eudothyra</i> 1	

and the line of distinction between it and the slaty strata below to be extremely obscure; and similar observations are recorded by Sir Roderick Murchison in the account which he gives of these rocks in Caernarthenshire and Pembrokeshire.

Mineral character alone will scarcely suffice, anywhere, for any but an arbitrary (and therefore unsatisfactory) boundary-line between the Silurian and Cambrian deposits. It is extremely probable, perhaps we may say it is already proved, that no distinction of higher value can be found on comparing the organic remains of these groups. In Snowdon (supposed to be very low in the Cambrian series of rocks) are shells and corals, which are perhaps the same, but certainly are congeneric with and very similar to Silurian fossils; and there is really as great (if not greater) difference between the Llandello and Wenlock rocks, in regard to fossils, than between the Silurian and Cambrian strata.

If we turn to other districts where Silurian fossils occur plentifully (North America, Ireland, Norway), the result appears the same. There is apparently only one great series of organic combinations distinguishable among the fossiliferous strata anterior to the old red-sandstone era, and it was with a perception of this important truth that Sir Roderick Murchison once proposed for the Silurian strata the title of Protozoic. If instead of this we employ Palæozoic (as suggested by Sedgwick), we shall rank all the fossiliferous strata of the Cambrian, Cambrian, and Silurian groups as Lower Palæozoic Strata.

The lower arbitrary boundary of the Silurian Strata being thus softened or erased, we may regard its upper surface as only locally more definite. Certainly in all the region around Wales the separation of the Silurian and old red-sandstone deposits is somewhat sudden: the colour changes from gray to red; the dull mudstones become micaceous sandstones; the richly fossiliferous Upper Ludlow loses its character in unproductive red marls and grits. What few fossils do occur in these overlaid strata (except near the very bottom) are of quite other types of organisation. But these are local truths, depending mainly on the introduction of new sediments poisonous to marine invertebral life; and as these sediments are very local, we may find in other countries groups of strata newer than the Silurian, older than the Carboniferous, with fossils intermediate in character and combination to both.

Of the above list, 496 were found in the Upper Silurian; 485 in the Lower Silurian; and 19 in the Cambrian.

SILURIDÆ, a family of Fishes belonging to the order *Malacopterygii*, placed by Cuvier, in his 'Règne Animal,' between the *Esocida*, or Pike tribe, and the *Salmonida*, or family of the Salmon; but in the 'Histoire Naturelle des Poissons,' the present group commences the *Malacopterygii*. The family *Siluridæ* constitutes a very extensive section of fishes, the species of which are for the most part confined to the fresh waters of warm climates. No group perhaps presents greater diversity of form than the *Siluridæ*, and their habits are equally interesting. Their most obvious external characters are, the want of true scales. The skin is generally naked, but in parts protected by large bony plates; the foremost ray of the dorsal and pectoral fins almost always consists of a strong bony ray, often serrated either in front or behind, or on both sides. These fishes moreover frequently are furnished with a small adipose fin on the hinder part of the back, as in the *Salmonidæ*. The mouth is almost always provided with barbules.

The genus *Silurus*, as now restricted, is distinguished by the dorsal fin being very small, without any distinct spine, and situated on the fore part of the back; the anal fin is of great length, extending along the whole belly of the fish, and sometimes joining the tail-fin; the maxillaries and intermaxillaries are furnished with small thick-set curved teeth, and there is a band of similar teeth on the vomer.

The species of this genus are confined to the Old World; the only known European species is the *S. glanis* (Linn.), a fish of very large size, which is found in the lakes of Switzerland, in the Danube, the Elbe, and all the rivers of Hungary. In Prussia and Sweden it is also found.

The *S. glanis* is introduced in several works on the fishes of this country. It has, however, says Mr. Yarrell, been suspected that the so-called *Silurus*, supposed to have been found formerly in some of the Scottish rivers, might have been the *Burbot*.

Cuvier states that this fish is sometimes upwards of six feet in length, and is said to weigh 300 lbs. (French). The body is elongated, and has the hinder part compressed, but towards the head its width gradually increases, and the head itself is depressed and large; its colour is dark green above, of a pale green below the lateral line,

and yellowish on the belly, and the whole body is covered with dark spots; six barbules surround the mouth, and two of these, which have their origin (one on each side) just above the angle of the mouth, are very long.

Mr. Yarrell observes, "The *Silurus* is represented as sluggish in its habits, and a slow swimmer, taking its prey by lying in wait for it, in a manner somewhat similar to the Angler, *Lophius*; hiding itself in holes or soft mud, and apparently depending upon the accidental approach of fishes or other animals, of which its long and numerous barbules may be at the same time the source of attraction to the victims, and the means of warning to the devourer. From its formidable size, it can have but few enemies in the fresh water; and from them, its dark colour, in addition to its habit of secreting itself either in holes or soft mud, would be a sufficient security. In spring, the male and female may be seen together, about the middle of the day, near the banks or edges of the water, but soon return to their usual retreats. The ova, when deposited, are green; and the young are excluded between the sixteenth and nineteenth days.

"The flesh of the *Silurus* is white, fat, and agreeable to many persons as food, particularly the part of the fish near the tail; but on account of its being luscious, soft, and difficult to digest, it is not recommended to those who have weak stomachs. In the northern countries of Europe the flesh is preserved by drying, and the fat is used as lard."

In the 'Histoire Naturelle des Poissons,' it is stated that the present fish is so voracious, that it has been known, in several instances, to devour children; and in one instance the body of a woman was found in one of these fishes.

Several examples of the restricted genus *Silurus* are found in Asia.

Cuvier separates from the typical *Siluri*, as a genus, the *Silurus mystus* of Linnaeus, and some others, on account of the compressed form of the body, and the dorsal fin having a strong bony spine in front, which is denticulated on the hinder margin. The body is deepest near the middle, but tapers somewhat suddenly towards the extremities. The head is small and depressed, and the eyes are placed low down.

The species upon which Cuvier founds this genus—to which he applies the name of *Schilbe*—are found in the Nile, but there are others described in this author's great work on fishes, one of which is found in the Senegal and another in India.

Cetopsis.—This genus is founded by Agassiz on certain species found in Brazil, which in their affinities approach the genus *Silurus*, but are distinguished by the extremely small size of their eyes.

Bugrus, Cuvier.—The species of this genus are distinguished from those of the genus *Silurus*, as restricted, by their possessing an adipose fin on the hinder part of the back. The body is naked—that is, unprovided with bony plates—and the mouth is provided with barbules, the number of which, varying in different species, has been selected for the minor divisions of the group. Numerous species are found in the Indian and African rivers.

Pimelodus, Lacép.—Differs from *Bugrus* in having no teeth on the vomer; the palatines however are often provided with teeth. The species are very numerous, and are found both in the Old and New World.

Præclocephalus, Agassiz.—This genus contains but one species, an inhabitant of the Brazils; its generic distinction consists in its possessing some incomplete osseous rays encaased in the upper margin of the adipose fin.

Platydoma, Agassiz.—It is composed of several South American species which have the muzzle depressed, and are remarkable for the great number of their branchiostegous rays, which amount in some to fifteen in number.

Galeichthys, Cuv. and Val.—This genus is nearly allied to *Bugrus*, but distinguished by the head being round and unprotected by any distinct bony plate; the branchiostegous rays are 6 in number. One species is found at the Cape of Good Hope, a second is said to be found both in North America and at Rio Janeiro; several species occur in Brazil, and the Ganges also furnishes a species of the present genus.

Silundia, Cuv. and Val.—This genus is founded upon a fish from the Ganges, which has the head small and smooth, a very small adipose fin, and a long anal fin:

Arius, Cuv. and Val.—Contains many species allied to the *Bagri*, but distinguished by their palatine teeth forming two distinct and widely-separated masses. They are found in the tropical portions of both continents, and also in North America.

Auchenipterus, Cuv. and Val.—Distinguished by the small size of the head, the very minute size of the teeth, and there being 5 branchiostegous rays. All the known species are from the tropical portions of South America.

Trachelyopterus.—Founded by Messrs. Cuvier and Valenciennes, upon a small Silurid from Cayenne, in which there is no adipose fin. The teeth are fine, like the pile of velvet, and the palate is destitute of teeth; the barbules are 6 in number.

Hypophthalmus (Spix), Cuv. and Val., is composed of but few species, and these are from the tropical portions of South America.

Ageneiosus (Lacépède), Cuv. and Val.—Characters the same as in *Pimelodus*, excepting that there are no barbules, properly so called. All the species are from South America.

Synodontis, Cuv., is composed of species found in the Nile and Senegal, which have an adipose fin; the muzzle narrow, and terminated by an ethmoid, which supports two small intermaxillary bones armed with bristle-like teeth; the lower jaw composed of two short and slender rami, bearing in front a mass of teeth, which are in the form of very slender laminae and closely packed. Each of these teeth is attached to the jaw by a flexible and very slender stalk.

Doras, Lacépède.—The species of this genus are distinguished by the lateral line being armed with bony plates, which are carinated and terminate in a spine. They are the most powerfully armed of all the *Siluridæ*; thus the Spanish colonists in South America have given to them the name of Mata-Cañan (or Crocodile-Killer), because it often happens that when they are swallowed by these large reptiles, the oesophagus and pharynx of those animals are so lacerated by the spines of the *Silurus* as to cause death. Strabo also (p. 324, Casaub.) attributes similar powers to certain fishes of the Nile, which he called *Noipos*, and which are supposed by some naturalists to belong to the modern genus *Synodontis*.

Doras is divided into two sections on account of the structure of the mouth. In some it is situated at the end of a depressed muzzle, and is provided with two broad bands of delicate teeth, both in the upper and lower jaws. In others the opening of the mouth is situated on the under side of a conical muzzle, and the opening is of a circular form—here the teeth are either wanting or are hardly visible; the maxillary barbules are sometimes furnished with small lateral branches. To the first of these sections belongs the *Silurus costatus* of Linnaeus, a species found in the rivers of Guiana.

A species of *Doras*, described by Dr. Hancock, in the fourth volume of the 'Zoological Journal,' p. 241, under the name of *D. costatus*, is a native of Demerara, where it is called the Flat-Head Hassar. It possesses the singular property of deserting the water and travelling over land. Dr. Hancock describes a second species, called the Round-Headed Hassar.

Both the species make nests, in which they lay their eggs in a flattened cluster, and cover them over most carefully. Their care does not end here. They remain by the side of the nest till the spawn is hatched, with as much solicitude as a hen guards her eggs; both the male and female hassar, for they are monogamous, steadily watching the spawn, and courageously attacking any assailant. Hence the negroes frequently take them by putting their hands into the water close to the nest, on agitating which the male hassar springs furiously at them, and is thus captured.

"The Round-Head forms its nest of grass; the Flat-Head of leaves. Both at certain seasons burrow in the bank; they lay their eggs only in wet weather. I have been surprised to observe the sudden appearance of numerous nests in a morning after rain occurs, the spot being indicated by a bunch of froth, which appears on the surface of the water over the nest; below this are the eggs, placed on a bunch of fallen leaves or grass, if it be the littoral species, which they cut and collect together. By what means this is effected seems rather mysterious, as the species are destitute of cutting teeth. It may possibly be by the use of their serrated arms, which form the first ray of the pectoral fins."

Callichthys, Linn., belongs to this family. [CALICHTHYS.]

Arges, Cuv. and Val.—The principal characters of this genus are—teeth bifid at the extremity, and with the points curved inwards; palate destitute of teeth; opening of the mouth large; maxillary barbules two in number; anterior dorsal fin small, and with the front ray feeble; adipose fin long; the other fins with the outer rays prolonged into a filament.

The species which forms the type of this genus (*A. sabalo*, Cuv. and Val.) is a small fish about 8 inches in length, which was brought by Mr. Pentland from Upper Peru, being found in the neighbourhood of the mission of Santa Anna, at a height of from 4500 to 4800 French metres above the level of the sea. The specimen was given to M. Valenciennes, who prized it much, since it threw a light on the affinities of a fish described by Humboldt under the name *Pimelodus Cyclopus*, relating to which that author has given such an interesting account. The *Pimelodus Cyclopus*, which M. Valenciennes thinks most probably belongs to the present genus, is about 4 inches in length, and is found in lakes at the height of 3500 metres above the level of the sea. But the most remarkable circumstance relating to these fishes is that they are frequently ejected in the eruptions from the volcanoes of the kingdom of Quito, and in such quantities that the fetid odour arising from their putrefaction was perceived at a great distance, and the putrid fevers which prevailed in those districts were attributed to the miasmata they produce. These fishes sometimes issued from the crater of the volcano, and sometimes from lateral clefts, but constantly at an elevation of from 5000 to 5200 metres above the level of the sea. In a few hours millions are seen to descend from Cotopaxi, with great masses of cold and fresh water.

Brontes, Cuv. and Val., is founded upon a fish possessing all the characters of the preceding genus (and which, it appears, like the *Pimelodus*, is thrown out from the volcanoes of Cotopaxi), but which differs in having no adipose fin.

Astroblepus, Cuv. and Val., consists of but one species, *A. Grisevii*, Humboldt. This fish possesses all the characters of the genus *Brontes*, having, like it, the head depressed, the eyes directed upwards, a single

dorsal fin, the external rays of the fins prolonged into a filament, and four branchiostegous rays, but it possesses no ventral fins. This fish is found at Rio de Palace, near Papayana, where it is known by the name of Pescado Negro: it attains about 15 inches in length.

Heterobranchus, Geoff.—The head is furnished with a rough bony shield, which is flat and broader than in the other Silurians, on account of the lateral laminae furnished by the frontals and parietals, which cover the orbital and temporal bones. The barbules are eight in number. The species inhabit the rivers of Africa, and some of those of Asia.

In some species the long dorsal fin is supported throughout by rays; these constitute the sub-genus *Clarias*, Val.; and in others there is a dorsal fin supported by rays, and a second behind this, which is adipose. To these the term *Heterobranchus* is restricted in the 'Histoire Naturelle des Poissons.'

Saccobranchus, Cuv. and Val., is founded upon the *Silurus Singio* of Hamilton's 'Fishes of the Ganges,' which possesses some interesting peculiarities in its internal organisation, pointed out by Mr. Wyllie in the 'Proceedings of the Zoological Society' for May, 1840.

Plotosus, Lacépède, is distinguished by the elongated form of the body and the possession of two dorsal fins, the hindermost being supported by rays as well as the other. The species inhabit India.

Apreto, Linn., presents very singular characters, particularly in the flattening of the head and in the dilatation of the anterior portion of the trunk, which chiefly arises from that of the bones of the shoulder; in the proportionate length of the tail; in the small size of the eyes, which are placed in the upper surface of the head. The species are found in the tropical parts of South America.

Chaca, Cuv. and Val., which is the next in succession in the 'Histoire des Poissons,' is founded upon the *Platyctacus Chaca* of Buchanan Hamilton. It inhabits the rivers of India.

Sisor is also founded upon a single species described under the name *S. rhabdophorus* by the author just mentioned, in his 'Fishes of the Ganges.'

Loricaria, Linn., is distinguished by the head and body being covered throughout by large angular bony plates.

This genus is subdivided into two sub-genera. In the one (*Hypostomus*, Lacép.) there are two dorsal fins; the hinder one is small, and provided with but one ray. In the second, to which Lacépède restricts the term *Loricaria*, there is but one dorsal fin. The species of both sub-genera are found in South America.

SILVER, a metal which has been well known and highly valued from the remotest period—circumstances which are readily explained by the facts of its occurring frequently native, and possessing great lustre and fitness for immediate use without being subjected to any metallurgical process.

Native Silver occurs crystallised, arborescent, or dendritic, capillary, reticulated, granular, and massive. The primary form of the crystal is a cube. It has no cleavage. Fracture hackly. Colour white, but externally often blackish, owing probably to the presence of a little sulphur. Hardness 2.5 to 3. Lustre metallic. Colour pure white, except when tarnished. Streak shining. Opaque. Specific gravity 10.47. Malleable, but commonly less so than pure silver, probably owing to an admixture of other metals. Soluble in nitric acid, and the solution colourless when pure, but blue if copper be present; and if antimony, a white substance; and if gold, a black one remains undissolved. Fuses into malleable globules before the blow-pipe.

Native Silver is met with in most parts of the world; in the British Isles, Germany, Hungary, in the north of Europe, but especially, and in largest quantity, in Mexico and South America. Silver occurs in mixture or combination with other metals.

Antimonial Silver. *Sibiuret of Silver*.—This occurs in crystals, in grains, and massive. The primary form of the crystal is a right rhombic prism. Cleavage parallel to the terminal plane and short diagonal of the prism. Fracture uneven. Colour silver white, or, when tarnished, yellowish-white. Streak silver white. Lustre metallic. Opaque. Slightly malleable. Easily frangible. Hardness 3.5. Specific gravity 9.44 to 9.8. Before the blow-pipe on charcoal it readily melts, with the formation of white antimonial vapour, into a grayish globule, which is not malleable, but eventually pure silver is obtained. It is not totally soluble in nitric acid, oxide of antimony remaining undissolved.

The Massive Varieties are amorphous, and have a granular or foliated structure.

Antimonial Silver is found in clay-slate at Andreasberg in the Hartz, in Baden, near Guadalcanal in Spain, at Salzburg, and at Allemont in France.

The Andreasberg mineral (1), analysed by Vauquelin, and the Baden (2), by Klaproth, gave the annexed results:—

	(1)	(2)
Silver	73	84.76
Antimony	22	16.24
	—100	—100

Telluric Silver occurs in coarse-grained masses. Colour gray. Lustre metallic. Soft. Somewhat malleable. Specific gravity about 8.5. It is dissolved by nitric acid, and when heated, and before the blow-pipe on charcoal, gives a fused blackish mass, containing specks of metallic silver.

It is found at the silver-mines of Savdinski, in the Altai Mountains, Siberia.

Its analysis by Rose gives—

Silver	62.42
Tellurium	36.96
Iron	00.24
	—99.62

Native Amalgam is a compound of silver and mercury. [MERCURY.] *Auriferous Native Silver* occurs crystallised in cubes, capillary, and disseminated. Colour yellowish-white. Specific gravity 14.0 to 17.0. Different varieties give the annexed results—

	Fordyce.	Klaproth.	Boussingault.			
Silver	72	34	15.5	17.6	26	35.07
Gold	28	64	84.5	82.4	74	64.93
	100	98	100	100	100	100

Arsenical Antimonial Silver, or rather *Arsenio-Ferruginous Antimonial Silver*.—This substance occurs mammillated or in small globular and reniform masses, and sometimes investing other substances. When untarnished it is nearly silver-white, but is commonly tarnished yellowish or blackish; its lustre is metallic. It is harder than antimonial silver, but is sectile and brittle. Specific gravity 9.4.

Before the blow-pipe antimony and arsenic are volatilised with the alliaceous smell, and a globule of impure silver remains. Its localities are nearly the same as those of antimonial silver. Klaproth obtained from a specimen from Andreasberg—

Silver	12.75
Antimony	4
Iron	44.25
Arsenic	35
	—96

The native compounds of silver next to be described are those in which it occurs in combination with the non-metallic elements. It is not found simply combined with oxygen, nor at all with azote, hydrogen, or fluorine.

Chloride of Silver; *Horn Silver*; *Muriate of Silver*; *Laxmannite*.—This ore occurs crystallised and massive. Primary form of the crystal a cube. No cleavage. Fracture uneven. Hardness 1.0 to 1.5. Yields to the pressure of the nail. Streak shining. Specific gravity 4.75 to 5.55. Translucent. Opaque. Lustre resinous. Colour gray, yellowish, greenish, and blue of various shades. Malleable and sectile. Fusible in the flame of a candle. Heated with potash by the blow-pipe, yields a globule of metallic silver. Insoluble in nitric acid, but dissolved by ammonia. When rubbed with a piece of moistened zinc, the surface becomes covered with metallic silver.

This ore occurs in various parts of Europe and America, along with others of the same metal. The largest masses, which are of a greenish colour, are brought from Mexico and Peru. It is found in veins, chiefly in primitive rocks.

Two specimens from Peru (1) and from Saxony (2), analysed by Klaproth, gave—

	(1)	(2)
Chlorine	24	21.50
Silver	76	67.75
Oxide of Iron	—	6.00
Alumina	—	1.75
Sulphuric Acid	—	0.25
	—100	—97.25

Buttermilk Silver; *Earthy Corneous Silver*.—This is regarded as a variety of the foregoing. It is described as being of a brownish colour, with occasionally a tinge of green or blue. It is opaque, dull, with an earthy fracture, and is soft, sectile, and heavy. It occurs massive, and also investing other substances. It occurs only at Andreasberg, in the Harz.

According to Klaproth, it is composed of—

Chlorine	8.28
Silver	24.64
Alumina	67.08
	—100

Iodide of Silver; *Herrerite*.—Occurs massive in thin plates, which are silver- or grayish-white, and which become bluish by exposure to the air. Transparent. Translucent. Lustre resinous to adamantine; in thin laminae flexible and malleable. Melts on charcoal before the blow-pipe, vapour of iodine being evolved, and globules of silver remaining. It is found at Abarradon near Mazapil, in the state of Zacatecas, Mexico, in serpentine.

Sulphuret of Silver; *Vitreous Silver*; *Silver Glance*; *Henkelite*.—Occurs crystallised and massive. Primary form a cube. Fracture fine-grained and uneven; sometimes small and flat conchoidal. Colour lead-gray; blackish when tarnished. Lustre metallic. Opaque. Hardness 2.0 to 2.5. Malleable. Sectile. Specific gravity about 7.2.

When heated by the blow-pipe, sulphur is expelled and silver remains. It occurs in Saxony, Bohemia, and in great abundance in Mexico. It has been occasionally found in Cornwall, and in most silver-mines.

Analysis (1) by Klaproth, of a specimen from Freiberg; (2) by Berzelius:—

	(1)	(2)
Sulphur	15	12.95
Silver	85	87.05
	—100	—100

Black Sulphuret of Silver; Earthy Silver Glance.—Derived from the decomposition of the last-mentioned. Occurs massive and pulverulent. Fracture uneven. Colour dark-lead gray, inclining to black. Devoid of lustre, or only feebly glimmering. Somewhat sectile. Streak shining, metallic. It is found in Norway, Siberia, Hungary, &c., usually investing other silver-ores or filling up cavities in them.

Sulphuret of Silver and Arsenic; Light Red Silver; Proustite.—Primary form a rhomboid. Colour cochineal to aurora red; streak lighter. Lustre adamantine. Translucent to transparent. Specific gravity 5.5 to 5.6.

It is found at Joachimsthal, Johanngeorgenstadt, Annaberg, &c. Rose's analysis (1) and Proust's (2) give the following as the composition of a specimen from Joachimsthal:—

(1)	(2)
Sulphur	Sulphuret of Silver 74.35
Silver	Sulphuret of Arsenic 25
Arsenic	—
Antimony	99.35
	—99.96

Sulphuret of Silver and Antimony; Ruby Silver; Dark Red Silver; Braandite.—Occurs crystallised and massive. Primary form a rhomboid. Cleavage parallel to the primary planes, usually indistinct. Fracture conchoidal. Colour, by reflected light, from lead-gray to iron-black; by transmitted light, from brilliant to dark-red. Lustre adamantine. Translucent. Opaque. Hardness 2.0 to 2.5. Extremely brittle. Streak red. Specific gravity 5.8 to 5.9.

Massive Varieties.—Structure granular, compact, lamellar, dendritic, amorphous. It is found in many parts of Europe and America, as Germany, Norway, Mexico, and Peru, and also in Cornwall.

According to Bonsdorff, a specimen from Andreasberg yielded by analysis—

Sulphur	16.609
Silver	58.949
Antimony	22.846
	—98.404

Sulphuret of Silver and Antimony; Miargyrite.—Occurs crystallised. Primary form an oblique rhombic prism. Cleavage imperfect. Fracture uneven. Colour iron-black in mass; but in thin fragments deep-red by transmitted light. Nearly opaque. Lustre bright metallic. Hardness 2.0 to 2.5. Very sectile. Streak dark-red. Surfaces of the crystals usually striated. Specific gravity 5.2 to 5.4.

It is found with argentiferous arsenical pyrites at Braunsdorf, near Freiberg, Saxony. According to Rose, it yielded—

Sulphur	21.95
Silver	36.40
Antimony	39.14
Copper	1.06
Iron	0.62
	—99.17

Sulphuret of Silver and a little Iron; Biegsamer Silberglanz.—Occurs crystalline and massive. Crystals small and tabular. Cleavage parallel to the terminal plane. Colour nearly black. Lustre metallic. Very soft. Readily separable into thin flexible laminae. It is found only in Hungary and at Freiberg.

According to Wollaston, this mineral (which is extremely rare) consists of sulphuret of silver with a little iron.

Sulphuret of Silver and Iron; Sternbergite; Flexible Sulphuret of Silver.—Occurs crystallised. Primary form a right rhombic prism. Cleavage parallel to the terminal plane, distinct. Laminae very flexible. Colour dark-brown, often with a blue tarnish. Streak black. Lustre metallic. Hardness 1.0 to 1.5. Specific gravity 4.2 to 4.25.

It is found at Johannsgeorgenstadt, Schneeberg, and Joachimsthal in Bohemia, with other silver ores.

A specimen from the last-mentioned locality yielded, according to the analysis of Zippe—

Sulphur	30
Silver	33.2
Iron	36
	—99.2

Brittle Sulphuret of Silver, Antimony, and Iron; Brittle Silver Glance.—Occurs crystallised. Primary form a right rhombic prism. Crystals commonly maced. Fracture usually conchoidal, with a shining metallic lustre. Colour dark-gray or iron-gray. Hardness 2.0 to 3. Specific gravity 5.9 to 6.4.

It is found in Saxony, Bohemia, Hungary, Siberia, and Mexico.

Analysis of a specimen from Freiberg by—

	Klaproth.	Rose.
Sulphur	12	16.42
Silver	66.5	68.54
Antimony	10	14.68
Iron	5	0.00
Copper	0.5	0.64
	—98.5	—100.28

Sulphuret of Silver and Copper; Silberkupferglanz.—Occurs massive. Compact. Fracture brilliant, granular, flat conchoidal. Colour dark lead-gray. Streak shining. Lustre metallic. Opaque. Soft. Specific gravity 6.25. It is found at Schlangenbergl, near Colivan in Siberia.

Its analysis by Stromeyer gives—

Sulphur	15.96
Silver	52.87
Copper	30.83
Iron	00.34
	—100

Sulphuret of Silver, Antimony, and Copper; Romelite; Mine d'Argent grise Antimoniale.—It occurs crystallised. Primary form a right rhombic prism. Cleavage parallel to the lateral planes. Colour nearly silver-white. Lustre shining, metallic. Opaque. Hardness 2.0 to 2.5. Extremely brittle. Specific gravity 5.5 to 5.6.

It consists principally of sulphur and the metals above named, but in proportions not yet determined.

Sulphuret of Silver, Arsenic, Antimony, and Copper; Polybasite; Brittle Silver.—It occurs crystallised. Primary form a right rhombic prism. Cleavage imperfect. Fracture uneven. Colour iron-black. Lustre metallic. Translucent. Opaque. Hardness 2.0 to 2.5. Specific gravity 6.269.

It is found in Bohemia, Saxony, and other parts of Europe; and in Mexico and Peru.

Analysis of a specimen from Mexico (1) by Rose, and from Freiberg (2) by Brande:—

	(1)	(2)
Sulphur	17.04	19.40
Silver	64.29	65.50
Arsenic	3.74	3.30
Antimony	5.09	0.00
Copper	9.93	3.75
Iron	0.06	5.46
	—100.15	—97.41

Sulphuret of Silver, Iron, Copper, Bismuth, and Lead; Bismuthic Silver.—It occurs in acicular crystals and massive. Fracture uneven. Colour, when first broken, lead-gray, but liable to tarnish.

Massive Varieties disseminated, amorphous. Fracture fine-grained, uneven. Lustre metallic. Opaque. Soft. Sectile and brittle.

It is found accompanying pyrites and galena at Schnappach in the valley of Kinzig, Baden.

Analysis by Klaproth:—

Sulphur	16.3
Silver	15.0
Iron	4.8
Copper	0.9
Bismuth	27.0
Lead	33.0
	—96.5

Seleniuret of Silver; Selsilver.—Occurs crystallised. Primary form a cube. Occurs in thin plates. Hardness between gypsum and calc spar. Flexible. Specific gravity 8.0. Colour iron-black; streak the same, but brighter. It is found at Tilkerode in the Hartz, associated with seleniuret of lead.

Analysis by G. Rose:—

Selenium	24.05
Silver	65.56
Seleniuret of Lead, with a little Iron	6.79
	—96.40

Seleniuret of Silver and Copper; Eukairite.—It occurs massive. Structure granular. Colour gray. Lustre shining. Disposed in films on calcareous spar. It is found in a copper-mine at Skrickerum in Smaland, Sweden.

Its analysis by Berzelius gives—

Selenium	26
Silver	38.93
Copper	23.05
Earthy matter	8.90
Carbonic Acid and loss	3.12
	—100

Carbonate of Silver and Antimony; Selbte.—It occurs massive and disseminated. Fracture uneven. Colour grayish-black. Structure fine granular. Lustre metallic. Opaque. Soft. Brittle. Heavy. It is found at Altwolfach in the Black Forest.

Its analysis by Selb gives—

Carbonic Acid	12
Silver	72.6
Oxide of Antimony and a trace of Copper	15.5
	—100.1

This analysis cannot however be correct, if the ore contain carbonate of silver.

Arseniate of Silver and Iron; Ganskohtig-erz; Goosedung Silver-Ore.—It occurs massive. Mammillated. Fracture conchoidal; sometimes earthy, and mixed with cobalt-ore. Colour yellow or pale-green. Streak white. Lustre resinous. It is found chiefly in the mines of Clausthal in the Hartz; and also in Cornwall, and at Allemont in France. It does not appear to have been accurately analysed.

The ores from which the silver of commerce is mostly obtained are the Vitreous Silver, Brittle, or Black Silver-Ore, Red Silver-Ore, and Horn Silver, in addition to Native Silver. Besides these, silver is obtained in large quantities from galena (lead-ore), and from different ores of copper; and some galenas are so rich in silver that the lead is neglected for the more precious metal. This metal occurs in rocks of various ages, in gneiss, and allied rocks, in porphyry, trap, sandstone, limestone, and shales; and the sandstone and shales may be as recent as the middle secondary, as is the case in Prussia. The silver-ores are associated often with ores of lead, zinc, copper, cobalt, and antimony, and the usual gangue is calc spar or quartz, with frequently fluor spar, pearl spar, or heavy spar.

The Silver of South America is derived principally from the Horn Silver and Brittle Silver-Ores, including Arseniuretted Silver-Ore, Vitreous Silver-Ore, and Native Silver. Those of Mexico are of nearly the same character. Besides, there are earthy ores called Colorados, and in Peru Pacos, which are mostly earthy oxide of iron, with a little disseminated silver; they are found near the surface, where the rock has undergone partial decomposition. The sulphurets of lead, iron, and copper, of the mining regions, generally contain silver, and are also worked. (Dana.)

The principal mines of silver in Europe are those of Spain, of Kongsberg in Norway, of Saxony, the Hartz, Austria, and Russia. In England, argentiferous galena is worked for its silver. Forty thousand tons of this ore were reduced in 1837, which contained upon an average about six ounces of silver in a ton of lead.

The annual product of the several countries of Europe is thus estimated by Dana in his 'Manual of Mineralogy':—

	Pounds Troy.
British Isles	7500
France	4150
Austria	63,000
Sweden and Norway	13,000
Spain	130,000
Saxony, the Hartz, and other parts of Germany	78,500
Belgium	440
Piedmont, Switzerland, and Saxony	1,560

making in all 298,150 troy pounds, or about 4,500,000 dollars annually. With the sum from Russia, about 730,000 dollars, it becomes 5,230,000 dollars a year. This is small compared with the amount from America, which at the beginning of the present century equalled 2,100,000 pounds, or 31½ millions of dollars, nearly six times the above sum; and it is probable that these mines will again yield this amount when properly worked. The whole sum from Russia, Europe, and America, makes nearly 2,000,000 pounds avoirdupois.

SILVER-GRAIN. [WOOD.]

SILVER-WEED. [POTENTILLA.]

SILYBUM, a genus of Plants belonging to the natural order *Compositæ*, the tribe *Cynarææ*, and the section *Silybææ*. It has an imbricated involucre with leafy scales at the base, narrowed into a long spreading spinous point. The receptacle is scaly. The fruit compressed, its terminal areola surrounded by a papillose ring.

S. marianum is the only species. It has a stem from 3 to 4 feet high, ribbed and furrowed. The leaves are very large, oblong-lanceolate, wavy, and clasping the radical leaves, pinnatifid, and usually variegated green and white. The involucre scales closely adpressed below. The florets are purple, with a very long tube. This plant is found in waste places in Great Britain.

(Babington, *Manual of British Botany*.)

SIMARUBA. [QUASSIA.]

SIMARUBACEÆ, *Quassiads*, a natural order of Plants belonging to the Gynobasic group of Polypetalous Exogens. The plants of this order are trees or shrubs, with alternate exstipulate usually compound leaves, and mostly without dots. The flowers are whitish-green or purple, on axillary or terminal peduncles, hermaphrodite, or occasionally unisexual; the calyx is 4-5-parted; petals 4-5, twisted in aestivation; stamens twice as many as the petals, arising from the back of an hypogynous scale; ovary 4-5-lobed; style simple; stigma 4-5-lobed. Fruit a drupe. Seeds pendulous, exalbuminous, with a superior short radicle drawn back within thick cotyledons. With one exception, they are all natives of Africa, India, and tropical America. This order was formerly included under *Rutaceæ*, but their differences from that order appear to many of sufficient importance to constitute a separate family. A. De Jussieu says, "They are known from all Rutaceous Plants by the coexistence of these characters, namely, ovaries with but one ovule, indehiscent drupes, exalbuminous seeds, a membranous integument of the embryo, and by the radicle being retracted within thick cotyledons."

The plants of this order are all intensely bitter. The *Quassia* on this account is used in medicine. [QUASSIA, in ARTS AND SC. DIV.] *Simaruba versicolor* is so bitter that no insects will attack it; and when all other specimens of plants in dried collections have been attacked by *Ptini*, &c., specimens of this plant have been left untouched. The Brazilians use an infusion of this plant in brandy as a remedy against the bites of serpents.

There are 10 genera and 35 species of this order.

Quassia amara.

a, branch, showing flowers and compound leaves; b, flower; c, stamens separated, attached to hypogynous scale; d, stamens surrounding ovary; e, ovary seated on a stalk, to which the stamens are attached.

SIMETHIS, a genus of Plants belonging to the natural order *Liliaceæ*, and the tribe *Anthericeæ*. The parts of the perianth are six, spreading, deciduous; the stamens are attached to the base of the perianth; the filaments bearded; the anthers incumbent; the capsules are 3-celled, and each cell contains two seeds.

S. bicolor is a recent addition to the British Flora. It is a native of the South of Europe, and is found on sandy heaths near the sea-shore. In England it was first found at Bournemouth, in Dorsetshire. It has also been found at Derrynane, Kerry, in Ireland. This plant has linear leaves, flat, or a little keeled upwards. The flowers are panicled, the petals are purple without, and white within. In Hooker and Arnott's 'British Flora' it is suggested that this plant may have been introduced with trees from France.

SIMIADÆ, the name of a Quadrumanous family of Mammalian Animals. It embraces the most highly-developed forms of the Moukeys, and the relations of this family are more or less given under the following articles:—APE; ATELES; BABOON; CHEIROPODA; CHIMPANZEE; HYLOBATES; LAOTHEIRIX; MACACUS; MYCETES; NASALIS; ORANO-OUTAN; QUADRUMANA; SAKIS; SAPAJOUS; and SEMNOPITHECUS.

These animals were known at a very early period. The Kophim of the Scriptures (1 Kings, x. 22; 2 Chron., ix. 21), the Ceph of the Ethiopians, the Keibi and Kubbi of the Persians, the Kēḥōi of the Greeks, and Ceph of the Romans, were clearly Apes. They are to be traced in some of the earliest paintings of the Egyptians. (Rosellini, &c.)

The Ceph exhibited by Pompey (Pliny, 'Hist. Nat.' viii. 19), as well as those shown by Cæsar, appear to have been Ethiopian apes; and in the Greek name inscribed near the Quadrumanous animals, in the Prænestino pavement, the oriental origin of the word is apparent. It is remarkable that the name *Cebus* [SAPAJOUS] is applied by modern zoologists to a genus of moukeys which could not have been known to the ancients; for the *Cebi* of our present catalogues are exclusively American.

The following is a definition of the family *Simiada*, which embraces the animals to which the term Ape is most properly applied. They are all of them inhabitants of the Old World:—The nostrils are divided by a narrow septum; they possess opposable thumbs on their fore and hind feet; the callosities on the rump are generally naked. Some of the species only are furnished with cheek-pouches. They usually possess a tail. Their dental formula is as follows:—

Incisors, $\frac{4}{4}$; Canines, $\frac{1-1}{1-1}$; Premolars, $\frac{2-2}{2-2}$; Molars, $\frac{3-3}{3-3} = 32$.

The following definition of the second family of the *Quadrumana*, the *Cebida*, will afford the means of contrasting the two families:—The *Cebida* are natives of America. The nostrils are separated by a broad septum; the thumbs are sometimes absent on the fore feet; callosities and cheek-pouches absent; the tail is always present, and sometimes prehensile.

In the list of the specimens of *Mammalia* published by Dr. J. E. Gray, we find almost a complete representation of this family. They are as follows:—

SIMIADÆ.

The Chimpanzee (*Troglodytes niger*, Geoff.; *Homo Troglodytes*, Linn.). West Africa. [CHIMPANZEE.]
 The Orang-Outan, or Pongo (*Simia Satyrus*, Linn.; *S. Wurmii*, Kuhl.; *S. Agrias*, Sebreb.). Borneo. [ORANG-OUTAN.]
 The Siamang (*Siamanga Syndactyla*; *Simia Syndactyla*, Raffles, Horsf.). Java.

The Siamang (*Siamanga Syndactyla*).

The Hoolock (*Hyllobates Hoolock*, Martin; *Simia Hoolock*, Harlan). [HYLORATES.]
 The Oungka (*H. agilis*, F. Cuv.; *Simia Lar*, Vigors and Horsfield; *Pithecius agilis*, Desm.). Himalaya and Malacca.
 The Gibbon (*H. Lar*; *Homo Lar*, Linn.; *S. longimana*, Schreb.). Malacca.
 The Silvery Gibbon, or Wou-Wou (*H. leuciscus*, Kuhl; *Simia leucisca*, Schreb.). Malacca.
 The Kalasie (*Presbytis rubicunda*). Borneo.
 The Simal (*P. melalophos*; *Simia melalophos*, Raffles). Sumatra.
 The Tianac (*P. flavimana*; *Sennopithecus flavimanus*, I. Geoff.). Sumatra.
 The Rufous Presbytis (*P. nobilis*, Gray; *Sennopithecus melalophos*, Desm.). Himalaya.
 The Lutung (*P. Pyrrhus*). Java.
 The Chingkau (*P. cristata*; *Simia cristata*, Raffles). Java and Sumatra.
 The Dusky Presbytis (*P. obscura*). Singapore.
 The Negro Presbytis (*P. maura*; *Simia maura*, Schreb.). China.
 The Hooded Presbytis (*P. Johnii*; *Simia Johnii*, Fischer). India, Madras.
 The Hoonuman (*P. entellus*). Bombay and Nepaul.
 The Nestor (*P. cephalopterus*; *Cercopithecus cephalopterus*, Zimm.). Ceylon.
 Pennant's Colobus (*Colobus Pennantii*, Waterh.). Fernando Po.
 The Red and Black Colobus (*C. rufoniger*, Ogilby, Martiu). Fernando Po.
 Temminck's Colobus (*C. Temminckii*, Desm.). West Africa, Gambia.
 The Black Colobus (*C. Satanas*, Waterh.). Fernando Po.
 The King Monkey (*C. polycomos*, Geoff.; *Simia polycomos*, Schreb.). Fernando Po.
 The Guereza (*C. guereza*, Ruppell). Abyssinia.
 The Vervet (*Cercopithecus pygerythrus*, F. Cuv.). Cape of Good Hope.
 The Grivet, or Tota (*C. enyithia*; *Simia enyithia*, Herm.). Abyssinia.
 The Callithrix (*C. sabæus*, Erxl.; *Simia sabæa*, Linn.). West Africa.
 The Talapoin (*C. Talapoin*, Erxl.; *Simia Talapoin*, Schreb.). West Africa.
 The Mona (*C. mona*, Erxl.; *Simia mona*, Schreb.). West Africa, Guinea.
 Burnett's Mona (*C. Burnettii*, Gray). Fernando Po.
 The Red-Eared Monkey (*C. erythrotis*, Waterh.). Fernando Po.

The Hocheur (*C. nictitans*, Erxl.; *Simia nictitans*, Linnæus). Fernando Po.
 The Diana (*C. Diana*, Erxl.; *Simia Diana*, Linn.). West Africa.
 The Bearded Moukey (*C. Pogonias*, Bennett). Fernando Po.
 The Patas (*C. ruber*, Kuhl.; *Simia rubra*, Gmel.). Africa, Senegal.
 The White-Collared Mangabey (*Cercopithecus collaris*; *Cercopithecus Ethiops*, Kuhl.). Africa.
 The White-Crowned Mangabey (*C. Ethiops*; *Simia Ethiops*, Linn.). Africa.
 The Sooty Mangabey (*C. fuliginosus*, Geoff.; *Cercopithecus fuliginosus*, Kuhl.). Africa.
 The Zati, or Capped Macaque (*Macacus radiatus*, Desm.). India.
 The Munga, or Bonnet-Macaque (*M. Sinicus*, Desm.; *Simia Sinica*, Linn.). India.
 The Bruh (*M. nemestrinus*, Desm.; *Simia nemestrina*, Linnæus). Sumatra.
 The Macaque (*M. cynomolgus*, Desm.; *Simia cynomolgus*, Linn.). India, Sumatra.
 The Rhesus (*M. Rhesus*, Desm.; *Simia Rhesus*, Audeb.). India, Beugal.
 The Oinops (*M. Oinops*). Nepaul.
 The Brilliant Macaque (*M. speciosus*, F. Cuv.). Japan.
 The Magot (*M. Inuus*, F. Cuv.; *Simia Inuus*, *S. vulgaris*, and *S. Sylvanus*, Linn.). Gibraltar Rock, Stora, North Africa.
 The Black Macaque (*M. niger*, Bennett; *Cynocephalus niger*, Desm.). Philippines.
 The Wanderoo (*S. veter*; *Simia Silenus*, and *S. Veter*, Linnæus). Ceylon, China, India.
 The Gelada (*Gelada Ruppellii*). Abyssinia.
 The Tartarin (*Cynocephalus Hamadryas*, Latr.; *Simia Hamadryas*, Linn.). Abyssinia.
 The Chaema (*C. porcarius*, Desm.; *Simia porcaria*, Bodd). South Africa.
 The Baboon (*C. babouin*, Desm.; *Simia cynocephalus*, Fischer). West Africa.
 The Papion (*C. Sphinx*, Latr.; *Simia Sphinx*, Linn.). Guinea.
 The Mandrill (*Papio Maimon*, Latr.; *Simia Maimon*, and *S. Mormon*, Linn.). Africa.
 The Drill (*P. leueophaea*). Africa.

CEBIDÆ.

The Chameek (*Ateles Chameek*; *Simia Chameek*, Humb.). Guiana.
 The Black Spider Monkey (*A. uter*, F. Cuv.). Brazil.
 The Coaita (*A. Paniscus*, Geoff.; *Simia Paniscus*, Linn.). Brazil.
 The Marimonda (*A. Belzebuth*, Geoff.). Brazil.
 The Chuva (*A. marginatus*, Kuhl.). Brazil.
 The Five-Fingered Miriki (*Brachyteles arachnoides*; *Simia arachnoides*, Humb.). Tropical America.
 The Black-Foreheaded Miriki (*B. frontatus*). Tropical America.
 The Miriki (*B. hypoxanthus*). Tropical America.
 The Caparro, or Negro Monkey (*Lagothrix Humboldtii*, Geoff.). Brazil.
 The Araguato, or Brown Howler (*Myctes urinus*). Guiana, Brazil.
 The Golden Howler (*M. Seniculus*, Kuhl.; *Simia Seniculus*, Linn.). Royal Monkey, Penn. (*Alouate*, Ruff.). Brazil.
 The Caraya, or Black-Howler (*M. Caraya*; *Simia Caraya*, Humb.). Brazil.
 The Guariba, or Yellow-Handed Howler (*M. Beelzebub*; *Simia Beelzebub*, Linn.). Brazil.
 The Tufted Capuchin (*Cebus cirrifer*, Geoff.). Brazil.
 The Kaite, or Horned Capuebin (*C. fatuellus*, Erxl.). Brazil.
 The Capuebin (*C. Apella*, Erxl.; *Simia Apella*, Linn.). Brazil.
 The Illeirang, or Yellow-Cheated Capuebin (*C. xanthosternon*). Brazil.
 The Sai, or Weeper (*C. Cupucinus*, Erxl.; *Simia Capueina*, Linn.). Brazil.
 The White-Headed Sapajou (*C. hypoleucus*, Geoff.). America.
 The Yellow Sapajou (*C. gracilis*, Spix). Brazil.
 The Golden-Handed Sapajou (*C. chrysopus*, F. Cuv.). Brazil.
 The Tee-Tee (*Callithrix sciureus*, Kuhl.; *Simia sciurea*, Linnæus). Brazil.
 The Sahuassu, or Masked Tee-Tee (*C. personatus*, Kuhl.). Brazil.
 The Oiabassu, or White-Handed Tee-Tee (*C. Moloch*, Geoff.). Brazil.
 The Collared Tee-Tee (*C. torquatus*, Hoffm.). Guiana, Brazil.
 The Cuxio, or Bearded Saki (*Brachyurus Satanas*; *Cebus Satanas*, Hoffm.). Guiana.
 The Yarle (*Pithecia irrorata*, Gray). Brazil.
 The Black Yarle (*P. leucocephala*, Geoff.). Brazil.
 The Whiskered Yarle (*P. poyonias*, Gray). Brazil.
 The Douroucoul (*Nyctipithecus trivirgatus*, Gray). Brazil.
 The Vito (*N. felinus*, Spix). Brazil.
 The Marmoset (*Jackus vulgaris*, Geoff.). Brazil.
 The Gnack-Gnack, or Black-Eared Marmoset (*J. penicillatus*, Geoff.). Brazil.
 The White-Eared Marmoset (*J. auritus*, Geoff.). Brazil.
 The Tamarin (*J. Midas*; *Simia Midas*, Linn.). Brazil.
 The Black Tamarin (*J. Tamarin*; *Cebus Tamarin*, Link.). Brazil.
 The White-Whiskered Tamarin (*J. labiatus*, Desm.). Brazil.
 The Marikina (*J. Rosalia*; *Simia Rosalia*, Linn.). Brazil.

The Pinche (*J. Edipus*, Desm.; *Simia Edipus*, Linn.). Brazils.
The following forms of *Simiadæ* and *Cebidæ* were existing in the Gardens of the Zoological Society, Regent's Park, between the years 1847 and 1852:—

Simiadæ.

Simia Satyrus, *Hylobates Hooleok*, *Sennopithecus Gulettus*, *Cercopithecus nictitans*, *C. petamista*, *C. melanogenys*, *C. cephus*, *C. albopilaris*, *C. Campbellii*, *C. Pluto*, *C. Mona*, *C. Pygerythrus*, *C. Sabaeus*, *C. cynosurus*, *C. callithricus*, *C. Talaponi*, *C. niger*, *Cercocobus fuliginosus*, *C. Ethiops*, *Macacus sinicus*, *M. pileatus*, *M. cynomolgus*, *M. erythræus*, *M. nemestrinus*, *M. Silenus*, *M. niger*, *Inuus sylvanus*, *Orynocephalus Hamadryas*, *C. Sphinx*, *C. Babouin*, *C. Porcarius*, *C. leucophaeus*, *C. Mormon*.

Cebidæ.

Ateles Chamek, *A. paniscus*, *A. ater*, *A. Beelzebuth*, *A. marginatus*; *Pithecia chiropotes*; *Lagothrix Humboldtii*; *Brachyurus Ouakari*; *Saimiri sciureus*; *Callithrix torquatus*; *Nyctipithecus trivirgatus*; *Cebus apella*, *C. capucinus*, *C. cirrifer*, *C. xanthosternum*, *C. hypoleucus*; *Hapale Jucuchus*, *H. aurita*, *H. penicillata*, *H. (Midas) Edipus*, *H. (Midas) rufimanus*, *H. (Midas) Tamarin*.

Fossil Simiadæ.—Remains of *Simiadæ* have been discovered and described from the tertiary formations of India, France, England, and Brazil. These fossils are illustrative of four of the existing types of quadrumanous or rather Simious forms. Thus we have *Sennopithecus* from India; *Hylobates* from the south of France; *Macacus* from Suffolk; and *Callithrix*, peculiar to America, found in Brazil. Nor is it unworthy of remark, that we here have evidence that so high a quadrumanous form as the Gibbon, a genus in which the skull is even more approximated to that of man than it is in the Chimpanzee, was living upon our globe with the Palæothere, Elephants, and other Pachyderms. We say that the skull of the Gibbon comes nearest to that of man, because, though the cranium of the young Chimpanzee approaches that of the human subject, it is far removed from it when the permanent teeth are developed.

From these evidences we have also proof that *Simiadæ* lived in our island during the Eocene period; whilst the presence of fossil vegetables, abundant in the London clay at Sheppy, and the remains of serpents in the same locality, show the degree of heat that must have prevailed here during that period, when *Simiadæ* were co-existent with tropical fruits and Boa Constrictors.

But Dr. Lund's observations relating to the extinct quadrumanous form detailed in his 'View of the Fauna of Brazil,' previous to the last geological revolution, require special notice. He states that it is certain that the family of *Simiadæ* was in existence in those ancient times to which the fossils described by him belong; and he found an animal of that family of gigantic size, a character belonging to the organisation of the period which he illustrates. He describes it as considerably exceeding the largest Orang-Utan or Chimpanzee that has yet been seen. From these, as well as from the Long-Armed Apes (*Hylobates*), he holds it to have been generically distinct. As it equally differs from the *Simiadæ* now living in the locality where it was discovered, he proposes a generic distinction for it under the name of *Protopithecus*, and the specific appellation of *Protopithecus Brasiliensis*.

The following is Professor Owen's account of the discovery and identification of the British fossil:—

"I have been so fortunate in my researches on the fossil *Mammalia* of Great Britain as to determine not only the remains of extinct Pachydermal animals (*Lophiodon* and *Hyracotherium*) in the Eocene beds called the London Clay, but likewise of a quadrumanous, or monkey, in a sandy stratum of the same formation, the epoch of which had been shown by Mr. Lyell, from the evidence of other organic remains, to have had a temperature sufficiently high for arboreal *Mammalia* of the four-handed order. The fossils manifesting the quadrumanous character were discovered in 1839 by Mr. William Colchester in a bed of whitish sand, beneath a stratum of tenacious blue clay, situated by the side of the river Deben, about a mile from Woodbridge, in the parish of Kingston, commonly called Kyson, in Suffolk.

"The first of these fossils submitted to my inspection was the fragment of the right side of the lower jaw, including the anterior part of the base of the coronoid process, and the last molar tooth entire in its socket. This tooth is fortunately a very characteristic one; and after a comparison of it with the corresponding tubercular tooth in the lower jaw of the Coati (*Nasera*), Raccoon (*Procyon*), Ratel, Opossum, Phalanger, and other small ungulate quadrupeds of a mixed or partially carnivorous diet, I proceeded to an examination of the *Quadrumanus*, and found in that order the desired correspondence. The extreme rarity of the fossil remains of such highly-organised animals in any part of the world, and the previous total absence of any in a land so far from the equator as England, prevented my examination, in the first instance, of the skeletons of the recent *Quadrumanus*; and it was not until I had tried all the more probable analogues of the fossil fragment in the lower forms of the *Mammalia*, that I began to test it by the side of the jaws of the apes and monkeys. The grinding surface of the fossil tooth supports five tubercles, the four anterior ones being arranged in two transverse pairs, the fifth forming a posterior heel or talon. This conformation of the crown of

the last molar in the lower jaw characterises two families of Catarrhine or Old-World Monkeys, namely, the *Sennopithecidæ*, including the genera *Colobus* and *Sennopithecus*; and the *Macacidæ*, including the genera *Macacus*, *Cynocephalus*, and *Papio*. The next step was to ascertain whether any special marks of resemblance would yield a further insight into the affinities of the fossil, and justify its reference to any of the genera of either family. A difference in the shape of the hinder tubercle of the tooth was first noticed in the recent *Quadrumanus*. In the *Sennopithecidæ* it was large but simple; in most of the *Macacidæ* it was partially subdivided into two cusps, the outer one being the largest. As this character was well marked in the fossil, it seemed decisive of its closer affinity to the *Macacidæ*; and as the smallest species in this family belongs to the typical genus, I referred the fossil to the *Macacus*, and now propose to designate the extinct species represented by it *Macacus Eocenus*, the Eocene Moukey, or Macaque. The portion of the fossil jaw is narrower from side to side, or more compressed, than in any of the existing Macaques; and the internal wall of the socket of the tooth in the fossil is fluted and thinner. The ridge on the outer side of the alveolus, which forms the commencement of the anterior margin of the coronoid process, begins closer to the tooth. These characters establish the specific distinction of the extinct Macaque to which the fossil fragment of the jaw belonged, and afford additional proof, if such were wanting, that it could not have been accidentally introduced in recent times into the stratum out of which it was disinterred." (Owen.)

Another tooth of the same species of *Macacus* was found in the same spot in 1838, but these teeth are the only remains of the *Quadrumanus* which have been found in this country. In other countries larger remains have been found. Thus, in 1836, Lieutenants Baker and Durand discovered, in the Sub-Himalayan Hills, near the Sutlej, an almost entire right superior maxillary bone, containing the five molar teeth and part of the canine. The strata in which this fossil was found was tertiary, and consisted of a mixed calcareous sandstone and clay. In the year following, Colonel Cautley and Dr. Falconer discovered in the same formation a considerable portion of the lower jaw, with all the molars of the right side, and a part of the teeth of the left side, together with two middle incisors and the right canine. These remains belonged to a species of *Sennopithecus*, which must have existed with the *Sivatherium* and *Hippopotamus*, whose remains were found in the same formation.

SINAPIS, the name of a genus of Plants belonging to the natural order *Crucifere*, or *Brassicaceæ*. All the species are known by the name of Mustard, a word derived from *Mustum ardens*, in allusion to their hot and biting character. The genus is known by its siliquose fruit, which is rather terete, with nerved valves; small short acute style; subglobose seeds disposed in one row in each cell, and spreading calyx. The leaves are of various forms, lyrate or deeply toothed; the flowers yellow, arranged on terminal branchless racemes; they are chiefly natives of the temperate parts of both hemispheres of the Old World. Between 40 and 50 species of this genus are enumerated. Of these, two species are well known and much cultivated in this country, *S. nigra* and *S. alba*, the Black and White Mustard.

S. nigra, Black Mustard, is known by its smooth, even somewhat tetragonal siliques closely pressed to the peduncle; lyrate lower leaves, and lanceolate upper leaves. It is found in cultivated fields, waste grounds, and roadsides throughout Europe.

S. alba, White Mustard. Siliques hispid, spreading, rather narrower than the ensiform beak; leaves lyrate, smoothish; stem smooth. It is a native of Great Britain and most countries in the south of Europe. It is frequently cultivated, and when young is eaten as a salad.

SINEW. [TENDON.]

SINTER. The silica deposited by hot-springs, as those of Iceland and the Azores, is called Sinter. [OPAL.]

SIPHONACEÆ. [ALOE.]

SIPHONARIÆ. [SEMIPHYLIDIANÆ.]

SIPHONIA. [SPONGIADÆ.]

SIPHONIA, a genus of Plants belonging to the natural order *Euphorbiaceæ*, consisting of two species, but one may be only a variety of the other. This is celebrated as being the tree which yields the large quantities of caoutchouc, called 'cahuchu' by the native Americans, annually imported from Para in South America.

S. elastica is a tree 50 to 60 feet in height, common in the forests of Guiana and Brazil, and which has been introduced into the West Indies. Condamine frequently mentions it in his voyage down the Amazon. Caoutchouc is the milky juice of the plant, which exudes on incisions being made, and solidifies on exposure to the air. [INDIA RUBBER.]

SIPHONIFERA, D'Orbigny, an order of Cephalopodous *Mollusca*.

SIPHONOBANCHIATA, an order of *Mollusca*. [SIPHONOSTOMATA; ENTOMOSTOMATA; MALACOLOGY.]

SIPHONOPS, Wagler, a genus of Pseudophilidius Apodal Bratrachians.

The first sub-order of Bratrachians, the *Péromèles* of Messrs. Duméril and Bibron, consists of but one family, the *Ophiosomes* (Snake-Bodied Bratrachians), or *Cœcilioidians*. Their round elongated form, without either tail or feet, approximates so closely to that of the

Serpents, that the greater number of authors have arranged them in the order Ophidians.

The characters which lead to the classification of these reptiles into one family, and to their separation from all others, are, 1st, a body extremely extended in length, and of a cylindrical shape; 2nd, the absence of limbs or lateral appendages proper for locomotion; 3rd, a skin naked in appearance and viscous, but concealing between the circular folds which it forms many rows or rings of flat delicate imbricated scales, with free and rounded borders, resembling those of

Scales of *Cecilia albiventris*.

the greater part of the fishes; 4th, the rounded orifice of their cloaca situated below, very near the posterior extremity of the body, which is sometimes truncated as it were, and rounded—sometimes obtusely pointed, as in the genus *Typhlops*; 5th, their head, as in all the Batrachians, is articulated to the spine by means of two distinct and separate condyles; 6th, their lower jaw moves upon the cranium without any separate articular bone, and the two branches which form it are short and very solidly soldered together towards the symphysis of the chin.

The bodies of the vertebrae of the Cæcilioidians are doubly excavated into cones, instead of being concave before and convex behind. Their tongue is large, papillose, fixed by its borders upon the gums in the concavity of the jaw, and not protractile, nor forked, nor susceptible of entering into a sheath.

Professor Owen observes, that in the extinct family of the Labyrinthodonts, the Batrachian type of organisation was modified so as to lead directly from that order to the highest form of reptiles, namely, the Loricata or Crocodilian Saurians; that some of the existing edentulous genera of the *Bufo* connect the Batrachian with the Chelonian order, and that the family founded upon the Linnæan genus *Cecilia* forms the transition to the Ophidian reptiles. "The characters," says the Professor, "which retain the *Cecilia* in the Batrachian order are generally known, and may be briefly enumerated as the double occipital condyle, the biconcave vertebrae, the smooth mucous integument with minute and concealed scales, and the branchial apertures retained by the young some time after their birth. In the fixed tympanic pedicle, and the ankylosed symphysis of the lower jaw, the *Cecilia* are also far removed from the typical Ophidian structures; but the teeth, in their length, slenderness, sharp points, wide intervals, and diminished number, begin to exhibit the characters of the dental system of the Serpent tribe." ("Odontography.")

The departure in a degree of the Cæcilioidians from the Batrachians is marked by the presence of small scales; by ribs which are forked at their vertebral extremity, and much more distinct than in the genus *Pleurodeles*; by the absence of a sternum; and especially by the form and structure of the mouth, the aperture of which is small, the lower jaw being shorter than the upper, and the teeth long, sharp, and generally curved backwards.

The Cæcilioidians resemble many species of the osseous fishes of the division of the *Muraenidae* in the form and structure of the skeleton, the articulation of the jaws, the mode of implantation of the teeth, &c.; but the mode of junction of the head with the spine by means of two condyles, the presence of lungs and nostrils, which open distinctly within the cavity of the mouth, and the entire absence of branchiae, remove these animals from that class. [CÆCILIDÆ.]

With regard to the teeth of the Cæcilians, Professor Owen states that they are implanted in a single row upon the maxillary, intermaxillary, and palatine bones, the upper jaw being thus provided with two semi-elliptical and sub-concentric series; that there are also two rows of equal-sized teeth on the premandibular bones of the lower jaw in certain species. The *Cecilia*, he remarks, is the last example in the ascending survey which he has taken of the dental system of this disposition of teeth, which was so common in the class of Fishes.

"There are," writes the Professor, "20 teeth in the anterior or outer premandibular row in the lumbricoid and white-bellied *Cecilia*, and 10 or 12 of much smaller size in the second row. There are 20 teeth in the outer row of the upper jaw, of which 6 are supported by the intermaxillaries, and 16 in the inner or palatine row. All these teeth are long, slender, acute, and slightly recurved. In the Rostrated *Cecilia* the first two teeth of the maxillary and premandibular series are longer and stronger than the rest; they are succeeded by small and recurved teeth; the median margins of the palatine bones are bristled with small teeth; the second row in the lower jaw is represented by two small recurved teeth on the internal border of the premandibular bones. In the modification of the dental system presented by this species may be perceived a retention of the Batrachian type. The Annulated *Cecilia* (*Siphonops annulatus*) has the maxillary and palatine teeth strong, pointed, and slightly recurved. In the Glutinous and Two-Banded *Cecilia* (*Epicrion*) the teeth are slender, acute, and more inclined backwards, thus approaching nearer to the Ophidian type; in the latter species (*Epicrion* (*Rhinatrema*)

birittatum) the palatal series, instead of ranging concentrically with the outer row, is chevron-shaped with the angle turned forwards and rounded off. The teeth of the *Cecilia* are sub-transparent; their intimate structure corresponds with that of the frog's tooth; but their mode of implantation resembles that of the teeth of the Labyrinthodonts, the base being ankylosed to the parietes of a shallow alveolus." ("Odontography.")

Head of *Cecilia lumbricoidea*.

The genus *Siphonops* (Wagler) has the following generic character:—Head and body cylindrical; muzzle short; maxillary and palatine teeth strong, pointed, and a little recurved; tongue large, entire, adhering on all sides, with a surface hollowed into small vermiculiform sinkings; eyes distinct through the skin; a fossa or false nostril in front of and a little below each eye.

Only two species are known, and they are both American.

S. annulatus (*Cecilia annulata*, Auct.) has the muzzle very short, very thick, very much rounded, hardly less than the back of the head; nostrils opening on the sides of the muzzle, entirely at the end and a little upward; false nostrils placed below each eye, and very slightly forward. Diameter of the body a sixteenth or seventeenth of its total length; it is rather strong, and perfectly cylindrical, of the same size throughout its extent. There are from 86 to 90 annular folds, slightly and equally separated from each other; these cease a little in front of the vent, so that the skin of the terminal extremity of the body, which is rounded, offers no wrinkles.

It is a native of Guiana and Surinam.

1, *Siphonops annulatus* very much reduced. a, head and neck seen in profile; b, mouth open, to show the tongue, the teeth, and the internal orifices of the nostrils; c, terminal extremity of its body seen below. (Duméril and Bibron.)

The genus *Ichthyophis* (Fitzing) has the head depressed, elongated; muzzle obtuse; maxillary and palatine teeth of loose texture (effilées), sharp, and couched backwards; tongue entire, with a velvety surface; eyes distinct through the skin, a fossa with a tentaculated border (f below the eye, near the border of the upper lip. Body subfusiform with numerous circular folds close-set one against the other. (Dum. and Bihr.)

I. glutinosus (*Cecilia glutinosa*, Linn.), the only species known. The diameter of the body taken near the middle is the twenty-second or twenty-third part of the total length. There are about 325 folds, rather uniformly approximated. The scales which these folds hide are small, numerous, delicate, transparent, sub-circular, and offering on their superior surface a small figure in relief, representing a net with quadrilateral meshes. A yellowish band extends to the right and left all along the body, from the muzzle to the anal extremity; above and below the tint is slate-colour.

It is a native of Java and Ceylon.

The genus *Rhinatrema* (Dum. and Bihr.) has the head depressed, elongated; muzzle obtuse; maxillary and palatine teeth of loose structure (effilées), sharp, and couched backwards; tongue entire, of a velvety surface; eyes distinct through the skin; no fossa, neither under the muzzle nor below the eyes. Body subfusiform, with numerous circular folds.

R. birittatum (*Cecilia birittata*, Auct.), the only species, has the head a little elongated and slightly depressed, bearing some resem-

blance in form to that of certain Ophidians, particularly of the *Coronelle*. The teeth very loosely constructed (effilées), and very much couched backwards; the second row above, instead of forming a curved line like the first, makes an angle rounded at its summit. The diameter of the middle of the trunk is one twenty-sixth of the total length of the body, round which there are 340 perfectly annuliform folds.

It is a native of Guiana.

Rhinatremia bicittatum. a, its scales.

SIPHONOSTOMA, an order of Suctorial Crustacea. It was established by Latreille, and comprehends all the Suctorial Crustaceans whose thorax, composed of many distinct joints, is furnished with natatory feet.

M. Milne-Edwards describes these animals as having the body divided into three parts; the head, the thorax, and the abdomen. The first is large, and carries a pair of antennæ, a sucker furnished with styliform mandibles, and anchor-like or prehensile jaw-feet, generally three pairs in number. This cephalic portion of the body is, in general, more or less clypeiform, and is confounded with one or two of the first thoracic rings. The normal number of the constituent segments of the thorax is five, but in consequence of the soldering of the parts, this middle portion of the body offers mostly only two, three, or four distinct joints. The last thoracic ring is apod, and, in the female, carries two or three oviferous tubes. Finally, the abdomen is in general rudimentary, and is only furnished with a single pair of appendages, disposed so as to constitute ordinarily a small caudal fin. The general form of the body varies much, and sometimes departs considerably from that which may be considered as normal in this class of annulose animals.

The *Siphonostoma* undergo considerable metamorphoses in their youth, and do not become parasites till they have changed their skin once or many times; they swim at first with ease, but after having fixed themselves, they become more or less deformed, and do not quit their place except slowly and with difficulty.

M. Milne-Edwards divides the *Siphonostoma* into two families—the *Peltocephala* and the *Pachycephala*.

Peltocephala.—This family has less affinity with *Cyclops* than some of the *Pachycephala*, but they offer a more complicated structure, and consequently appear to M. Milne-Edwards to deserve precedence.

The head is very large, shield-like, and in general much larger than the thorax or abdomen; it resembles a disc slightly convex above, delicate on its edges, and truncated behind, where it is confounded with the first rings of the thorax. On its upper surface two small smooth eyes may be almost always distinguished; they are closely approximated to the median line. Forward it is continued with two frontal blades more or less distinct, and directed transversely. The thorax is composed of a variable number of joints; sometimes two only are distinguishable, sometimes three or even four may be counted, according as the three first segments are confounded with the head, or this soldering extends to but two of these rings, or even to one only. For the rest, the aspect of this portion of the body varies much, for sometimes the dorsal segment of these rings presents nothing remarkable, and sometimes it gives rise to great laminae, which resemble the elytra of insects.

The abdomen is but little developed, and presents no appendage below, but terminates by two small natatory blades ciliated on the edges, or by a species of trifoliated fin.

The appendicular system presents, in all the animals of this division, the same essential characters, and is composed of a pair of antennæ, a buccal apparatus, and four pairs of feet.

The antennæ, two in number only, are inserted very far from each other, and are short, flattened, and directed outwards; they are always composed of two or three small lamellar joints, and are never setaceous nor annulated.

The buccal apparatus is composed of a sucker, of divers rudi-

mentary appendages, situated on each side of its base, and of three pairs of anchor-like jaw-feet. The sucker is large, conical, and directed backwards; two unequal pieces are there to be distinguished, which are soldered by the edges throughout the greatest part of their length, but remain free towards the end, and leave between them, at the summit of this species of beak, a circular or triangular aperture; one of these laminae is inserted between the mouth and the front, and represents the labrum, or upper lip; the other, situated backwards, is analogous to the lower lip of the masticating crustaceans. Between the base of these two lips springs, on each side, an appendage, which evidently replaces the mandibles of these last animals; but which, instead of being short, stout, and dentiform, is slender, very much elongated, and similar to a stylet with a denticulated point; these styliform jaws penetrate into the beak by means of a slit situated near its base, and advance into its interior, so as to come out by the terminating aperture, and serve as a pair of lancets when the animal wishes to suck its prey. A little onwards is found a second pair of appendages, which is reduced to a nearly rudimentary state, and seems to be the representative of the first pair of jaws of the ordinary Crustacea. In general there is to be distinguished near the same point a styliform, or forked horny piece, which seems to be the vestige of a third pair of buccal appendages, appendages which, in the masticating crustaceans, constitute the second pair of jaws. The jaw-feet, three pairs in number, offer considerable dimensions, and are ranged on each side of the siphon: the first pair seems to be reflected (refonlées) forward, for they spring in front of the edge of the upper lip, between the sucker and the antennæ, and by some naturalists they are considered as antennæ; they are stout, short, more or less misshapen, and each terminated by a hooked claw, by the aid of which the animal attaches itself to its prey. The second pair of jaw-feet are slender, and always composed of two principal joints of nearly equal length, the second of which carries, near its middle, a small appendage, and terminates by one or two hooks but little bent. The third pair of jaw-feet, situated more backward, are stout, in general short, and more or less completely subcheliform; the crooked claw which terminates them can be bent back on the penultimate joint, in manner of a claw.

The feet are four pairs in number, and are always more or less completely natatory; two pairs, and sometimes all, terminate by two oars, each composed of three joints, offering generally a very remarkable disposition of a nature to favour their action as natatory instruments, and which consist in a very considerable development of their basilar joint, and the soldering of that joint with an unequal sternal piece, so as to form, with the whole, a single transversal blade, as for the two feet. It is even to be remarked, that in general this basilar piece, which occupies the whole width of the corresponding ring, is much more developed than the terminal oars of those limbs, and constitutes by itself nearly the whole of the fin formed by the pair of feet thus modified. These four pairs of limbs belong to the first four thoracic rings, and spring, some from the cephalic buckler, others from the postcephalic portion of the thorax, varying in number according to that of the thoracic rings, which are confounded with the head. The last ring of the thorax carries none; but in general a pair of tubercles, or lobules, may be distinguished there, which appear to be the vestiges of a fifth pair of limbs reduced to a rudimentary state.

These Crustaceans live as parasites upon fishes, but they are not permanently fixed to them, and when they let go their hold, they can change their place either by crawling slowly or swimming. The male is in general distinguished from the female by some peculiarities of structure, and by a very inferior size. The female nearly always carries her eggs in cylindrical tubes, which spring near the posterior border of the last thoracic segment on each side of the abdomen, and which often attain a very considerable length. The young, at their birth, resemble the young of *Cyclops*, and must undergo many moults before they finish their metamorphosis; little however is known at present of these changes. It is also to be noted that one often finds in the neighbourhood of the vulva small ampullæ, which are fixed there by a very narrow neck, and which may be spermathecal reservoirs analogous to those which M. Siebold made known in *Cyclops*.

M. Milne-Edwards divides this natural family into three divisions or tribes—the Argulians, the Caligians, and the Pandarians.

The Argulians consist of a single genus, *Argulus*, which infests fresh-water fish and the tadpoles of Batrachians, to which they adhere, but they are also found free, swimming about with vivacity.

A. foliaceus is known to most anglers: it is figured in Desmarest ('Crust.', pl. 50, fig. 1), and there is a woodcut of it in Yarrell's 'British Fishes,' vol. ii. p. 399. [ARGULUS.]

Caligiana.—There is nothing abnormal in the conformation of the thorax of this tribe, the thoracic rings being simple, and without dorsal appendages. The cephalic buckler is large, more or less oval, delicate on its edges, and furnished anteriorly with very well-developed frontal laminae, the lateral extremity of which covers the base of the antennæ. The posterior angles of this carapace are prolonged more or less far on each side of the thorax, and the portion of its posterior border comprised between these two prolongations is confounded with the first, or even the second or third first thoracic segments. The result is, that the thorax is only composed of two, three, or

four distinct joints. The feet are furnished with long plumose bristles; and the abdomen is terminated by two small plates directed backwards, and carrying no lateral appendages. [CALIGUS.]

Pandarians.—The small Crustaceans collected by M. Milne-Edwards under this name, are remarkable for the lamellar prolongations with which the upper part of their thorax is furnished. These appendages, he observes, often resemble the elytra of insects, and their number is sometimes considerable; there may be as many as three pairs counted. In general the head is less enlarged and less clypeiform than in the *Caligians*, and the feet are only rarely furnished with plumose setæ; their terminal oars are often only represented by foliaceous sub-membranous lobes; and the abdomen frequently presents on each side of its terminal piece a more or less projecting lamellar appendage.

M. Milne-Edwards subdivides this tribe into two small groups, principally characterised by the general form of the body, and by the disposition of the oviferous tubes, which in the one are exposed and extended in a straight line behind the body, whilst in the other these tubes are coiled upon themselves, and hidden between the superior surface of the abdomen and a clypeiform lamina which springs from the last thoracic ring.

The genera *Euryphorus*, *Dinemoura*, *Pandarus*, and *Phyllophora*, form the first of these groups. *Cecrops* and *Lamarius* belong to the second.

Phyllophora is very remarkable from the lamellar appendages with which its back is covered. In its aspect it approaches the Anthosomes, but in the structure of its feet and in its general organisation it is not separable from the Paudarians. The only species known is *P. cornuta*. Length about ten lines. It is taken near Tongataboo.

Phyllophora cornuta (Milne-Edwards.)
a, seen from below.

Pachycephala.—In this division of the order *Siphonostoma* M. Milne-Edwards describes the head as not enlarged, but lamellar and clypeiform, as in the preceding family, and the antennæ, instead of being short, flattened, and biarticulate, as slender, cylindrical, elongated, and composed of five or six joints, the size of which diminishes gradually from the base towards the point of the organ. It is also to be noted that the apparatus of suction is in general less developed in these Crustaceans than in the *Peltocephala*, and the mode of conformation of these appendages, which would appear to represent the jaw-feet, is less constant; the feet are not soldered on the median line, and consequently do not constitute unequal fins, as is often the case in the preceding family.

M. Milne-Edwards divides the *Pachycephala* into two natural groups, the *Ergasilians* and the *Dichelestians*: the first, he observes, establishes the passage between *Cyclops* and the *Lernæide*; the second, between these last and the *Pandarians*.

Ergasilians.—This small group closely approximates to *Cyclops*, and is remarkable for the pyriform conformation of the body, the size of the head, and the development of the abdomen. The genera are—*Ergasilus*, *Bomolocus*, and *Nicothoa*. Species of *Ergasilus* are found attached to the gills of the pike and carp (*E. Sieboldii*); to those of the eel (*E. gibbus*); and to those of a *Silurus* (*E. trisetaceus*). The only species of *Bomolocus* known (*B. Belones*) is found attached to the branchiæ of the gar-fish (*Esox Belone*). *Nicothoa* includes but one species (*N. Astaci*) which is of a rosy colour, about a line in length, and is found upon the branchiæ of the lobster. The young *Nicothoe*, on leaving the egg, resemble the young of *Cyclops*, and want the thoracic lobes, which, when they are adult, give so strange an aspect to these animals.

Dichelestians.—This tribe is easily distinguished from the Ergasi-

lians by the elongated form of the body, the smallness of the head, and the frequently rudimentary state of the abdomen. It is also worthy of note that their feet are much less developed than in the *Ergasilians*, and that the organs by the aid of which they fix themselves on their prey are, on the contrary, more developed, announcing a more essentially parasitic life. The genera are—*Anthosoma*, *Dichelestium*, *Nemesis*, *Lamproglena*.

But one species of *Anthosoma* is known (*A. Smithii*), about ten lines long, and found upon a *Squalus*. M. Milne-Edwards remarks that the *Caligus crassus* of Abildgaard much resembles this species, but seems to be more stout about the head, and to have the cephalic buckler wider forwards.

Dichelestium comprises but one species (*D. Sturionis*). It is about one inch in length, and fixes itself on the branchial apparatus of the Sturgeons. The thorax is divided into four portions in the male, and into five in the female, by interannular divisions. The abdomen is very small in the female, about half as large as the last thoracic ring in the male. Neither does *Lamproglena* include more than one species (*L. pulchella*), which is found on the gills of the chub.

M. Milne-Edwards states that it is not without doubt that he has arranged the *Pycnogonidae* in this place, with the *Siphonostoma*. Amongst the Suctorial Crustaceans, according to M. Milne-Edwards, are the *Pycnogonidae*, or Araneiform Crustaceans, as they have been considered by the greater part of zoologists as belonging to the class of *Arachnida*, but which seem to him to have more analogy with the *Crustacea*, for they have no tracheæ nor pulmonary sacs for aerial respiration, and appear to respire oxygen beneath the water only by means of the general surface of the common teguments, as he had already pointed out in many inferior Crustaceans.

In the general form of the body these animals approach the *Lemnodipoda*, and especially *Cyamus*. Their head is elongated, sometimes cylindrical, sometimes conical, and presents at its extremity a trilobate buccal orifice. The thorax is constantly divided into four segments, and the abdomen is only represented by a small tubular joint fixed to the posterior edge of the last thoracic ring. The head carries no appendages, and the eyes, four in number, are grouped on a small median tubercle, situated on the dorsal surface of the first joint of the thorax. This segment often carries at its extremity a pair of jaw-feet terminated by a well-formed pincer, and sometimes furnished with a palp, which is elongated, and composed of many joints. In the male the number of pairs of feet is equal to that of the joints of the thorax; but in the female there is a pair of pediform supplementary appendages fixed to the first joint of the thorax, bent back under the feet properly so called, much smaller than them, and serving to carry the eggs. The feet are very long, directed outwards, and composed of nine joints, the last of which constitutes a more or less sharp claw.

The digestive tube traverses the body in a straight line, and presents in one of the genera of this family (*Nymphum*) a very remarkable disposition; it gives origin, to the right and left, to a series of prolongations, which are tubular and closed above, which advance very far in the interior of the corresponding feet, and which are the seat of a peristaltic motion. There exists besides a vague circulation. No trace of respiratory organs is perceptible, and the disposition of the organs of generation is not known; it is only to be remarked, that in the *Pycnogonidae* may be perceived, on the second joint of the posterior feet, a pore, which seems to be the orifice of this last apparatus.

The *Pycnogonidae* are all of small proportions, and live in the sea; some are found under stones, others live, it is said, hooked on to fish or other marine animals; but otherwise nothing is known relative to their habits.

The genera are—*Nymphum*, *Pallene*, *Phoxichilidium* (*Orythia*, Johnston), and *Pycnogonum*.

Our limits will only allow us to illustrate this group, which still requires the close attention of the physiologist and comparative anatomist, by one genus. *Pycnogonum* is distinguished from its congeners by the stoutness of its form, and the size and shortness of its

Pycnogonum littorale, magnified.
a, foot of the same, more highly magnified.

feet, which are strongly contrasted with those of *Nymphum gracile*. Only one species appears to be known, *Pycnogonum littorale*. The

accessory feet of the female are very short. Length about 4 lines. This Araneiform Crustacean inhabits our seas and those of France, and is found on Ascidians and various fishes.

SIPHONOSTOMATA, M. De Blainville's name for his first family of Siphonobranchiate Mollusca.

The forms comprised under this family are principally to be found under the extensive genus *Murex* of Linnaeus. It is sometimes applied to several families forming a section of Prosobranchiate Mollusca. In Woodward's 'Manual' the following families are included:—

1. Strombidae. [STROMBIDÆ.]
2. Buccinidae. [BUCCINUM.]
3. Conidae. [CONIDÆ.]
4. Volutidae. [VOLUTIDÆ.]
5. Cypræidae. [CYPRÆIDÆ.]

All the known animals belonging to it are carnivorous and marine, and all are furnished with a horny operculum. The Siphonostomata are thus subdivided by M. De Blainville:—

* No persistent bourrelet on the right lip.

Pleurotoma (Lam.).—Shell fusiform, slightly rugose, with a turriculated spire; aperture oval, small, terminated by a straight canal more or less long. The right lip trenchant and more or less incised. Operculum horny.

A. Species in which the incision is a little behind the middle of the lip, and the tube of considerable length.

P. Babylonia. The shell fusiform-turrit, transversely carinated and belted, white, with black-spotted belts, the spots quadrate; whorls convex; tube or canal rather long. It is found in the East Indian Seas and the Moluccas.

Pleurotoma Babylonia.

B. Species in which the incision is entirely against the spire, and whose tube is short. (Genus *Clavatulula*, Lam.)

P. auriculifera. This genus has been taken on different bottoms at depths varying from 8 to 16 fathoms.

Pleurotoma auriculifera.

The distribution of this genus is world-wide, and 430 recent species have been described. Those of which the localities are known are thus distributed:—

British Islands and Greenland	17
Mediterranean	19
Africa	15
Red Sea and India	6
China	90
Australia	15
Western America	52
West Indies and Brazil	20

The fossil species are found principally in the chalk, and number

about 300. Many sub-genera have been formed, as *Clavatulula*, Lam.; *Tornella*, Swainson; *Mangelia*, Leach; *Bela*, Leach; *Daphnella*, Hind.

Fusus (Lam.).—Animal not differing much from that of *Murex*. Shell fusiform, often ventricose in the middle, rugose, thick, and with a very elevated spire; canal very straight and elongated; aperture oval; right lip trenchant, the left smooth. Operculum horny.

Animal of *Fusus*. a, operculum.

A. Turriculate or subturriculate, but not umbilicated species.

F. Colus (*Murex Colus*, Linu). Shell fusiform, narrow, transversely furrowed, white, the apex and base rufous; whorls convex, nodulously carinated in the middle; canal long and slender; the lip sulcated within, and denticulate on the margin. It is a native of the East Indian Ocean.

Fusus Colus.

B. Species subturriculated and umbilicated. (Genus *Latirus*, De Montfort.)

F. filosus. Shell fusiform-turrit, thick, knotty, but smooth to the touch, whitish-yellow girt with numerous orange-red lines; whorls knotty above, the knots hemispherical; the aperture white; the lip striated within. Found in the seas of Australia.

C. Subturriculate species, with the canal notched at the extremity.

F. articulatus. Shell fusiform-turrit, very delicately striated transversely, shining, saffron-coloured or violaceous-cærulescent, girt with articulated bay lines; lip sulcated within; columella with one plait above; canal short and emarginate.

D. Species with the whorls of the spire rounded and convex.

F. Islandicus. Shell fusiform-turrit, ventricose below, not knobbed, transversely striated, white, the whorls convex; the lip thin, smooth within; the canal rather short and subcurved. It is found in the seas of Iceland.

E. Muricoid species.

Ex. *F. muriceus*.

F. Buccinoid species.

Ex. *F. buccineus*.

Fusi have been found on bottoms of mud, sandy mud, and sand, at depths ranging from the surface to eleven fathoms. They are found distributed all over the world. About 100 recent species and 320 fossil have been described. The latter have been found from the Gault to the Eocene Tertiary.

The sub-genera are—*Trophon*, Montfort; *Clavella*, Sw.; *Chrysodomus*, Sw.; *Fusionella*, Gray. *F. colopus* and *F. proboscidioides* are two of the largest living Gasteropoda. *F. antiquus*, called the Red Whelk, on the coasts of the Channel, and Buckie in Scotland, is used for eating. It is the Roaring Buckie, in which the sound of the sea is said to be heard. In the Zetland cottages it is used as a lamp. *P. contrarius* has its lips reversed. It is found fossil in the crag of the counties of Suffolk and Essex in great abundance, and also recent in the Mediterranean Sea and on the coasts of Spain. *F. deformis* is also reversed.

Pyrgula (Lam.).—Shell pyriform, in consequence of the lowness of the spire; the canal conical and very long or moderate, sometimes slightly notched; aperture oval, rather large; columella smooth and bent; right lip trenchant. Operculum horny.

A. Subfusiform species; the spire being slightly elevated.

P. carnaria (*P. Vespertilio*, Lam.; *Fusus carnarius*, Mart.; *Murex Vespertilio*, Gm.). Shell subpyriform, thick, ponderous, muricated anteriorly, of a rufous-bay colour; the last whorl crowned above with compressed tubercles; spire rather prominent; the sutures simple; canal sulcated and subumbilicated. It is a native of the Indian Ocean.

Pyrgula carnaria.

B. Species with a long and rather narrow tube; spine very short.

P. spirillus. Shell ventricose anteriorly, the canal very long, delicately striated transversely, white, spotted with saffron-colour; body-whorl abbreviated; carinated in the middle, flattened above, tuberculated below the middle; spire very much depressed, its apex mamilliferous. It is a native of the East Indian Ocean and the coasts of Tranquebar.

C. Species with a long and rather narrow tube, but sinistrorsal or left-handed, and with the indication of a plait on the columella or pillar. (Genus *Fulgur*, De Montf.)

P. perversa. Shell sinistrorsal, pyriform, very ventricose, smooth, yellowish-white, ornamented with broad rufous longitudinal lines; the last whorl crowned above with tubercles; the upper whorls tuberculiferous at the base; the canal or tube rather long and striated. It is a native of the Antilles and Bay of Campeachy.

D. Species more ventricose and delicate.

P. fusa. Shell fig-shaped, delicately decussated, corulescent-gray; sprinkled with variegated bay or violet spots; transverse striae the largest and most crowded; the spire short, convex, mucronated at the centre; mouth corulescent-violaceous generally. It is a native of the Indian Ocean and the Moluccas.

Pyrgula fusa.

E. Ventricose species, with a short tube; aperture very large and wide, sensibly notched.

P. Melongena. Shell pyriform, turgidly ventricose, corulescent, glaucous, or rufous, banded with white; the whorls channelled at

the sutures; the last sometimes unarmed, but more frequently muricated, with various sharp tubercles; spire short, acute; aperture smooth and white. It is found in the West Indian Seas and the Antilles.

F. Species still shorter; aperture very wide; the right lip subalated.

P. abbreviata. Shell subpyriform, very ventricose, rather rough, transversely sulcated, cinerous-white; the spire rather prominent; the canal short, widely umbilicated; muricated on the back with subechinate elevated furrows; outer lip striated within, and its margin denticulated.

Pyrgula have been found on mud, sandy mud, and sand, at depths ranging from the surface to nine fathoms.

There are 39 recent species and 30 fossil. The recent are found in the West Indies, Ceylon, Australia, China, and West America. The fossil are found in the Neocomian beds of Europe, India, and Chile.

Fasciolaria (Lam.).—Shell fusiform, not very thick, rather convex in the middle, with a moderate spire; aperture oval; canal rather long; sometimes slightly bent; right lip trenchant, often wrinkled internally; columellar lip with some very oblique plaits. Operculum horny.

Animal of *Fasciolaria*. a, operculum.

A. Fusiform, but not tuberculous species.

F. Tulipa. Shell fusiform, ventricose in the middle, unarmed, smooth, sometimes orange-rufous, sometimes marbled with white and bay, gilt with transverse brown lines unequally congregated; whorls very convex; sutures fimbriated at the margin; tube sulcated; outer lip white and striated within. It is a native of the West Indian seas and the Antilles.

Fasciolaria Tulipa, with the operculum in situ.

B. Fusiform and tuberculous species.

F. Trapezium. Shell fusiform, ventricose, tuberculiferous, rather smooth, white or rufescent, gilt with rufous lines; the tubercles conical, subcompressed, and in a single series in the middle of the whorls; columella reddish-yellow; outer lip elegantly striated within, the striae red. It is found in the East Indian Ocean.

C. Tuberculated and turriculated species.

F. filamentosa. Shell elongated, fusiform, turreted, transversely sulcated, white, painted with longitudinal orange-red stripes; middle of the whorls subangulated, and the whorls themselves crowned with short and compressed tubercles; the canal rather long; the outer lip striated within. It is found in the East Indian seas.

Fasciolaria have been found on muddy bottoms, at depths ranging from the surface to seven fathoms.

There are 11 recent and 23 fossil species. The former are found in the West Indies, Mediterranean, West Africa, India, Australia, the South Pacific, and Western America. The latter are found in the Upper Chalk.

Turbinella (Lam.).—Shell ordinarily turbinated, hut also sometimes turriculated, rugous, thick; spire rather variable in form; aperture elongated, terminated by a straight canal, often sufficiently short; the left lip nearly straight, and formed by a callosity hiding the columella, which has two or three unequal, nearly transverse plaits; right lip entire and trenchant.

A. Fusiform and nearly smooth species.

T. Rapa. Shell subfusiform, ventricose in the middle, thick, very ponderous, unarmed, white; the whorls above covering the base of the preceding one; canal rather short; columella subquadriplicated. It is found in the East Indian Ocean.

Turbinella Rapa.

B. Turbinaceous and spiny species.

T. Scolymus. Shell subfusiform, ventricose in the middle, tuberculated, pale yellow; spire conical, tuberculato-nodose; the last whorl crowned above with great tubercles; canal transversely sulcated; the columella orange-coloured and three-plaited. It is a native of the East Indian Ocean.

C. Turriculated, subfusiform species.

T. Infundibulum. Shell fusiform-turricated, narrow, many-ribbed, transversely sulcated, the ribs longitudinal and thick, the furrows smooth and red, and the interstices yellow; canal perforated, the aperture white.

Turbinellæ have been found on bottoms of sandy mud, at depths varying from the surface to 18 fathoms.

There are 70 recent species, chiefly tropical, and 20 fossil, from the Miocene Tertiary beds.

** A persistent hourrelet on the right lip.

Columbella (Lam.).—Shell thick, turbinated, with a short obtuse spire; aperture narrow, elongated, terminated by a very short canal slightly notched, narrowed by a convexity at the internal side of the right lip and the plaits of the columella. Operculum horny, very small.

C. mercatoria. Shell ovate-turbinated, transversely sulcated, white, painted with small, rufo-fuscous, transverse, subfasciculated lines, sometimes banded; outer lip denticulated within. Found in the Atlantic Ocean.

Columbella mercatoria.

Columbellæ have been found on bottoms of sandy mud and mud at depths ranging from the surface to 16 fathoms.

The recent species are very numerous; they are chiefly subtropical: 200 species have been described. They are small prettily-marked shells, living in shallow water on sandy flats, or congregating about stones.

Triton (Lam.).—Animal a good deal resembling that of *Murex*. Shell oval, with the spire and canal straight and moderate; ordinarily rugose, furnished with few varices, which are scattered and arranged longitudinally; aperture suboval, elongated, terminated by a short open canal; the columellar lip less excavated than the right, and covered by a callosity. Operculum horny and inclined to oval.

A. Comparatively smooth species, with cordons slightly or not at all marked, with the exception of that of the right lip.

T. variegatus, the Marine Trumpet, or Triton's Shell. Shell elongated-conical, trumpet-shaped, ventricose below, girt with very obtuse smooth ribs, white, elegantly variegated with red and bay; the sutures crisped at the margin; the aperture red; the columella wrinkled with white and with a single plait above; the edge of the outer lip spotted with black, the spots bidentated with white. It is a native of the seas of the West Indies and the Asiatic seas, especially those of the torrid zone.

Animal of *Triton*, a, operculum.

Marine Trumpet or Triton's Shell (*Triton variegatus*).

B. Species more tuberculous, or spiny, whose aperture is more open, and terminated by a more or less ascending canal. (Genus *Lotorium* of De Montfort.)

T. Lutorium. Shell fusiform-turricated, distorted below, very much tuberculated, transversely rugous, and striated, rufous; the whorls above angulate-tuberculated; canal tortuous, the extremity recurved; the aperture trigono-elongated and white; the outer lip toothed within. It is a native of the East Indian Ocean.

C. Species with a shorter spire, always very tuberculous, most frequently umbilicated, a sinus at the posterior junction of the two lips. (Genus *Aquillus*, De Montfort.)

T. cutaceus. Shell ovate, ventricose-depressed, cingulated, tuberculato-nodose, yellow-rufescent; the belts rather prominent, separated by a furrow; the whorls above angulate-tuberculate, rather flattened above; canal short, umbilicated; the outer lip notched within. It is found in the Atlantic Ocean.

D. Species like those of section C, but whose aperture is closely narrowed by a callosity and irregular teeth. (Genus *Persona*, De Montfort.)

T. Anus, the Grimace. Shell ovate, ventricose-gibbous, distorted, flattened beneath; nodulous above, subcancellated, white, spotted with rufous; the aperture narrowed, sinuous, irregular, ringent; the lip very much toothed; the canal short and recurved. It is found in the East Indian seas.

Tritons have been found on various bottoms at depths ranging from the surface to 30 fathoms.

There are 100 recent species, and 45 fossil: the latter are Eocene. *T. tritonis* is the great conch blown by the natives of Australia and the Polynesian Islanders.

Struthiolaria (Lam.).—Shell oval, the spire elevated, the aperture oval and wide; canal very short, very much notched; right lip sinuous, not toothed, furnished with a bourrelet; columellar border callous, extended; a sinus at the posterior union of the two lips; operculum horny.

S. nodulosa. Shell ovate-conical, thick, transversely striated, white, painted with undulated, longitudinal, saffron-coloured, flame-like lines; whorls angulated above, flattened on the upper side, nodulous at the angle; the sutures simple, the outer lip luteo-rufescent within. It is found in the seas of New Zealand.

Lamarck regards two living species; so does M. Deshayes, who also records one fossil, with a query, from Paris.

Ranella (Lam.).—Shell oval or oblong, depressed, having only two varices situated laterally; aperture oval; canal short, and a sinus at the union of the two lips, backwards.

A. Non-umbilicated species. (Genus *Bufo*, De Montfort.)

Ex. *R. granulata*, a native of the East Indian Ocean.

B. Umbilicated species.

Ex. *R. foliata*, found in the vicinity of Mauritius.

Ranella foliata.

Ranella have been taken on different bottoms at depths varying from the surface to 20 fathoms.

Fifty recent and 23 fossil species have been described.

Murex (Linn.).—Animal furnished with two long and approximated tentacles; mouth without jaws, but armed with hooked denticles in lieu of a tongue; foot rounded, generally rather short; mantle large, often ornamented with fringes on the right side only; branchiae formed of two unequal pectinations; anus on the right side, in the branchial cavity; orifice of the oviduct on the right side, at the entrance of the same cavity; orifice of the deferent canal at the end of the exciting organ, on the right side of the neck; shell oval, oblong, more or less elevated on the spiral side, or prolonged forwards; external surface always interrupted by rows of varices in the form of spires or ramifications, or simply tubercles, generally arranged in regular and constant order; aperture oval, terminated anteriorly by a straight canal, which is more or less elongated and closed; right lip often plaited or wrinkled; columellar lip often callous; operculum horny.

Animal of *Murex*. a, operculum.

A. Species with a very long and spiny tube. (Thorny Woodcocks of collectors.)

M. Tribulus, Linn. (*Murex tenuispina*, Lam.).—Shell ventricose anteriorly, the tube very long, elegantly spired throughout its length, the spires set in the triple order, each row at regular intervals, grayish or purplish gray; the spires very long, thin, rather closely set and somewhat hooked; body of the shell transversely sulcated and striated; the spire prominent. It is a native of the Indian Ocean and the Moluccas.

This is the Venus's Comb of collectors, and when perfect is a most delicate and striking shell.

Common Thorny Woodcock (*Murex Tribulus*, Linn.; *Murex variispina*, Lam.)

B. Species with a very long tube and without spines. (Genus *Brontes*, De Montfort.)

M. haustellum (Snipe's or Woodcock's Head of collectors). Shell anteriorly ventricose, naked, scarcely armed, fulvous inclining to red, lineated with bay; body of the shell rounded and furnished with three or more ribs between the varices; the tube very long and slender; the spire short; mouth rounded, red. It is a native of the East Indian Ocean and the Moluccas.

Snipe's Head, or Woodcock's Head (*Murex haustellum*).

C. Species with three elevated, flattened, and comparatively thin varices.

M. acanthopterus. Shell oblong, fusiform, trialated, transversely sulcated and striated, white; the alae membranaceous; whorls angulated; aperture ovate-rounded. It is a native of the East Indian Seas.

D. Species with three ramified varices. (Genus *Chicoreus*, De Montf.)

Ex. *M. adustus*. It is a native of the East Indian Ocean.

E. Species which have a greater number of varices; tube nearly closed.

Ex. *M. regius*.

No description can convey an adequate idea of the splendid colouring of this species. It is a native of the western coast of Central and South America.

F. Subturriculated species.

Ex. *M. lyratus*.

G. Subturriculated species; the tube closed; a tube pierced towards the posterior extremity of the right side, and persistent upon the whorls of the spire. (Genus *Typhis*, De Montfort.)

Ex. *M. pungens*, fossil.

H. Species more globular; the spire and canal shorter, very open; the aperture rather wide.

Ex. *M. vitulinus*.

I. Species which have an oblique fold very much anterior to the columella, and an umbilicus. (Genus *Phos*, De Montfort.)

Murex have been found on different bottoms at depths ranging from 5 to 25 fathoms; and species of *Typhis* on sandy mud at depths varying from 6 to 11 fathoms.

There are 180 recent species of *Murex* described. Their distribution is world-wide. All the species of *Murex* yield a dye, and many of them were used as well as *Purpura Lapillus*, for obtaining the Tyrian purple of the ancients. Heaps of the broken shells of *Murex trunculus* are still to be found on the Tyrian shore. On the coast of the Morca there is evidence of the employment of *M. brandaris* for the same purpose. *M. erinaceus*, a very abundant species on some parts of our coast, is called by fishermen Sting-Winkle. It makes holes in other shell-fish with its beak.

Murex regius.

The *Siphonostomata* and *Entomostomata* may be considered as the two great tribes of carnivorous gastropods or trachelipods appointed to keep down the undue increase of the *Conchifera* and Herbivorous Gastropods, whose shells the majority of those carnivorous testaceous penetrate by means of an organ which makes a hole as truly round as if it had been cut by an awl, and then feed on the juices of the included animal.

Dr. Buckland notices this habit with a view to the condition of the testaceous inhabitants of the earlier seas of our planet with his wonted felicity. "Most collectors," he says, "have seen upon the sea-shore numbers of dead shells, in which small circular holes have been bored by the predaceous tribes, for the purpose of feeding upon the bodies of the animals contained within them: similar holes occur in many fossil shells of the tertiary strata, wherein the shells of carnivorous trachelipods also abound; but perforations of this kind are extremely rare in the fossil shells of any older formation. In the green-sand and oolite they have been noticed only in those few cases where they are accompanied by the shells of equally rare carnivorous molluscs; and in the lias and strata below it, there are neither perforations, nor any shells having the notched mouth peculiar to perforating carnivorous species. It should seem from these facts that, in the economy of submarine life, the great family of carnivorous trachelipods performed the same necessary office during the tertiary period which is allotted to them in the present ocean. We have further evidence to show that in times anterior to and during the deposition of the chalk, the same important functions were assigned to other carnivorous molluscs, namely, the testaceous cephalopods: these are of comparatively rare occurrence in the tertiary strata and in our modern seas; but throughout the secondary and transition formations, where carnivorous trachelipods are either wholly wanting or extremely scarce, we find abundant remains of carnivorous cephalopods, consisting of the chambered shells of *Nautili* and *Ammonites*, and many kindred extinct genera of polythalamous shells of extraordinary beauty. The molluscous inhabitants of all these chambered shells probably possessed the voracious habits of the modern cuttle-fish; and by feeding like them upon young *Testacea* and *Crustacea*, restricted the excessive increase of animal life at the bottom of the more ancient seas. Their sudden and nearly total disappearance at the commencement of the tertiary era would have caused a blank in the 'police of nature,' allowing the herbivorous tribes to increase to an excess that would ultimately have been destructive of marine vegetation, as well as of themselves, had they not been replaced by a different order of carnivorous creatures, destined to perform in another manner the office which the inhabitants of the ammonite and various extinct genera of chambered shells then ceased to discharge. From that time onwards we have evidence of the abundance of carnivorous trachelipods, and we see good reason to adopt the conclusion of Mr. Dillwyn, that in the formation above the chalk the vast and sudden decrease of one predaceous tribe has been provided for by the creation of many now genera and species possessed of similar appetencies, and yet formed for obtaining their prey by habits entirely different from those of the cephalopods. The design

NAT. HIST. DIV. VOL. IV.

of the Creator seems at all times to have been to fill the waters of the seas and cover the surface of the earth with the greatest possible amount of organised beings enjoying life; and the same expedient of adapting the vegetable kingdom to become the basis of the life of animals, and of multiplying largely the amount of animal existence by the addition of *Carnivora* to the *Herbivora*, appears to have prevailed from the first commencement of organic life to the present hour." ('Bridgewater Treatise.')

SIPUNCULOIDEA, an order of Echinodermatous Animals, embracing the families *Sipunculidae*, *Priapulidae*, and *Thalassemidae*. This order is thus defined: The cutaneous envelope is coriaceous, and free from calcareous corpuscles; there is no calcareous ring about the oesophagus; the body is cylindrical; the digestive canal usually asymmetrical.

1. The *Sipunculidae* (Syphon-Worms) have a retractile proboscis, at the base of which is placed the vent, and round the extremity of which there is a circle of tentacles. This family embraces the genera *Syrinx*, *Sipunculus*, and *Phascolosoma*.

Syrinx (Bohadsch) has a cylindrical proboscis shorter than the body, having a circle of short-fingered tentacles around its tip. In his 'History of British Star-Fishes,' Forbes refers three British species of *Sipunculus* of other authors to this genus—*S. nudus*, *S. papillosus*, and *S. Harveti*.

Sipunculus (Linnaeus) has a cylindrical proboscis about as long as the body, and a circle of simple linear tentacles around its tip. The following are British species of this genus:—*S. Bernhardus*, *S. Johnstoni*, *S. saccatus*, *S. tenuicinctus*, *S. Forbesii*, *S. granulosus*, *S. punctatissimus*, and *S. Pallastii*.

2. The *Priapulidae* (Tailed-Worms) have a retractile proboscis with no tentacles, and the vent at the end of a long thread-like tail.

Priapulus (Lamarck) has the body truncated behind, and the tail much branched and pointed.

The only British species is *P. caudatus*, which is only rarely taken.

3. The *Thalassemidae* (Spoon-Worms) have a body oval or oblong, a proboscis with a long fleshy appendage; vent at posterior extremity, tentacles none.

Thalassema (Cuvier) has a cylindrical body rounded and smooth behind; the proboscis retractile, short, furnished at one side with a long fleshy furrowed simple sheath, which is not retractile. *T. Neptuni* is a British species.

Echiurus (Cuvier) has a cylindrical body, set at its hinder extremity with circles of bony points, and a proboscis as in *Thalassema*. [ECHINODERMATA.] *E. oxyurus* is a British species.

(Manual of Natural History; Gosse, Marine Zoology; Forbes, British Star-Fishes.)

SIRE'DON, Wagler's name for the *Axolotl*. We subjoin an illustration of the *Axolotl* from Messrs. Duméril and Bibron's great work on Reptiles. [AXOLOTL; AMPHIBIA.]

Siredon or *Axolotl* seen in profile; a, mouth seen in front, open to show the teeth.

SIREN, a genus of Reptiles belonging to the *Perennibranchiate Batrachia*. [AMPHIBIA.] It has the following characters:—Form elongated, nearly like that of the eels; branchial tufts three on each side; no posterior feet, nor any vestige of a pelvis; head depressed; gape of the mouth not wide; muzzle obtuse; eye very small; the ear concealed; lower jaw armed with a horny sheath and several rows of small teeth; the upper jaw toothless; but numerous small pointed retroverted teeth occur on the palatal region.

Dr. Garden appears to be the first who called attention to this form, which is declared by Cuvier to be one of the most remarkable of the class of Reptiles, and indeed of the whole animal kingdom, from the anomalies of its organisation, and its apparent relationship with different families, and even classes. Dr. Garden (1765-1766) sent a description of this reptile to Linnaeus and Ellis, and the former, relying upon Dr. Garden's assurance that the *Siren* did not change its form, established an additional order for it in his class *Amphibia*, with the name of *Meantes*.

Pallas, Hermann, Schneider, and Lacépède however saw, as Cuvier remarks, nothing more in the *Siren* than the larva of some large unknown Salamander; whilst Camper, followed by Gmelin, went so far as to give it a place among the fishes. The latter arranges it at

the end of the Eels, under the name of *Murena Siren*. These differences of opinion sufficiently show the doubts which arose on the examination of this extraordinary form.

Cuvier in 1807 satisfactorily established, in a memoir read to the Institute of France, and inserted in the first volume of the 'Zoological Observations of Humboldt,' that whatever changes it might undergo, the Siren was a reptile sui generis, which never could have hind feet, and whose whole bony framework differed essentially from that of the Salamanders; that there was no probability that it ever changed its form or lost its branchiæ; and that the Siren is consequently a true Amphibian, which respire at will throughout its life, either in the water by means of branchiæ, or in the air by means of lungs. This conclusion rested upon that solid basis which has given such value—a value daily becoming more appreciated—to the views of this great zoologist—his personal observations made on the osteology and splanchnology of the animal.

That the Siren is a perfect animal belonging to the Poreunibranchiate Batrachians is now admitted by all zoologists. Cuvier indeed remarks ('Règne Animal'), that the branchiæ of *Siren intermedia* and *S. striata* have been regarded as not participating in their respiration, and that in consequence Dr. J. E. Gray has formed them into the genus *Pseudobranchius*. Cuvier however adds that it is nevertheless not difficult to see on their lower surface folds and a vascular apparatus, the use of which does not appear doubtful to him; and that M. Leconte has satisfactorily demonstrated that both these species, as well as *Siren lacertina*, are perfect animals.

Cuvier remarks that the Siren should be judged of not after *Amphiuma*, but from itself. He accordingly procured some Sirens, and saw an osteology so finished and so firm, that it was impossible to believe that they were not adult. The branchiæ of these individuals were perfectly entire, and their lungs completely developed, and rich in well-filled vessels. No doubt therefore existed in his mind that the animals used both.

The simultaneous existence, he observes, of a larynx and a trachea with a branchial apparatus not only permanent, but perfectly ossified in many of its parts, is also worthy of especial attention, and proves, as is evident in the frogs and salamanders, that the branchial apparatus is no other than a more complicated os hyoides, and not a combination of pieces proceeding from the sternum and larynx. He adds, that it is to the Salamanders that the Sirens approach most nearly by the structure of the head, although neither the general form nor the proportions of the parts have so near similarity.

The skull of the Siren is narrowed in front by reason of the excessive reduction of the maxillary bones, which consist only of a very small osseous point. Behind there is a strong occipital crest on the parietal and petrous bones. The pieces which form the lower jaw, instead of being transverse like the branches of a cross, are directed obliquely forwards. The parietal bones occupy the greatest portion of the upper part of the cranium. They have each in front a point, expanding so as to lodge between them the posterior part of the principal frontal bones, which have each a groove for the lodgment of the posterior point of two slender bones, which proceed beside each other to the end of the muzzle. At their sides are attached two other bones, which are slender and pointed backwards, and which descend and widen far in order to raise the anterior edge of the jaw. Cuvier takes the first for the nasal bones, and the others for intermaxillary bones. These last are toothless, but their edge is trechant, and furnished, when the animal is alive or well preserved, as well as the edges of the lower jaw, with a sheath which is nearly horny, is easily detached from the gum, and has its analogue in the tadpoles of the frogs. All the lower part of the cranium and the face is composed of a large and wide sphenoid, which extends from the occipital hole to the intermaxillaries. The sides of the cranium, in the orbital region and the front of the temporal bone, are closed by a single bone, in which are pierced, forward, the olfactory aperture; farther back, the optic hole, and another for the first branch of the fifth pair, and probably for the small nerves of the eye. To the palate, under the anterior and lateral part of the sphenoid and orbital bones, are fitted two delicate plates beset with hooked teeth.

The lower jaw of the Siren is composed of four bones on each side; one of which forms the symphysis and the trechant border of the jaw, which it invests externally up to near its posterior extremity. The whole of this bone is beset with small pointed teeth disposed quincuncially like those of the palatal plates.

The os hyoides of the Siren is an os hyoides of the larva of a Salamander or of the Axolotl, but very much ossified in many of its parts.

The shoulder-blade of the Siren is slender, nearly cylindrical, narrowed in its middle, and augmented on the spinal side by a cartilaginous lamina. The clavicle and the coracoid are represented by two cartilaginous lobes, one directed forwards, the other much wider, proceeding upon the breast and crossing upon that of the opposite side. In the external border of this coracoid cartilage, near and a little behind the articular fossa, is a bony semilunar lamina, which is the sole representative of the bony coracoid; but there is nothing similar for the clavicle. The humerus, compressed laterally above, from before backwards below, and narrowed in its middle, has its extremities cartilaginous. It is the same with the two bones of the fore arm, both rather

slender, and the internal bone or radius widened below. The bones of the carpus remain cartilaginous.

Each of the four fingers has a metacarpian, and two phalanges only.

Anterior portion of the skeleton of *Siren lacertina*. a, dorsal vertebra seen behind; b, the same seen before.

There is no vestige of a pelvis, nor of any posterior extremity, either osseous or cartilaginous.

Cuvier did not find in a large individual more than 43 vertebrae in the trunk and 44 in the tail: but the individual which he described in 1807 had three more.

In the vertebrae which carry the ribs, the upper lamina of the transverse apophysis is but little marked, and the point is stout and divided into two lobes for the two tubercles of the rib, as in the salamanders. Cuvier only found eight of these vestiges of ribs on each side, commencing from the second vertebra. The two last have the head simple. At the tail, the transverse apophyses, which have already

Entire skeleton of *Siren lacertina*.

become rather small, promptly disappear; the articular apophyses diminish also by degrees. The body of the vertebra takes a very compressed form, and gives below two small laminae, which intercept a canal for the vessels, like the chevron bones in the lizards.

Johu Hunter, in 1766, gave the following accurate and interesting description of the twofold respiratory apparatus of the Siren:—"On the posterior and lateral parts of the mouth are three openings on each side; these are similar to the slits of the gills in fish, but the partitions do not resemble gills on their outer edges, for they have not the comb-like structure. Above and close to the extremity of each of these openings, externally, so many processes arise, the anterior the smallest, the posterior the longest; their interior and inferior edges and extremity are serrated, or formed into fimbriae: these processes fold down and cover the slits externally, and would seem to answer the purposes of the comb-like part of the gill in fish. At the root of the tongue, nearly as far back as these openings reach, the trachea begins, much in the same manner as in birds. It passes backwards above the heart, and there divides into two branches, one going to each lobe of the lungs. The lungs are two long bags, one on each side, which begin just behind the heart, and pass back through the whole length of the abdomen, nearly as far as the anus. They are largest in the middle, and honeycombed on their internal surface through their whole length." ('Phil. Trans., lvi, 1766.)

In the Museum of the Royal College of Surgeons in London this part of the organisation of the Siren is well illustrated.

John Hunter describes the heart of the Siren as consisting of one auricle and ventricle. "What answers," says Hunter, "to the inferior vena cava, passes forwards above, but in a sulcus of the liver, and opens into a bag similar to the pericardium: this bag surrounds the heart and aorta as the pericardium does in other animals; from this there is an opening into a vein which lies above and upon the left of the auricle, which vein seems to receive the blood from the lungs, gills, and head, is analogous to the superior vena cava, and opens into the auricle which is upon the left ventricle. The aorta goes out, passing for a little way in a loose spiral turn, then becomes straight, where it seems to be muscular: at this part the branches go off, between which there is a rising within the area of the aorta like a bird's tongue, with its tip turned towards the heart. This account of the venæ cavæ opening into the cavity of the pericardium may appear incredible; and it might be supposed that, in the natural state of the parts, there is a canal of communication going from one cava to the other, which, being broken or nipped through in the act of catching or killing the animal, would give the appearance above described. I can only say that the appearances were what have been described in three different subjects which I have dissected, and in all of them the pericardium was full of coagulated blood. But besides the smallness of the subjects, it may be observed that they had been long preserved in spirits, which made them more unfit for anatomical inquiries. They had been in my possession above seven years." ('Phil. Trans., lvi, 1766.)

The structure of the heart and other organs of this interesting animal, are illustrated in the preparations in the Museum of the Royal College of Surgeons of England.

The following remarks on the blood of the Siren, by Professor Owen, were published originally in the 'Penny Cyclopædia':—

"Among the important generalisations which the numerous observations of recent microscopical anatomists have enabled the physiologist to establish respecting the form and size of the blood-discs in different classes of animals, the most interesting seems to be that which Professor Wagner has enunciated respecting the relation of the magnitude of the blood-disc to the persistency of the branchial apparatus in the Batrachian order of reptiles, on the occasion of his description of the blood-discs of the *Proteus anguinus*.

"The absolute size of these particles in that Perennibranchiate Reptile, in which they may be distinguished by the naked eye, renders them peculiarly adapted for minute investigations into the structure of the nucleus and capsule of the blood-disc: but the value of the relation between their size and the persistency of the external gills must depend upon the correspondence of other perennibranchiate reptiles with the *Proteus* in this respect. The superior size of the blood-discs of the Newts to those of the Land-Salamanders and Tailless Batrachians has been confirmed by Professor Van der Hoeven's observations on the blood-discs of the gigantic Newt of Japan [SIEBOLDIA], of which a fine specimen has been for several years kept alive at Leyden [AMPHIBIA]; and I have been able to add another instance of the still greater relative size of the blood-discs in the Perennibranchiate Reptiles by the examination of those of the largest existing species of that family, the *Siren lacertina*, of which a specimen, twenty inches in length, is now (October 15th, 1841) living at the Zoological Gardens. The blood was obtained from one of the external gills, and immediately subjected to examination. The blood-discs presented the elliptical form which hitherto, without exception, has been found to prevail among the air-breathing oviparous vertebrate animals: the ellipse was not quite regular in all the blood-discs; several were sub-ovate, a few slightly reniform and thicker at the more convex side: all were as compressed, or disc-shaped, as in other Batrachians, with the nucleus slightly projecting from each of the flattened surfaces.

"The nucleus did not partake in the same degree with these varieties of form, but maintained a more regular elliptical form; the varieties in question appearing to depend on pressure acting upon the capsule and the coloured fluid surrounding the nucleus. Yet when the ellipse of the blood-disc was, as it happened in a few cases to be,

longer and narrower than the average, the form of the nucleus presented a similar modification of size.

"The following is a table of the averages of many admeasurements of these blood-discs, made with the screw-micrometer:—

	English inch.
"Long diameter	1-150th
Short diameter	1-850th to 1-870th
Long diameter of nucleus	1-1000th
Short diameter of ditto	1-2000th
Thickness of ditto	1-3800th

(As viewed edgewise covered by the capsule.)

"The nucleus was circumscribed by a double line, the outer one more regular than the inner one, which appeared crenated. This appearance was due to the structure of the nucleus, or the contents of the nucleolar capsule, which was indicated by the outer line. These contents consisted, in every blood-disc examined, of a number of moderately bright spherical nucleoli, sufficiently distinct to be counted, when viewed by a Powell's 1-10th inch objective, with the eye-piece, magnifying 700 linear diameters: the ordinary number of nucleoli seen in one plane or focus being from twenty to thirty, the total number was of course much greater. The facility as well as certainty of the demonstration of such a structure in a good microscope of the present day will be readily admitted, when it is remembered that the nucleus of the blood-disc of the Siren is three times the size of the entire human blood-disc. These tuberculate nuclei, when removed from the capsule, were colourless; the component granules or cells have a high refracting power: viewed in situ they present a tinge of colour lighter than that of the surrounding fluid, and dependent upon the thin layer of that fluid interposed between the nucleus and the capsule.

"The external capsule of the blood-disc is smooth, moderately resisting, elastic, as was easily seen by the flattening of the parts of two blood-discs that might come in contact, and the recovery of form when they were floated apart.

"As the fluid contents of the blood-disc in part evaporated during the process of desiccation, the capsule fell into folds in the interspace between the nucleus and the outer contour, these folds generally taking the direction of straight lines, three to seven in number, radiating from the nucleus." (R. Owen, Sept. 25, 1841.)

Blood-discs of Man and Siren, drawn by the camera lucida under a magnifying power of 700 linear dimensions.

a, Human blood-discs; a', ditto viewed edgewise; b, Siren's blood-disc; b', ditto viewed edgewise; c, folds of external capsule, produced by desiccation; d, capsule of nucleus; e, nucleoli.

Siren lacertina grows to the length of three feet; its colour is blackish. The feet have four toes, and the tail is compressed into an obtuse fin.

This Siren inhabits the marshy grounds of Carolina, especially those where rice is cultivated. It lives in the mud, from whence it makes excursions, sometimes on land and sometimes in the water. From the swampy places by the sides of pools and under the overhanging trunks of old trees, where it is found, it was called by the inhabitants 'the Mud Iguana.' Garden was of opinion that it feeds on serpents, and that it uttered a cry similar to that of a young duck; but Bartou contests these statements. Its food is generally believed to consist of earth-worms, insects, &c. Specimens have been occasionally kept in the Zoological Gardens, Regent's Park. One in 1841 was kept in a vessel of pond-water with a deep bottom of mud, in which it used to hide itself. It was twenty inches long, as large as the wrist of a stout child of six months old, and very eel-like in its movements and appearance. About a dozen and a half of earth-worms were supplied to it as food every other day.

S. striata is blackish, with two longitudinal yellow stripes on each side; has only three toes on each foot, and is about nine inches in length.

Siren striata.

a, head and anterior part seen in profile, shewing the branchiæ and foot.

SISKIN. [CARDUELIS; ABERDEVINE.]

SISMONDINE, a Mineral of a deep-green brilliant colour. It cleaves readily, affording highly lustrous laminae. Brittle, easily powdered; colour of the powder bright grayish-green. Scratches glass. Specific gravity about 3·565. It is found at St. Marcel in Piedmont. Its analysis by Delesse gives—

Silica	24·1
Alumina	43·2
Protoxide of Iron	23·8
Water; trace of Titanium	7·6

—98·7

SISON, a genus of Plants belonging to the natural order *Umbellifera*. It possesses the following characters:—calyx obsolete; petals broadly obovate, deeply notched, and curved with an inflexed point; styles very short; fruit ovate, laterally compressed; carpels with five filiform equal ridges, of which the lateral ones are marginal; interstices with single short club-shaped vittæ; seed gibbous, convex, plane in front; universal and partial involucre of few leaves.

Several species were formerly referred to this genus which are now placed under various genera. The only species that is now decidedly referred to Sison is the *S. Amomum*, Hedge Bastard Stone Parsley. It is a native of France, Sicily, Italy, Greece, and Great Britain. It is not unfrequent in this country, especially in chalk soils in rather moist ground, under hedges, &c. It is known by its erect, terete, paniculately branched stem; pinnate leaves, the lower leaflets rather toothed and lobed, upper ones cut into narrow segments. The flowers are cream-coloured. The green plant when bruised has a peculiarly nauseous smell, something like that of bugs. The seeds are pungent and aromatic, and were formerly celebrated as a diuretic, but are now little used.

SISSOO. [DALBERGIA.]

SISYMBRIUM (from *Σισυμβριον*), the name of a genus of Plants belonging to the natural order *Crucifera*. It possesses a roundish siliqua seated upon a torus; two stigmas, somewhat distinct, or connate into a head; calyx equal at the base; ovate or oblong seeds; flat, incumbent, sometimes oblique cotyledons; stamens not toothed. The species are mostly perennial or annual herbs, with yellow or white flowers, and leaves very variable on the same plant. About 58 species are enumerated, but comparatively few of these are cultivated. The genus, however, belongs to an order which possesses no injurious plants, and a few of the species are well known on account of their uses.

S. officinarum, Common Hedge-Mustard, has muricate pilose leaves, a pilose stem, and subulate pods pressed to the rachis. It is a native of Europe, and grows in waste places and way-sides, among rubbish, and along the sides of walls. It is plentiful in Britain, and also the north of Africa. The whole plant is warm and acrid, and is often cultivated for use as a pot-herb.

S. Iria, London Rocket or Broad-Leaved Hedge-Mustard. Stem and leaves smooth; leaves runcinate; lobes toothed; pod erect. It is a native of waste places throughout Europe, but especially about London. It is said to have entirely covered the ground in the following spring of the great fire of London in 1666. The former species is also remarkable for appearing on the ground where fires have existed.

S. Sophia, Five-Leaved Hedge-Mustard, or Flixweed. Leaves doubly

pinnatifid, slightly hairy; lobes linear or oval; pedicels four times longer than the calyx; petals shorter. It grows on dry banks, waste ground, dung-hills, and among rubbish in most parts of Europe. It is frequent in Great Britain.

S. millefolium, Millfoil-Leaved Flixweed. Leaves somewhat tripinnate, hoary; lobules blunt, small; stems shrubby; petals larger than the calyx. A native of Teneriffe, on the rocks in the lower parts of the island. It is a small branched shrub, with corymbose flowers.

S. strictissimum, Spear-Leaved Hedge-Mustard. Leaves lanceolate, stalked, toothed, pubescent. It has intensely yellow flowers, with pods two inches long; the stem is erect, and branching at the top.

SISYRINCHIUM. [IRIDACEÆ.]

SITTA, a genus of Birds belonging to the family *Certhiada*. Mr. Swainson places the genus in the sub-family *Sittina*, being the second of his family *Certhiada*. Ponce Bonaparte makes it the first sub-family of that family.

It has the following generic characters:—Bill straight, cylindrical, slightly compressed, subulated, acuminate. Tongue short, horny, and armed at the point. Nostrils basal and rounded, partly hidden by reflected bristles. Feet with three toes before and one behind, the outer toe being joined at its base to the middle one; hind toe of the same length as or longer than the middle one, with a long and hooked claw. Tail of 12 feathers. Wings rather short; the first quill very short, the third and fourth the longest. (Gould.)

S. Europæa, the Common Nuthatch, or Nuttjohber. The plumage above is fine blue-gray; quills and base of tail-feathers, except the two middle ones, black, the outer tail-feather on each side with a black spot near the tip. A black band passes from the bill through the eye down the sides of the neck, ending abruptly near the shoulders; throat whitish; rest of plumage below rufous-brown blending into chestnut on the flanks; bill and feet black; iris hazel. Sexes alike.

Common Nuthatch (*Sitta Europæa*).

This bird is in all probability the *Σίττα* of the Greeks, and *Sitta* of the Latins. It is the Ziolo, Picchio Grigio, Raparino, and Picchio Formicajo, of the Italians; Muratore of Savi; Torehepot and Pie-Magon of the French; Kleiber and Blauspecht of the Germans; Notwacka and Notpacka of the Swedes; Spett-Meine of the Danes; Nat-Bake of Brunich; Kleuer Nuszhacker of Kramer; and Delor y Cnan of the Welsh.

Like the Woodpeckers and Creepers, the Nuthatch runs with facility upon and about the trunks and branches of trees; but the tail, which is short and rounded, is of no assistance to the bird in its progress. Unlike the Woodpeckers, however, the Nuthatch runs with the head downwards as well as upwards, and indeed the former position of the head appears to be the favourite one; it generally alights on a branch with the head in the downward position, and sleeps in that posture. It is almost constantly in motion. Its food consists of insects and their larvæ, berries, and nuts. The latter it fixes in some chink, and cracks them by repeated strokes of the bill. "It is a pretty spectacle," says Willughby, "to see her fetch a nut out of her hoard, place it fast in a chink, and then, standing above it, with its head downwards, striking it with all its force, break the shell and catch up the kernel." The same author found beetles in the muscular stomach or gizzard of one opened by him. The fihbert gives the Nuthatch but comparatively little trouble; but the more

denae hazel-nut calls forth greater energies, and when employed upon one of those nuts, the bird makes the neighbourhood resound with the strokes of its bill. Its call-note in the spring is a clear shrill whistle. The nest is generally made with only a few dry leaves in the hole of a tree, and the eggs, which are from five to seven in number, are of grayish-white spotted with reddish-brown. If the hole selected be too large, the bird plasters up a part of it with mud, and will renew the plaster if destroyed, whence one of its French names.

The female, when surprised on the eggs or her young, makes a most determined defence with bill and wings, hissing at the intruder violently at the same time. It seems indeed to be a very attached bird. The old French quatrain says—

“Le Torchepot et sa femelle ensemble
Vivent en paix tout le long de l'Esté.
Parquoy l'on dit, que qui est arrêté
A son mesnage au Torchepot ressemble.”

Of its bravery and courage when made captive, a painful story is told in the ‘Magazine of Natural History.’ A Nuthatch had been winged by a sportsman, and was put into a small cage made of oak and wire. During a night and day, the period of his confinement, his tapping labour was incessant, and at the end of that time the wood-work of his prison was pierced and worn like worm-eaten timber. His impatience of his situation was excessive; his efforts to escape were unremitting, and displayed much cunning and intelligence. He was fierce and fearlessly familiar, and voraciously devoured the food placed before him. His hammering is described as having been peculiarly laborious, for he did not peck as other birds do, but taking a firm grasp with his great feet, he turned upon them as upon a pivot, striking with his whole weight, and thus assuming with his body the appearance of the head of a hammer in motion. This unfortunate bird sank at the close of the second day under the combined effects of his vexation, assiduity, and voracity. The Rev. T. L. Bree mentions one which he caught in a common brick-trap: when the bird was found, the bill appeared to be truncated, and he inferred that it had been fairly ground down to about two-thirds of its original length by the pecking of the bird at the bricks in its efforts to escape.

This bird is an inhabitant of Europe generally.

Mr. Gould describes and figures two other species, *S. rupestris* and *S. Asiatica*, in his ‘Birds of Europe.’

The genus is found in India and America; and there are closely allied forms in the Indian Archipelago and in Australia.

SIUM, a genus of Plants belonging to the natural order *Umbelliferae*. The calyx possesses 5 teeth or is obsolete; petals obcordate, with an inflexed point, or entire and ovate; fruit laterally compressed or contracted, and subdidymous, crowned with the reflexed styles with their depressed bases; carpels with 5 equal filiform rather obtuse ridges, of which the lateral ones are marginal; interstices with one or many vittæ; seed subterete. The universal involucre varies; the partial one is composed of many leaves.

S. Sisarum, Skirret, is the best-known plant of this genus. The root is composed of fascicles of fusiform tubers; stem terete; leaves pinnate, upper ones ternate; leaflets ovato-lanceolate, acute, serrated; involucre of 5 reflexed leaves; commissure, according to Koch, with 4 vittæ. It has white flowers. The tubers of the root are about the size of the finger, and were formerly greatly esteemed in cookery, but are now gone much into disuse. The French call this plant *Chervis*, the Germans *Zucker-Wurzel*, and in the north of Scotland, where it is much eaten when cooked, it is called *Crummock*. It is a native of China.

S. nodiflorum, Fool's Water-Cress, or Procumbent Water-Parsnip, possesses a rooting, procumbent, striated stem; pinnate leaves, oblong equally serrated leaflets; umbels sessile, opposite the leaves. It is a native of Europe, in ditches and rivulets, and is common in Great Britain. A small and large variety are recorded, the one not attaining more than three or four inches in height, the other as many feet.

S. latifolium, Broad-Leaved Water-Parsnip, has oblong-lanceolate leaflets, equally serrate, pointed; umbels terminal. It is found in ditches and watery places in Great Britain.

S. angustifolium, Narrow-Leaved Water-Parsnip, has an erect stem; leaflets unequally lobed and serrated, umbels pedunculate, opposite to the leaves. It is common in Great Britain.

SIVATHERIUM (from Siva, an Indian deity), a genus of extinct animals belonging to the family *Elephantidae*. The remains of species of this remarkable genus were found by Dr. Falconer and Colonel Cautley in the valley of Mackanda, in the Sewalik Hills of the Himalaya.

Two species of this genus, *S. giganteum* and *S. Perimense*, have been described. A cranium, lower jaw and teeth, and bones of the extremities of *S. giganteum* are now in the British Museum. The skull of this animal is nearly as long as that of the Elephant, the neck was shorter and stronger than in the Giraffe. The posterior portion of the skull is greatly developed, and formed of cellular cavities, as in the Elephant. “The face is short, and the nasal bones are remarkable for the manner in which they are prolonged into a pointed arch above the external nostrils, indicating a trunk, or proboscis. The very inclined direction of the front of the face in relation to the triturating surface of the teeth, imparts a physiognomy altogether peculiar. Two horns arise from the brow between the orbits, and diverge from

each other, and it is probable that the posterior protuberances of the forehead also supported a pair of short massive horns.” (Mantell.)

When living the Sivatherium must have resembled an immense Gnu, or Antelope, with a short thick head surmounted with two pairs of horns. The front pair of these horns were small, whilst those behind were probably palmated. The eyes were small, and it had a nasal proboscis, an organ unknown amongst the *Ruminantia*.

(Mantell, *Petrefactions and their Teachings*; *Journal of the Asiatic Society*.)

SKAPOLITH. [SCAPOLITE.]

SKATE. [RAIIDE.]

SKELETON (from *σκελεω*, ‘I dry,’) is the name applied to those harder parts of organised bodies which form the framework upon which the softer tissues are fixed. It is more particularly applied to the collection of bones which in an animal either serve as fixed points for the attachment of the soft parts, or form cavities for inclosing and protecting important organs, or constitute the apparatus of support and the passive instruments of voluntary motion.

In this article we shall confine ourselves to the description of the bones as they are found in the human body. In the article **VERTEBRA** will be found an account of the common plan of the Vertebrate Skeleton of Man, in relation to the lower animals, as well as of the plan on which the skeleton is constructed in the higher and lower animals.

The human skeleton is divided into three principal parts: the Trunk (2), the Head (1), and the Extremities (3 and 4). Neither the whole number of bones composing it nor that in each main division can be exactly stated, for many which are in early life separated, are subsequently united; but as an approximation, the following enumeration may be adopted:—Cranium, 8; face, 14; internal ears, 8; vertebral column, 24; chest, 26; pelvis, 11; upper extremities, 68; lower extremities, 64: in the whole, 223.

Fig. 1.

The Trunk is composed of the spine, or vertebral column (extending from *a* to *d* in the annexed fig. 2), the chest, including the ribs and sternum or breast-bone (*c*), and the pelvis, the circle of bones on which the spine rests. The spine is the column of bones which, in the erect posture, supports the head on its summit (*a*), and rests with its base (*d*) upon the sacrum. It consists of 24 bones, called vertebrae (from ‘*verto*, I turn), because it is their motion upon each other which enables the trunk to be turned round. Of the 24, the 7 upper (*a-b*) are called cervical, the 12 middle (*b-c*) dorsal, and the 5 lowest (*c-d*) lumbar vertebrae. With the exception of the

first two, they are all connected by interposed discs of a very elastic substance, the intervertebral cartilages.

Fig. 2.

The general characters of the Vertebrae may be best studied on one from the lumbar region; in which the following parts, common to nearly all of the 24, are well marked:—a body, a ring, a spinous process, two transverse processes, four articulating processes, and four notches. In the annexed plate two lumbar vertebrae are represented: that in the figure A, as seen obliquely from behind, from above, and from the right side; and that in the figure B, as seen from above and behind.

Fig. 3.

The Body (1) is a disc of bone with a nearly oval outline, larger above and below than at its middle, and having its greatest dimension from side to side. Its texture is spongy, invested with a thin layer of compact tissue. Its upper and lower surfaces, by which it is affixed to the two adjacent intervertebral cartilages, are nearly flat, and slightly marked by radiating lines. At its posterior border the oval outline is interrupted by a slight concavity (2), which forms a portion of the ring surrounding the spinal marrow, and in which there are several apertures larger than those on the rest of the body, for the exit of the veins from the interior.

To either side of the posterior part of the body, and near its upper border, is affixed one of the extremities of the arch (3) by which the

ring is completed behind. It is composed of two flat laminae, which spring from the sides of the body, and meet at an obtuse rounded angle in the middle line behind, where they bear the spinous process (5). The space (4) included between the body and these laminae is called the vertebral foramen; it is occupied by the spinal cord; it is of a somewhat triangular form, and in the lumbar vertebrae is of large size.

Close to the attachments of the laminae to the body there is in each of their borders a rounded notch (6); and when the vertebrae are applied one on another, these notches form oval holes (the intervertebral foramina, see next figure (8), through which the spinal nerves pass, one pair going out between each two vertebrae. [NERVOUS SYSTEM.] To the rest of the laminae are attached the interlaminae ligaments, or ligamenta subflava, bands of very elastic tissue by which the spaces between the adjacent arches are filled up, and the spinal canal completed behind, as it is by the intervertebral cartilages before.

The Spinous Process (5) is a broad flat quadrilateral portion of bone directed horizontally backwards from the meeting of the laminae. Its posterior border is thickened, and to it, as well as to the upper and lower borders, are attached strong ligaments binding the spinous process of each vertebra to those next above and below it. The transverse processes (7) project horizontally outwards on either side; they are thin and long, and are enlarged and rough at their ends, to which several strong muscles and ligaments are attached. The articulating processes are flat and oval; each has a smooth surface, by which it is connected with the corresponding part of the next vertebra above or below. The upper pair (8) are set most widely apart, and their articulating surfaces are concave and turned inwards; the lower pair (9) are nearer together, and have their articulating surfaces turned outwards. When the lumbar vertebrae are put together, the lower processes of each are locked within the upper processes of the one next below, so that scarcely any lateral or rotatory motion is in this part of the spine possible.

The Dorsal Vertebrae, which in the adjacent plate are drawn, as seen in A and B, from behind and from the left side, and in C from

Fig. 4.

before and from the same side, have the same general characters as the lumbar, but are distinguished from them by the following:—

The body (1) is small but deep, and longer from before backwards than in any other direction; its general outline is heart-shaped; it has at each border, just in front of the attachment of the laminae, a shallow depression (2); and when the vertebrae are set together, the depressions on either side of each adjacent pair form one cavity, into which the head of one of the ribs (O 3) is received for articulation. The laminae are broad and thick; the vertebral foramen is oval and small. The spinous process (5) is long and narrow, and projects obliquely downwards; those of adjacent vertebrae are imbricated at their bases (fig. B). The transverse processes (6) are long and directed backwards as well as outwards; each of them (except those of the two last vertebrae) has a smooth surface in front of its outer extremity, by which it articulates with the tubercle of the corresponding rib. The articulating processes (7), both superior and inferior, are equally wide apart; the former have their smooth surfaces turned backwards, the latter theirs forwards. The notches and foramina are smaller than in the lumbar vertebrae.

The Cervical Vertebrae, of which one is represented in the following cut, as seen from behind and above, are distinguished by the body (2) being small, broad, and shallow, and wider above than below. In its

upper surface also it has two elevations (1), between which the lower part of the vertebra next above is received. The laminae (3) of the arch are long and narrow, and inclose a large somewhat triangular vertebral foramen (4). The spinous process is short and bifurcated. The transverse processes (6) are short, horizontal, and bifurcated; and each has a foramen at its base, through which the vertebral artery passes. The superior articular processes have their smooth oval surfaces directed backwards and inwards, and they receive between them the inferior processes of the vertebra next above, whose articular surfaces are turned in the opposite direction.

But these distinctive characters of the several sets of vertebrae are only general: they are merged at the extremes of each set, the lowest dorsal being very like the upper lumbar, and the upper dorsal like the lowest cervical. Some single vertebrae, moreover, have particular characters. The first of the cervical set, or Atlas, is scarcely more than a flat ring of bone with two long transverse processes, two superior articulating processes, with large oval concave surfaces opposed to those of the occipital bone, and two inferior, with large flat horizontal surfaces, which articulate with those of the second vertebra. By the former joint the chief movements of depression and elevation of the head upon the neck are permitted; by the latter, those of rotation. The second cervical vertebra (named Axis, or Vertebra Dentata) has a large pointed process, which rises from the upper part of its body, and is inclosed in a ring formed by the anterior half of the Atlas, and a transverse ligament passing from one side to the other of its body. In this ring the process of the Axis rotates freely; or rather, the Atlas, with the head supported on it, moves round that process, and upon the flat superior articulating surfaces of the Axis. The seventh cervical vertebra has a remarkably long spinous process, to which is attached the Ligamentum Nuchae, a strong elastic band for the support of the head when inclined forwards, but which, as well as the spinous processes of all the adjacent vertebrae, is much more developed in animals that move horizontally and graze, than in man. This vertebra is also marked by having a small rib-like process in front of its transverse process; it is a rudimentary rib, and is analogous to the cervical ribs of serpents and many other animals in whom the chest is more elongated than in man. The first and the last three dorsal vertebrae have each, at the upper borders of the body, surfaces for articulation with the whole head of the corresponding rib. The fifth lumbar has its lower surface cut obliquely upwards to articulate with the top of the sacrum and form the promontory of the pelvis.

Viewed as a whole, the human vertebral column forms a kind of pyramid with its base at the sacrum, and its truncated summit at the head. It is not however regularly pyramidal; for, as seen from the front, it becomes gradually smaller from the base to the fourth dorsal vertebra; then it widens to the seventh cervical, and then again becomes narrower to the second. In the adult it has well-marked curvatures. (Fig. 2.) From the head it is first curved slightly forwards to the last cervical vertebra; then its dorsal portion forms an arch with its convexity backwards and ending at the last dorsal; and then again in the lumbar region it arches forwards to the base of the last lumbar vertebra. These directions of the column have relations to the naturally erect posture of the human body [MAN]: in correspondence with them the bodies of the cervical and lumbar vertebrae, and their intervertebral cartilages, are thicker before than behind, and those of the dorsal thicker behind than before.

The Spine serves several offices in the economy. One is that of guarding the spinal marrow, which, with the roots of its nerves, is inclosed in the long canal formed by the superposed rings of the several vertebrae. The spino-cerebrate form of nervous system, which consists of a brain and longitudinal axis, both placed on the same side of the digestive canal, is intimately connected with all the rest of the organisation of the animals in which it exists; and being always inclosed in a skull and spinal canal, the vertebral column is taken as the most obvious character of the four classes of animals which have this plan of nervous system. These therefore, namely, Mammals, Birds, Fish, and Reptiles, are called *Vertebrata*; and the other portion of the animal kingdom, whatever be the plan of their nervous centres, *Invertebrata*.

The spine is also the main support of all the rest of the skeleton. The head, the ribs, and the pelvis directly articulate with it; and through the medium of the pelvis and sternum, it suspends both the lower and upper extremities. It is the passive instrument of all the motions of the trunk, and the centre about which each of the limbs as a whole is moved. For these purposes it is adapted by combining

firmness with flexibility and lightness. Flexibility is obtained by its being composed of so many pieces separated from each other by layers of elastic tissue; and its strength is secured by these layers, which are at the same time firm bonds of union, and by numerous other strong ligaments passing from bone to bone. In its own movements, extent is combined with security by each vertebra (except the first) having but little motion on those next to it; the larger movements being the result of the combination of a number of such small ones. The directions of the processes and the diverse modes in which they are locked one within another, determine the degrees in which, in each part of the column, the several motions of flexion and extension in all directions, and of rotation, can be performed. The pyramidal form of the whole is adapted to the accumulated weight which the lower vertebrae have to bear. The curvature in the back increases the capacity of the chest. The spinous and transverse processes especially serve for the attachments of muscles of the head, chest, back, shoulders, and pelvis. The elastic cartilages interposed between the bodies break the shock of any violence upon one end of the body, and both they and the interlaminar ligaments tend to keep the spine straight, and so diminish the muscular action necessary to hold the body erect.

The base of the spinal column rests on the top of the Sacrum (fig. 2, 5), which, though commonly described as part of the pelvis, is indeed a continuation of the column, and is composed of five or six rudimentary vertebrae, which after about the tenth year become consolidated. The Sacrum (fig. 6, A) has a triangular outline, the base being above; and it articulates with the last lumbar vertebra, so as to form an obtuse angle, the promontory, by means of an intervertebral substance and the other parts common to the rest of the vertebral joints. Its anterior surface, which in the erect posture looks obliquely downwards, is concave, and on it are four or five transverse lines, the traces of the divisions between the bodies of the original vertebrae. At each end of these lines are as many holes (the anterior sacral foramina), which give passage to the anterior branches of the sacral nerves. Outside these holes the Sacrum has a smooth surface composed of the coalesced transverse processes of its several vertebrae. Along the posterior convex surface the Sacrum presents corresponding traces of its composition. Its upper border is surmounted by two regularly-formed articular processes, which are connected with those of the last lumbar vertebra, and leading downwards from these, in converging lines on either side of the middle, is a series of slight elevations, the traces of other rudimentary articular processes. Along the middle line are three or four higher ridges, the traces of spinous processes, and between these and the former are on either side four or five foramina, which give passage to the posterior branches of the sacral nerves. These and the anterior sacral foramina already mentioned are analogous to the intervertebral foramina; and they both lead into the sacral canal, which runs through the whole length of the Sacrum, and contains the cauda equina, or tuft of the last roots of the spinal nerves. The outline of the sacral canal is triangular; it grows smaller from above downwards, and is closed in behind by a layer analogous to the arches of the regular vertebrae. It is continuous above with the spinal canal, and below is, in the dry bones, open in the middle line, the arch of the last sacral vertebra being deficient; but in the recent subject is closed by dura mater and dense ligament. The sides of the Sacrum are thick above, and become gradually thinner below. In the former situation they are marked by large rough oval surfaces, directed backwards and somewhat outwards, by which the Sacrum is on either side articulated immovably with the iliac bones to form the sacro-iliac symphyses. The lower end of the Sacrum has a plain oval surface, which is fitted to the upper surface of the first bone of the coccyx.

The Coccyx is the lowest part of the whole vertebral column. Its bones form the interior frame of the tail in brutes, but in man are small, short, and not more than four or five in number. The uppermost is by far the largest, and is surmounted by two processes called Cornua, the extremities of which are adapted to those of two similar processes by which the sides of the lower end of the sacral canal are bounded. The three or four lower pieces of the Coccyx have a somewhat oval outline, and are rather deeper than they are broad. Up to a late period of life they are articulated moveably with thin layers of interposed cartilage.

The Sacrum and Coccyx form the middle posterior part of the Pelvis; its sides and front are formed by the bones called Ossa Innominata (fig. 6, B). Each of these is in the young subject composed of three parts, which are usually described separately, as the Ilium, or Haunch-Bone (a), the Ischium (b), and the Pubes (c). These three meet at the acetabulum (1), the hemispherical cavity in which the head of the thigh bone is lodged, and of which the Ischium forms nearly three-fifths, the Ilium somewhat more than one-fifth, and the Pubes rather less than one-fifth.

The Ilium forms the upper broad and expanded part of the Pelvis. Its outline is somewhat fan-shaped, and in the greater part of its extent it is flat and thin. That surface which is directed forwards and inwards towards the cavity of the pelvis is slightly concave, and gives attachment to the strong iliac muscle by which the thigh is raised towards the pelvis. Its upper border has a thick strong rim (2), the crista ili, to which parts of the three broad muscles of the abdomen are attached, and which serves for a fixed point towards

Fig. 6.

which the ribs are drawn down by those muscles in strong expirations. The extremities of this rim, and the anterior and posterior edges of the ilium, into which it is continued, have at either end two strong projections for the attachment of muscles of the thigh, which are named Spinous Processes. In *fig. 6*, 3 is the anterior superior, and 4 the anterior inferior spinous process; 5 is the posterior superior spinous process, and 6 the posterior inferior. At the posterior part of the inner aspect of the ilium is a rough oval surface, which is fixed behind that at the back of the sacrum, with which its fore part forms the sacro-iliac symphysis. (*Fig. 2*.) From the upper part of this symphysis a line, continuous with that of the top of the sacrum and the promontory of the pelvis, passes in a curve across the lower part of the ilium to the upper and inner edge of the pubes, along which it is continued to the middle line at the symphysis pubis. This line, by which the pelvis is divided into an upper and a lower cavity, is called the Brim, and the space it incloses is named the Upper Strait of the Pelvis. (*Fig. 2*.) At and just below the brim is the thickest part of the ilium; its inner surface, which is opposite the acetabulum, is smooth, and gives attachment to muscles of the pelvis and thigh. The outer and back surface of the ilium (which is represented in *fig. 6*, B) forms the Haunch, that is, that expansion of bone which is felt above the hip-joint. It is marked by curved lines for the attachment of the strong glutei muscles of the buttock, and of the ligaments connecting it with the sacrum and last lumbar vertebra. At its lowest and narrowest part it swells outwards, and is then suddenly and deeply hollowed, to form the upper part of the wall of the acetabulum. In this cavity it is united with the pubes before, and the ischium behind, by flat surfaces, which in the adult bones are indicated only by slightly elevated lines tending to the deepest part of the cavity.

The ischium is the bone on whose lowest part, or tuberosity, the body rests in sitting. It is described as composed of two principal portions: a body (7), consisting of the tuberosity and the thick strong part above it; and a ramus (8), which passes from the tuberosity obliquely upwards, forwards, and inwards. The upper part of the body is united to the lower part of the ilium, and its outer and anterior surface is deeply hollowed to form the lower and back part of the acetabulum. At its posterior and inner border there is a strong pointed process, the spine of the ischium (9), to which one of the main ligaments of the pelvis, the lesser sacro-sciatic, is attached. Above the spine, the body of this bone and the adjacent posterior border of the ilium, as far as its posterior inferior spinous process, are cut out in a crescentic form; they thus form the ischiatric notch, and, with the ligament just mentioned and the outer border of the sacrum, inclose an oval aperture, the great ischiatric foramen, through which there pass from the pelvis to the thigh the pyriform muscle, and the gluteal, ischiatric, and pudic blood-vessels and nerves. Below the spine, another foramen, the lesser ischiatric, is inclosed between the same and another stronger ligament, the great sacro-sciatic, and the lower part of the body of the ischium; through this, together with some vessels and nerves, passes the internal obturator muscle, which, on its way to the femur, winds round a smooth oval surface on the back of the ischium directly below its spine. The posterior thick surface of the body is rough, for the attachment of muscles, especially those of the hamstrings, which form the greater part of the back of the thigh. From the lowest part of the tuberosity, and forming an acute angle with it, ascends the ramus, which at its anterior extremity (10) unites with the descending ramus of the pubes.

The Pubes forms the anterior part of each os innominatum, and is composed of a body (11), and a descending ramus (12). The body is the upper, anterior, and larger part. At its outer extremity it articulates with the ilium just below the anterior and inferior spine, from which it descends in an even gentle curve, over which the iliac and psoas muscles, the chief vessels, and one of the principal nerves of the thigh, pass beneath the crural arch. Its outer end is hollowed to form part of the acetabulum. The horizontal part of the body has a somewhat pyramidal form with three sides. Along its posterior and upper

border is the line which forms part of the brim of the pelvis. Near the termination of this line is an elevation, the spine of the pubes, for the attachment of one end of the crural arch, the strong ligament already mentioned, whose other end is fixed to the anterior superior spine of the ilium. The inner ends of the bodies of the two pubic bones are opposed by flat oval surfaces, which, with ligaments and a strong intermediate cartilage, form the symphysis pubis. From below and on the side of this, the ramus descends outwards and backwards to meet the ascending ramus of the ischium, with which it forms one flat and thin beam. Between these rami below, the body of the pubes above and on the inner side, and the meeting of the pubes and ischium at the acetabulum on the outer side, is an oval aperture, the foramen ovale or obturatorium (13), which in the recent body is nearly closed by the obturator ligament, and of which the borders, as well as the surfaces of the ligament, give attachment to the two obturator muscles, which thence proceed to the back of the thigh-bone, which it is their office to rotate outwards. The space included between the rami of the pubes and ischia on either side and in front, and the great sacro-sciatic ligaments, passing from both borders of the sacrum and coccyx to the tuberosities of the ischia, behind, is named the Lesser Aperture, or Strait of the Pelvis. The meeting of the two rami in the middle line makes the angle of the pubes.

The general purposes served by the pelvis are—to support the abdominal viscera, to inclose and guard those in its own cavity, to give insertion to muscles of the abdomen, back, and thighs, and to be such an intermedium between the rest of the trunk and the lower limbs that the latter may move freely and yet firmly support the body. In all its dimensions it is larger in women than in men.

The last main division of the trunk is the Chest, or Thorax, composed of the dorsal vertebrae behind, the sternum in front, and the twelve ribs and their cartilages on either side. (*Fig. 7*.) All the Ribs articulate with the Spine, but only the seven uppermost on each side have distinct connections with the sternum; these are therefore called True Ribs, and the five lower on each side False Ribs. Of these last the three upper have their cartilages united before they reach the sternum; and the two lower, which are sometimes called Floating Ribs, have short cartilages, which are not attached to the sternum at all.

Fig. 7.

In each of the greater number of the Ribs there are a head, a neck, a tuberosity, an angle, a body or shaft, and a cartilage. The head is that part which articulates with the vertebral column. It is larger than the neck, and its articulating surface has a somewhat oval outline, and is divided into two parts by a transverse elevation. This elevated line corresponds to the intervertebral cartilage, to which it is affixed by a ligament. The motion permitted at the joint between the head of the rib and the border of each of the vertebrae next above and below it is not extensive; but it is sufficient to give the body of each rib, which has the relation of a long lever to the joint as a fulcrum, a wide sweep outwards and upwards in the act of deep inspiration. Proceeding outwards from the head, and passing over the neck, which is the smallest and roundest part of the rib, the next object is the tubercle, an elevation on the posterior surface, by which the rib is articulated with the end of the transverse process of the vertebra next below it. Farther outwards is the angle, an oblique projecting line at which each rib turns somewhat more upwards and becomes flatter. The remainder of the rib is its shaft. This is thin and flat; its surfaces are both nearly smooth, the outer being slightly convex, the inner as slightly concave; the upper edge is rounded; the lower (which is also directed somewhat outwards) is sharp, and, from the angle inwards, is grooved on its inner aspect, where the intercostal vessels and nerves lie. The end of the osseous part of each rib has a rough surface, to which is adapted one end of the costal cartilage, of which the other end (except in the instances already mentioned) is attached to the sternum. The costal cartilages have each the same general form and direction as the part of the rib to which they are

appended; they may be regarded as mere prolongations of the ribs, the purpose of their being cartilaginous instead of bony being that of giving more elasticity to the walls of the chest. Each of them, except the first, is articulated with a slight capacity of motion to a depression on the border of the sternum.

The Sternum, or Breast-Bone, is single only in the adult; in youth it is composed of at least two pieces (of which the upper, *fig. 8, A*, is named Manubrium), and in the fœtus of many more. Considered as one bone, its form is elongated, broader and thicker above than below, where it terminates in a long narrow process, which is generally carti-

Fig. 8.

laginous, and is named the Ensiform or Xiphoid Cartilage (B). The anterior surface of the sternum is marked by four transverse lines (3, 4, 5, 6), which indicate the divisions between the five principal parts of which it is composed. These marks are repeated on the posterior surface. Along its borders, there are (proceeding from above downwards), first, at each of the angles between its upper and lateral edges, a shallow depression (1), into which the extremity of the clavicle is received; then immediately below this an oval depressed surface (2), to which the cartilage of the first rib is fixed; and lastly,

Fig. 9.

along each side six other similar surfaces separated by notches, with which the cartilages of the six following ribs articulate. Of these six, NAT. HIST. DIV. VOL. IV.

the upper four are placed at the ends of the transverse lines; so that each of these ribs articulates at its sternal end with two pieces of the sternum, just as, at its other extremity, it articulates with two vertebrae. [RESPIRATION; LUNGS.]

The Bones of the Skull are divided into two chief sets—those of the Cranium, or case for the brain, and those of the Face. They are represented in the annexed sketches separated, yet in their natural relative positions, in three different aspects: in *fig. 9*, as seen from the front; in *fig. 10*, as seen in profile; in *fig. 11*, as seen when, after removing the top of the skull, one looks from above upon the bottom of its interior.

The Bones of the Cranium are—the Frontal (*a*), the two Parietal (*b*), the two Temporal (*c*), the Occipital (*d*), the Sphenoid (*e*), and the Ethmoid (*f*); those of the face are—the two Nasal (*g*), the two Superior Maxillary, or Upper Jaw-bones (*h*), the two Palate, the two Malar (*i*), the two Lachrymal (*j*), the two Inferior Turbinate, the Vomer (*k*), and the Inferior Maxillary (*l*).

Fig. 10.

Fig. 11

The Frontal Bone (*fig. 12, a, b*) forms the Forehead and the roof of the Orbit. The front or frontal portion is the larger. Its anterior surface, which is represented in *fig. 9*, is convex and smooth; it is bounded below by two arched, thick, and rounded borders, separated by a rough notch in the middle line. The borders (1, 1) are called

the orbital arches or ridges, and they form the front and prominent part of the orbita. The notch (2) is named the nasal notch; on either side of it are fixed parts of the upper jaw, and in the middle the nasal bones, which rest behind on a process called the nasal spine (3). At the outer extremity of each orbital arch is the external angular process (4, 4), and at the inner extremity the internal angular process (5, 5); the former is articulated with the malar, the latter with the upper jaw and lachrymal bones. Near the internal process is the Supra-Orbital Foramen, or notch (6, 6), through which the frontal vessels and nerve pass from the orbit to the forehead. Just above it, and by its side, is a rounded elevation, the frontal protuberance (7), which marks the situation of the subjacent frontal sinuses, air-cavities, between the two layers of which the bone is composed. They vary much in size in different persons, and communicate with the interior of the nose. On either side of the middle line, and extending above the orbital ridge, the surface of the bone is again elevated in the superciliary ridge (8, 8), an arched prominence behind the eyebrow. The rest of this anterior surface is smooth and even, but in different persons its form is as varied as that of any other feature. On either side it terminates rather abruptly with a curved border (9), which forms the front boundary of the temporal fossa (10), and behind which there is a smooth surface, to which the fore part of the temporal muscle is attached.

The posterior or cerebral surface of the Frontal bone (*fig. 12, b*) is concave. Along the middle line there is a broad groove (1), in which a part of the longitudinal sinus [BRAIN] lies; and at the fore and

Fig. 12.

lower end of this a ridge, to which a process of dura mater called the Falx is attached. The ridge ends at a hole named the Foramen Cæcum. The rest of this surface is marked by depressions and ridges fitting to the convolutions of the surface of the brain.

The orbital portions (b, 3, 3) of the frontal bone are thin plates extending almost horizontally backwards from the orbital arches. Between their inner borders is a space, the ethmoid notch, into which the ethmoid bone fits, and just anterior to which are the apertures (4, 4) leading into the frontal sinuses. The nuder surface of each plate is concave, smooth, and even; and has at its outer and fore part a shallow depression, in which the lachrymal gland is lodged, and at its inner and fore part a mark to which the pulley of the trochlearis muscle of the eye is attached. The upper surface is marked in correspondence with the irregularities of the under part of the anterior lobe of the brain, which rests upon it.

The posterior and upper margin of the frontal bone (b, 5, 5) is joined by the coronal suture to the two parietal bones; and it is cut obliquely in such a manner that its edges rest upon theirs above, and their overlap its below. The lower part of this margin is covered by the ala of the sphenoid, where they rise into the temporal fossae. The frontal is usually in the adult only a single bone, composed (as all the bones in the middle plane of the skeleton are) of two equal and similar halves: these are developed separately, and they sometimes remain undivided by a continuation of the sagittal suture which passes from between the two parietal straight down the middle of the frontal.

The construction of the Parietal Bones, which form all the upper and middle part of the skull, is very simple. In *fig. 13, a* the

exterior, and at *b* the interior, of the right parietal is represented. They are quadrilateral, and of nearly equal thickness throughout. The outer convex surface is everywhere smooth, except at its lower border (1), where it is overlapped by the temporal bone in the squamous suture, and just above this part, where there is a slight arched ridge (2) for the attachment of a portion of the temporal

Fig. 13.

muscle. The inner concave surface has impressions of the cerebral convolutions, and a deep branching groove, which, beginning at the fore and lower angle (3), thence ramifies diffusely. It lodges the middle meningeal artery of the dura mater. [BRAIN.] Along the upper border is a broad shallow groove (4), which lodges part of the longitudinal sinus, and is continuous with that on the interior of the frontal bone. The borders of the parietal bones are all, except the lower, deeply and irregularly indented; and by the dove-tailing of such irregular teeth they form, with the frontal bone in front, the coronal suture, with the occipital behind, the lambdoid, and, in the middle line at their own meeting, the sagittal.

The Temporal Bones (*fig. 14, a* as seen from without) are placed in the middle, lateral, and inferior parts of the skull. They present each three distinguishable parts, which in the foetus are separated—namely, a Squamous portion (1), which forms the middle of the side of the skull; a Mastoid portion (2), which forms the thick protuberance that may be felt behind the ear; and a Petrous portion (not visible in *fig. 14*, but in *fig. 11* marked *c*), which passes from the lower part of the squamous forwards and inwards in the base of the

Fig. 14.

skull. The squamous bone or portion has a roundish form. Its upper edge covers in the lower border of the parietal. Its exterior surface is smooth, and gives attachment to some of the temporal muscle. At the hinder part of its lower border is an oval aperture (3) leading to the Meatus Auditorius Externus [EAR], a passage which goes forwards and inwards to the tympanum in the interior of the petrous portion. Immediately anterior to this, and under the fore part of the bone, is the Glenoid Cavity (4), a deep transversely oval hollow, with which the condyle of the lower jaw is articulated, and behind which is a narrow chink, the Fissura Glaseri, separating it from a strong ridge which runs along the upper surface of the petrous bone. In front of the glenoid cavity is a prominence, which forms its border, the Tuber Articulare (5); and from its outer part there proceeds horizontally forwards, as if springing from the tuber and two other slightly elevated lines running backwards, a long narrow portion of bone, the Zygomatic Process (6), the enlarged end of which joins a short process of the malar bone to form the Zygoma, an arch beneath which the temporal muscle plays, and whose size and strength are generally in direct proportion to those of that muscle, and to the force with which the lower jaw is worked in gnashing with the teeth.

Behind the meatus auditorius is the Mastoid portion. It is prolonged downwards in a strong conical projection, the mastoid process (7) giving insertion to muscles upon and just above it, and of which the interior is occupied by numerous cells communicating with the cavity of the tympanum. Behind and within the mastoid process is the digastric groove, to which the muscle of the same name is attached; and farther back another more shallow groove for the trachelo-mastoid muscle.

The cerebral surface of the Squamous Portion has a very obliquely cut and grooved upper border, which articulates with the lower border of the parietal bone. On the same surface of the mastoid portion is a deep fossa, which lodges part of the lateral sinus. Both are marked by the impressions of the brain.

The Petrous Process or portion of the temporal bone (*fig. 11, c*) has received its name from the peculiar hardness of its tissue. It has the form of an irregular three-sided pyramid, directed from either side forwards and inwards, and fitting, at the base of the skull, into the angle left between the sphenoid and the occipital bones (*c* and *d*). Its base is affixed to the interior and lower part of the squamous bone; its summit fits in the apex of the angle just mentioned. On its posterior surface the most prominent object is the oval aperture of the meatus auditorius internus, the passage leading to the internal ear, and traversed by the auditory and the facial nerves. On the anterior surface there are a shallow groove leading to a small hole, through which the Vidian nerve and bloodvessels pass, a slight hollow on which the Gasserian ganglion of the fifth pair of nerves lies, and a prominence which indicates the position of the superior semicircular canal of the ear. On the inferior surface, which is placed outside the skull, there are seen, at the posterior and outer border, a deep fossa (the Jugular), in which the upper part of the internal jugular vein is lodged; before and on the inner side of this, and separated from it by a prominent ridge, a large oval aperture, through which the internal carotid artery passes into a tortuous canal, whose other extremity is at the very apex of the bone; between the jugular fossa and the mastoid process a hole, the Stylo-Mastoid Foramen, through which the facial nerve passes on its way to the face, after penetrating the bottom of the meatus auditorius internus; and just anterior to this, a long pointed process, the Styloid (8), to which several muscles and ligaments are attached, and whose base is surrounded by an irregular sharp-edged elevation, the Vaginal Process (9).

The anterior border of the Petrous Bone is articulated with the posterior part of the ala of the sphenoid, leaving an intermediate space, named Foramen Lacerum Medium; the posterior border is similarly united with the side of the basilar process of the occipital bone, leaving another space, the Foramen Lacerum Posterius, through which the internal jugular vein and the nerves of the eighth pair pass. Near the angle where the anterior border joins the squamous bone is an irregularly-shaped aperture, to which the cartilaginous part of the Eustachian tube is affixed.

The small bones of the internal ears, and all the other parts of the organ of hearing, which lie within and near the petrous bone, are described in the article EAR.

The Occipital Bone (*fig. 15* is a view of the internal surface) forms the posterior and lower part of the middle of the skull, a portion being at the outer wall and a portion at the base. Its lower and

Fig. 15.

anterior part is narrow, and has a rough surface (1) in front, which is united with the body of the sphenoid bone. Viewing it at its internal surface, it presents, as one proceeds from this surface backwards and upwards, a smooth hollow surface, which gradually widens, and is limited behind by a large oval opening. The surface 2 is that of the Basilar Process, in which the medulla oblongata and pons varolii [BRAIN] rest; the aperture 3 is the Foramen Magnum, through which the medulla passes into the spinal canal, where it is continued into the spinal cord. By the sides of this foramen, near where the basilar process joins the back and expanded part of the bone, there are four foramina, two on either side—the anterior and posterior Condylod

Foramina, of which the anterior transmit the hypoglossal nerves, on which the motions of the tongue depend, and the latter give passage to veins communicating with the vertebral veins. Opposite the fore part of the foramen magnum the basilar process suddenly widens into the greater portion of the occipital bone, which forms the back of the head. In this part are four large hollows (4, 4, 5, 5), of which the two upper lodge the surfaces of the posterior lobes of the cerebrum, the two lower those of the lobes of the cerebellum. They are separated by two ridges, which bisect each other at nearly right angles. The upper part of that which runs vertically has attached to it a portion of the falx major, and to its lower part is affixed the falx cerebelli; that which runs transversely gives insertion to the back part of the tentorium cerebelli, whose anterior borders are fixed to the upper angles of the petrous bone. By these ridges are broad shallow grooves, which lodge parts of the sinuses of the brain. By the upper half of the vertical ridge is the extremity of the longitudinal sinus, the grooves for which, in the frontal and parietal bones, have been already mentioned, and which, at the internal occipital spine, where the ridges bisect each other, meets the inferior longitudinal and other sinuses, to form what is named the Torcular Herophili, their common point of meeting. From this there proceed the two lateral sinuses, which run above the transverse ridge on either side, then cross over the posterior inferior angle of each of the parietal bones, then lie for a short distance on the inside of the mastoid portion of the temporal, from which they pass through the foramen lacerum posterius by a special aperture, marked by a deep notch in the border of the occipital bone, near the angle (6), which separates the basilar from the other portion.

The inferior and outer surface presents on the Basilar Process numerous irregularities, from which the back part of the pharynx is suspended, and into which certain muscles and ligaments of the front of the spine are inserted. The Foramen Magnum has here an even and grounded border; and by its sides two elevations, each with a smooth convex oval surface, whose larger axis is directed forwards, inwards, and downwards; these are the Condyles, by which the occipital bone articulates moveably with the first vertebra of the spine. Near these also are the outer orifices of the anterior and posterior condylod foramina, and around them very rough surfaces for the insertion of ligaments and muscles. On the outer surface of the expanded posterior portion of the bone are three ridges, one of which passes from the border of the foramen magnum backwards and upwards in correspondence with the internal vertical ridge, and is crossed on its way by two transverse arched ridges. At the crossing of the upper of these two is a sharp prominence, the occipital spine or protuberance. The two transverse ridges and the spaces below them give attachment to muscles; the spine, to the ligamentum nuchæ. Above the upper ridge the surface is smooth.

The upper and lateral borders (7) of the Occipital Bone are deeply toothed, and form the Lambdoidal Suture, with the parietal bones above and the mastoid below. In the course of this suture there occur, more often than in that of any other, insulated portions of bone, of various size and form, called Ossa Wormiana, surrounded by margins toothed as in the regular line of suture.

The Sphenoid Bone (*fig. 11, e*) is placed in the middle of the base of the skull, and has a very complicated form. *Fig. 16, a*, gives a front,

Fig. 16.

and *b*, a back and upper view of it. Its principal parts are described as a body (1, 1), two Greater Alæ (2, 2), two Lesser Alæ (3, 3), and, on each side, two Pterygoid Processes (4, 4, 4). The body is the central part, and has somewhat the form of a hollow cube. The chief part of its upper or cerebral surface is hollowed, forming what is called the Sella Turcica (5, 4), and lodging the pituitary gland. [BRAIN.] It is bounded at its four corners by bluntly pointed prominences called Clinoid Processes (see *fig. 11*), to which prolongations of dura mater are attached. Between, and a little in front of the two anterior of these, is a level surface (6, 5) on which the commissure of the optic nerves rests, and which has behind a slight elevation, the

Olivary Process, and in front a pointed one, the Ethmoid Spine (b, 6) which fits into the Ethmoid Bone. The sides of the body slope obliquely downwards towards the great ala, and the cavernous sinus and internal carotid artery of each side rest against them. The posterior surface (b, 7) of the body is rough, and unites with the end of the basilar process of the occipital. The anterior presents the openings of large cells which occupy the whole interior. These are divided by a middle septum (a, 5), and are partly closed in by two small portions of bone called Sphenoidal Cornua; where not thus closed, they open into the posterior ethmoidal cells. The under surface of the body is chiefly flat, but has a ridge called the zygous process along the middle line, which fits to the Vomer.

The Greater Ala (2) are affixed by the sides of the body, and project from it outwards, upwards, and forwards. On each there are three principal surfaces, turned towards the brain, the temple, and the orbit, respectively. The inner or cerebral (b, 8) is concave, supports part of the middle lobe of the brain, and presents three particular orifices, namely, the foramen rotundum, near its anterior and inner margin, through which the superior maxillary nerve passes from the Gasserian ganglion of the fifth pair; the foramen ovale, much larger and near the posterior and inner border, through which the inferior maxillary nerve goes from the same ganglion; and the foramen spinosum, near the outer and posterior angle, which transmits the middle meningeal artery. This outer angle (b, 9), which fits in between the petrous and squamous parts of the temporal bone (see fig. 11), is named the spinous process. The outer or temporal surface (a, 6) is slightly hollowed, and forms part of the temporal fossa, rising up at the lower part of the side of the skull as far as the anterior inferior angle of the parietal bone. At its lower border it turns abruptly inwards at a slight ridge, below which it is continued to the pterygoid processes, and forms part of the zygomatic fossa; its posterior border articulates with the squamous, its anterior with the frontal bone. The anterior or orbital surface (a, 7) is flat and smooth, and forms part of the outer wall of the orbit, where it articulates with the malar, frontal, and upper jaw bones.

The Lesser Ala (b, 3, 3) are long, narrow, sharp-pointed processes projecting horizontally outwards from the front and upper part of the body. Internally and behind they bear the anterior clinoid processes, beneath which are the optic foramina for transmitting the ophthalmic arteries and the optic nerves from the commissure to the orbit. The upper surface of these ala is flat, and supports part of the brain. The anterior border is articulated with the orbital plates of the frontal bone on either side, and in the middle, where the ethmoidal spine projects, with the ethmoid bone. The posterior border lies in the Fissura Sylvii, between the anterior and middle lobes of the brain. The under surface is smooth: between it and the anterior edge of the great ala is a gap, the foramen lacerum anterius, transmitting nerves and a vein to the orbit.

The Pterygoid Processes (a, 4, 4) are directed downwards from the under and outer part of the body. On each side there are two lamellae, an external and an internal; they are long and narrow quadrilateral plates nearly meeting in front, where they articulate with the palate bone, and diverging behind so as to leave a space, in which the internal pterygoid and circumflexus palati muscles are attached. The internal and longer of the lamellae has at its lowest extremity a hook, the Hamular process, round which, as on a pulley, the tendon of the last-mentioned muscle plays. At the upper part, where the pterygoid processes join the body, is a canal, the Vidian, running from before backwards and transmitting the Vidian nerve.

The Ethmoid Bone (fig. 11, f) is situated in the front and middle part of the base of the skull, between the orbits. Fig. 17 gives a profile view of it from the left side. It presents six different aspects,

and for the most part is of a very light spongy texture. Its upper surface, which is presented to the brain, has in front and in its middle line a strong triangular process, the Crista Galli (1), to which the front of the falx cerebri is attached. The apex of this process is directed straight upwards; the base is continuous below with the perpendicular or nasal plate (2), which divides the ethmoid bone into two equal lateral halves, and which, with the Vomer, which it joins below, forms the greater part of the Septum of the nose. The Crista Galli, sloping downwards and backwards, is gradually lost behind, where the Ethmoid bone receives the spine of the sphenoid. On either side of it is a narrow quadrangular plate (the Cribriform Plate), on which the bulb of one of the olfactory nerves rests. Each is perforated by a number of holes through which the branches of the olfactory and another smaller nerve pass to the interior of the nose. In front, and along part of the border of each plate, are the orifices of numerous

cells, which, in the entire skull, are closed in by the frontal bone and its orbital plates, and communicate with the frontal sinuses.

The surface of the upper part of each side of the ethmoid bone is formed by a thin smooth quadrilateral plate, the orbital plate (3), which forms great part of the inner wall of the orbit, and unites above with the corresponding plate of the frontal (leaving two small apertures, the anterior and posterior internal orbital foramina, for the passage of small nerves and vessels), in front with the lachrymal, below with the orbital portions of the upper jaw and palate bones, and behind with the sphenoid. Between the orbital and nasal plates, each half of the bone is formed of cells and folds of very thin lamellae, which form part of the chambers of the nose, and have the olfactory membrane and nerves spread out upon them. [SMELL.] The principal parts are the middle turbinated or spongy bone (4), a roll of thin bone, which forms the lower border of the cells; and a smaller but similar roll higher up, and confined to the back part, called the superior turbinated or spongy bone (5). Under each roll at its posterior part is a passage to the cells, called respectively the Superior and the Middle Meatus of the nose. The ethmoidal cells communicate in front with the frontal, and behind with the sphenoidal cells or sinuses.

The six bones just described inclose the Brain, forming a cavity whose size, compared with that of the crania of brutes, is one of the most distinguishing marks of the human species. [BRAIN.]

The formation of the sutures seems to have the same end. The outer tables of the exposed bones have their edges finely dovetailed, and are thus so immovably held together that none but a violently expansive force exercised at once on the whole interior of the cavity can separate them. The inner tables are simply apposed with a very thin intermediate layer of cartilage; an arrangement which, as Sir Charles Bell (who has written most ingeniously on this subject in his 'Animal Mechanics'), says, is often imitated in works of art, in which tough materials, such as wood, are joined by mutually fitting dentations; and brittle ones, such as glass or marble, by smooth edges and a layer of cement. A similar mode of opposition is seen between all the bones of the skull that are not exposed to direct violence.

The top of the skull presents transversely an arched formed by the two parietal bones (fig. 9), whose most prominent parts, like those of the frontal, occipital, and others, are stronger and thicker than any others; a circumstance adapted for greater resistance to force, whether applied directly against those parts, or to the summit of the arch, from whence it would fall chiefly on them. The strength of this arch is further secured by the lower parts of the parietal bones being held in by the overlapping upper borders of the temporal and sphenoidal bones, other parts of which, passing across the base of the skull, hold the parietal bones, which by pressure from above might be made to start outwards or pushed inwards, as beans hold the walls of a house from being driven either in or out by the weight of the roof. Taking the whole upper part of the skull as a dome, the same strength of resistance to superincumbent pressure is obtained at every part by nearly similar means, especially at the coronal suture, where, as has been already said, the parietal bones overlap the frontal at the supports of its arch, and are themselves overlapped by it at the summit of their own. In this regard also may be noticed the strength and thickness of the angular processes, and of the orbital arches extended between them (fig. 11), which serve as supports for the front of the dome; and the thickening of the bones along the course of the longitudinal and lateral sinuses, resembling groins in masonry.

The second chief division of the Skull includes the bones of the Face, the principal of which are represented in figs. 9 and 18.

The Nasal Bones (figs. 9, 10 18, g) form the upper part of the bridge of the nose. They are narrow and quadrilateral; thick above, where

Fig. 18.

they fit into the nasal notch of the frontal bone; broad and thin below. The outer border of each articulates with that of the ascending process of the upper jaw-bone; the inner is in contact with that of the

other; the lower are in contact with the cartilages that form the rest of the groundwork of the nose. The anterior surface is concave from above downwards, and convex from side to side; the posterior has opposite directions, and in the middle line, where the two bones are in contact, is applied on the nasal spine of the frontal, and the edge of the perpendicular plate of the ethmoid bone.

The Superior Maxillary or Upper Jaw Bones (*figs. 9, 10, 18, h*) form the greater part of the front of the face. *Fig. 19* gives a view of the outer part of that of the left side. This surface is bounded below by a narrow border, the Alveolar Border or Process (1), in which the upper teeth are set in their sockets. Its outline is an elliptical arc, and from it the outer surface ascends to the orbit, of which it forms the inner and great part of the lower margin (2). It is unevenly depressed in two or three places for the attachment of muscles of the face. At the outer part, near the orbit, it presents a rough surface, the Malar eminence (8), by which it is united with the cheek-bone. Below and in front of this is a depression called Fossa Canina, and on its inner side, just below the orbital margin, is the infra-orbital foramen, through which the superior maxillary nerve passes to the face. The anterior border of this external surface first ascends vertically where the two bones are in contact in the middle line (*fig. 9*); then is suddenly cut out in a crescentic arch (4), so as to leave between the two the large aperture into the nasal cavities, and then again ascends where the upper maxillary bone unites with the nasal of the same side. This ascending part is called the Nasal Process (5); its summit is fixed in the nasal notch of the frontal bone; its outer surface looks towards the orbit, is deeply grooved, and with the lachrymal bone, to which its posterior border is attached, forms a channel for the lachrymal duct; its inner surface is directed towards the cavity of the nose, has an oval roughness which is united with the inferior turbinated bone, and above closes some of the anterior ethmoidal cells. Below and behind the malar eminence the surface is excavated to form part of the zygomatic fossa; and above this it swells out, and is perforated by numerous foramina, through which the nerves of the upper teeth pass.

Fig. 19.

The upper, or orbital, surface (6), consists of a thin plate, forming the floor of the orbit, and presenting a groove which leads to the infra-orbital canal, and a depression for the insertion of the inferior oblique muscle of the eye. The under or palatine surface is rough and concave, and forms part of the roof of the mouth. Its outer border is arched, and bounded by the alveolar process; the inner is straight, and is set against that of the opposite side in the middle line; the posterior is united with the corresponding process of the palate bone. The inner or nasal aspect presents below a rough surface, by which the bone is united to its fellow on the opposite side, and which is deeper in front than behind. It is surmounted by a ridge which extends from before backwards, and between which and that of the other bone is a narrow groove to receive the vomer. The anterior part of the ridge (7) is called the Anterior Nasal Spine, and close by it is the Foramen Incisivum, which leads down to the roof of the mouth, and transmits the anterior palatine nerve. On the outer side of the ridge is a concave smooth surface, the upper surface of the palatine process, of which the lower surface forms, as already said, the roof of the mouth. From the outer part of this surface, which forms part of the floor of the nostrils, the bone rises almost vertically towards the nasal spine and the inner edge of the orbital plate, and, at about its middle, presents a large aperture leading into the Antrum Highmorei, a cavity occupying the whole interior of the body of the bone.

The Palate Bones (*fig. 20*) are placed backward between the superior maxillary and the pterygoid processes of the sphenoid. The lower horizontal or palatine portion (1) of each is attached behind the palatine process of the upper jaw, to which it is similar in form, and it completes the back part of the roof of the mouth, or hard palate, and of the floor of the nostrils. Its posterior border has the Velum Palati [PALATE] attached to it: its under surface presents two foramina, through which the posterior palatine nerves pass. From its outer border a thin plate (2) ascends vertically; where it commences there is, behind, a rough process (3), articulating with and filling up the gap between the pterygoid processes of the sphenoid. (*Fig. 16, a, 4, 4.*) The nasal or inner surface of this ascending portion articulates with the inferior turbinated bone, and forms part of the outer wall of the nostrils; the outer surface articulates with the back and inner part of the superior maxillary bone, and forms with it the posterior palatine

canal. The upper border has a notch, which, in the entire skull, is completed by the sphenoid bone into a hole, called the Spheno-Palatine, for the transmission of nerves of the same name: behind it is a triangular process (5), of which one surface articulates with the body of the sphenoid; and before it is another (4), of whose surfaces one closes some of the ethmoid cells, and another forms a small part of the back and floor of the orbit.

Fig. 20.

The Malar, or Cheek Bones (*figs. 9, 10, 18, i*) form the most prominent part of the cheeks. The form of each is quadrangular. The front surface is slightly convex, and has small apertures for vessels and nerves: the back covers the front of the zygomatic fossa; the upper surface is the narrowest, and forms part of the floor of the orbit, of which also part of the front border is formed by the upper margin of this bone. By its posterior surface and inner border the malar is united to the upper jaw-bone, as already described; and by its posterior and outer angle to the zygomatic process of the temporal bone (*fig. 14, 6*), with which it forms the zygoma.

The Lachrymal Bones (*fig. 10, j*) are two small thin lamellæ of bone at the fore part of the inner wall of the orbit. Each of them in some measure resembles a thumb-nail, whence they are also called Ungual Bones. Each is composed of two parts: the anterior is deeply grooved on the surface turned towards the orbit, and contributes to the formation of the lachrymal canal with the nasal process of the upper jaw-bone, with which its anterior margin articulates. The posterior part is flat, and closes those of the ethmoidal cells which lie anterior to its orbital plate. The posterior margin of this part articulates with the ethmoid bone, the upper with the orbital plate of the frontal, and the lower with that of the upper jaw-bone.

The Inferior Turbinated or Spongy Bones are thin rough lamellæ, whose lower border is rolled up somewhat like a scroll. They lie within the nasal cavities, and, except in being larger, they closely resemble the bones of the same name which are appended to the ethmoid. They are attached at either end to the inner surfaces of the nasal processes of the upper jaw and palate bones, and, in the middle, to the lachrymal and the lower portion of the orbital plate of the ethmoid bone: upon these they are suspended before the aperture of the Antrum, which, in the entire skull, they nearly conceal. Like all the bones which form part of the cavities of the nose, they are covered by mucous membrane. Beneath their outer concave surface runs the inferior meatus of the nose.

The Vomer (*fig. 9, k*) is a thin quadrilateral plate which forms a considerable part of the middle partition of the nose. Its upper border is the thickest, and is articulated with the azygos process and under surface of the sphenoid bone; the lower border fits into the groove between the ridges in the apposed surfaces of the palatine processes of the upper jaw and palate bones; the anterior joins the vertical part of the ethmoid above, and the cartilaginous part of the septum of the nose below: the posterior is free, and divides the passage from the nostrils into the pharynx behind.

The Inferior Maxillary, or Lower Jaw-Bone (*figs. 9, 10, l, and fig. 21*), has a form something like that of a horse-shoe. It is made up of a

Fig. 21.

body or horizontal portion (1), and a ramus or ascending portion (2). The former is convex anteriorly, and on its very front presents the prominence which contributes to form the chin (3). This is marked in the middle line by the Symphysis, at which the two portions of which the jaw was first composed are united. On either side of this is a slight depression, the Fossa Incisiva; and farther out a hole, the mental (4), through which branches of the inferior dental nerve and vessels pass to the chin. A raised line, giving insertion to muscles, passes hence obliquely outwards to the upper border; and on the

inner surface there is another line corresponding to this, and giving origin to the mylo-hyoideus muscle, whence it is called the Mylo-Hyoidean ridge. On the inner surface there are also prominences near the symphysis for the insertion of muscles. The lower border is smooth and rounded; the upper, or alveolar process, is marked by notches corresponding with the sockets of the lower teeth, which are set in it.

The rami ascend almost vertically from the ends of the two parts of the body. They are broad, flat, and quadrilateral. At the angle (5), where each joins the body, there are on both surfaces rough prominences; the external gives attachment to the masseter, the internal to the internal pterygoid muscle. The internal surface has also, near the end of the mylo-hyoidean ridge, a hole, the inferior dental (6), through which the nerve of the same name passes into the interior of the jaw, from which it again emerges at the mental hole (4). Leading from the dental foramen is a small groove for a branch of the dental nerve. The anterior border of the ramus terminates in a sharp projection, the Coronoid Process (7, 7), to which the temporal muscle is attached; the posterior, in a transversely oval process, with a smooth summit, the Condyle (8, 8), which articulates with full freedom of motion in the glenoid cavity of the temporal bone. Below this is the Neck (9), to which the external pterygoid muscle is in part attached; and the space between the condyle and the coronoid process is the Sigmoid Notch (10, 10).

The bones of the face serve as a groundwork to many parts whose structures and functions are already described in separate articles; and since, in each case, the parts which the bones take are at the same time considered, an account of their adaptation to the several offices performed by the different portions of the face is not here necessary. Their relations to the features are described in the article MAN.

The last main division of the Skeleton consists of the Upper and Lower Extremities (fig. 1; 3, 4). The upper are composed of the Scapula, Clavicle, Humerus, Radius, Ulna, Carpus, Metacarpus, and Fingers. The scapula and clavicle are analogous to the Ossa Inuominata in the lower extremities.

Fig. 22.

The Scapula, or Shoulder-Blade, of which in fig. 22 the back is represented, with parts of the clavicle and humerus, is triangular in its outline, and flat, being formed of two compact layers, and an intermediate diploe, varied in thickness. It has three borders, or Costae; a superior (1), posterior (2), which lies nearly parallel with the spine, and an inferior (3), which is also the longest. They are all thicker than the body of the bone, and give insertion to various muscles moving the shoulder. From the posterior border, about one-third from the upper and two-thirds from the lower angle, there commences a ridge called the Spine (4), which, as it passes along the back of the scapula towards the outer angle, gradually increases in depth, and at its end, projecting beyond and above the angle, bears a strong arched process, called the Acromion (5), which articulates with the clavicle, overhangs the shoulder-joint, and gives attachment to some of its muscles and ligaments. The spine divides the back of the scapula into two parts, of which the lower is much the larger, and which are named, according to their position, Supra- (6) and Infra- (7) Spineous Forera. They give origin to muscles of the same names. The anterior surface, or belly of the scapula, is slightly concave, and gives insertion to the subscapularis muscle, for the attachment of whose several parts it is marked by alternate longitudinal elevations and depressions. At the outer angle the bone is terminated by the Glenoid Cavity (8), an ovate surface slightly hollowed, narrower above than below, and with which the head of the humerus (9) articulates with very extensive freedom of motion. Its border is thick, and is rendered deeper in the recent subject by a rim of fibro-cartilage, the glenoid ligament, similar to that which borders the acetabulum. Between this border and the base of the spine the scapular is narrower than elsewhere; and this part is called the Neck. From the superior costa, near this neck, a

long and strong curved process, the Coracoid, projects forwards, and gives attachment to several muscles and ligaments; and at its root there is in the superior costa a hole, or a notch, through which the supra-scapular nerve (and sometimes its accompanying vessels) pass.

The scapula is attached to the trunk only through the medium of the clavicle, and by the muscles which connect it to the spine and ribs. It can therefore slide freely on the back of the chest; and, to a certain extent, it follows all the larger movements of the humerus, so that its glenoid cavity, and the head of that bone, which have but a small surface of mutual contact, almost always preserve the same relation to each other, and are less likely to be dislocated than they would be if the scapula were more closely fixed.

The Clavicle, or Collar-Bone, extends transversely from the notch in the upper angle of the sternum to the anterior and outer margin of the acromion (fig. 22). With both of these its ends are articulated with a moderate extent of mobility; with the sternum, by the apex of a broad triangular surface; with the acromion, by a small flat oval surface on its posterior edge. The clavicle has nearly the direction of the double-curved line of beauty, being slightly arched forwards at the sternal, and backwards at the scapular, half. At the former it is thick, strong, and triangular; in the latter, broad and flattened. On the upper surface, which lies just under the skin, it is smooth; on the lower it has, near its sternal end, a mark where a ligament fixing it to the first rib is attached; farther out a larger elevation, to which the subclavian muscle is fixed; and near the acromial end, other prominences, to which the ligaments connecting it with the coracoid process of the scapula (which projects just below it) are affixed.

The chief purpose of the clavicle is to keep the arm at a distance from the trunk for all its outward motions; and in adaptation to this, its length and strength form one of the most characteristic features of the human skeleton.

The Humerus, the bone of the upper arm (fig. 23, A), is articulated above with the scapula by a hemispherical smooth portion called the

Fig. 23.

Head (1), which is bounded at its outer and lower part by a narrow groove called the Neck. The axis of the head forms, with that of the shaft or body of the bone, an angle of about 130°. Close by the neck, the upper and outer part of the shaft is surmounted by two Tuberosities: the larger and posterior (2) has three flat surfaces, to each of which a muscle from the scapula is attached; the lesser (3) gives attachment to the subscapularis muscle. The rest of the upper part of the shaft is round and nearly smooth; but just above the middle of its outer surface is a rough elevation (4), to which the deltoid, the chief muscle of the shoulder, is attached. About half-way down the shaft begins to be flatter and wider, and at either border of it commences sharp ridges, which, as they descend, become prominent, and which terminate below at the External (5) and Internal (6) Condyles. Each of the condyles gives insertion to a ligament and several muscles of the fore arm; the inner is the more prominent, but the outer is the larger. Between the condyles is the inferior articular surface, which is composed of two parts for articulating separately with each of the bones of the fore arm. On the outer side, just within the external condyle, the surface has a smooth rounded prominence or tuberosity (7), against which the summit of the head of the radius is apposed; more inwards there is a deep groove (8), separated from the tuberosity by a slight ridge, and from the inner condyle by one much more prominent, in which the raised portion of the sigmoid cavity of the ulna moves as in a hinge-joint. This part of the joint is named the Trochlea. Both before and behind it is bounded above by a depression: into that on the posterior surface, which is the deeper, the olecranon of the ulna is received when the fore arm is extended; and into the anterior, the coronoid process of the same bone, when the fore arm is much bent.

The Fore Arm contains two bones, the Radius and the Ulna (fig. 23,

B, C): the former being that with which the movements of rotation are effected, the latter that which takes the chief part in flexion and extension. The radius (B), when the palm of the hand is turned forwards, is on the outer side of the arm; and it is the shorter of the two bones. At its upper end it has a circular disc, the Head (1), hollowed on its upper surface, where it articulates with the tuberosity on the lower end of the Humerus (A, 7), and smooth on its circumference, where it is encircled by a ring, within which it rotates, and which is formed in part by the ulna, and in part by a ligament. Just below this is the Neck (2), of which the upper part is similarly encircled; and below it, on the anterior and inner surface, is a knob, the Tubercle (3), to which the tendon of the biceps, the chief flexor muscle of the fore arm, is attached. Yet lower, the shaft (6, 6) of the radius becomes three-sided, and as it descends grows wider. At its lowest part it is much expanded, is flattened before and behind, and terminates with a prominent border, to which ligaments of the wrist-joint are attached. The posterior and outer surfaces of this lower end are deeply grooved for the passage of tendons; and the latter is prolonged into a blunt-pointed process, the Styloid (4), to which the external lateral ligament is attached. The inner surface has a small smooth cavity, the Semilunar, which articulates with the outer part of the lower head of the Ulna. The terminal surface (at 5) is smooth, somewhat triangular, and slightly hollowed; it articulates with the carpus, and is continuous over the inner border with that which articulates with the ulna.

The Ulna (C) is situated on the inner side of the fore arm. At its upper and larger extremity it has a broad and deep crescentic notch, the Greater Sigmoid Cavity (1), whose smooth surface is divided into two parts by a middle ridge, and which is received in the trochlea of the humerus. It is bounded at either end by a sharp process. The upper and posterior is the larger, and is named the Olecranon (2); it forms the rough prominence behind the elbow; and when the arm is extended, its point, which is curved forwards, rests in the fossa at the back of the humerus. The lower and anterior (3) is the Coronoid Process, whose point, when the arm is fully bent, rests in the anterior fossa of the humerus. On the outer side the smooth surface of the great sigmoid cavity is continued over a small oval concave portion of the side of the bone just behind the coronoid process. This is the Lesser Sigmoid Cavity; upon which the side of the head of the radius rotates, and to whose borders the coronary ligament by which that head is encircled is attached. The body or shaft (4, 4) of the ulna grows smaller from above downwards, and is for the most part three-sided; its external and sharp margin giving origin to the interosseous ligament, which, being attached also to the opposed margin of the radius, fills up the space between these bones. At its lower end the ulna becomes nearly cylindrical, and then is a little enlarged: at its termination it presents a double articular surface; one, on the end, which is nearly circular, and (through the medium of a fibro-cartilage) articulates with part of the carpus; the other, on the outer border, which is narrow and convex, and is received in the semilunar cavity of the radius. The inner border of this lower extremity bears a short and blunt process, the Styloid (5), to which the internal lateral ligament of the wrist-joint is fixed.

The motions of which the Fore-Arm is capable are Flexion and Extension, and Rotation on its axis. The two former are effected at the hinge-like joint between the greater sigmoid cavity of the ulna and the trochlea of the humerus; the head of the radius moving at the same time forwards and backwards on the lower tuberosity. The elbow affords the best specimen of a hinge-joint in the body, for no lateral motion is permitted in it, the ulna being locked in the groove between the two side-ridges of the trochlea. Rotation, by which also the rotation of the hand is effected, is performed by the upper head of the radius moving round in the ring formed by the coronary ligament and the lesser sigmoid cavity of the ulna; and by its lower head at the same time being carried round on the outer border of the lower head of the ulna. In this movement the ulna is almost fixed, its lower end only being carried outwards as that of the radius is moved far inwards, when in extreme pronation of the hand the two bones are made to cross each other.

The Hand (23, D) consists of the Carpus, Metacarpus, and Fingers. The Carpus (1) is composed of eight small bones arranged in two rows, and so nearly immovably united by ligaments, that, except in being more elastic, they serve the purpose of a single bony arch. Those of the first row, which lie nearest to the fore arm, are (from the outer to the inner side) the Scaphoid, Lunar, Cuneiform, and Pisiform bones: those of the second row, following the same order, are named Trapezium, Trapezoid, Magnum, and Unciform. The three first-named articulate with the radius directly, and with the ulna indirectly; the trapezium has a surface of peculiar form, concave from side to side, and convex from before backwards, by which the thumb, articulating with it, is permitted to have a very wide extent of motion.

The Metacarpus (between 2 and 2) is composed of five bones, which are called by number according to the order in which they stand, that of the thumb being taken as the first. Each is described as consisting of a body and an upper and lower heads. The form of the upper head is adapted to one or more of the bones of the carpus; that of the lower is in all very convex, and rather narrow. The body

is compressed from side to side, and is broader behind than before, and on its dorsal than on its palmar aspect. The first metacarpal bone only has free mobility.

The bones of the fingers are called Phalanges. The thumb has two, each of the fingers three. Their form and proportionate sizes are plainly exhibited in *fig. 23, D*. They are articulated with each other, and with the metacarpal bones, so as to permit free extension and flexion; and at the joints between the phalanges and metacarpus there is also permitted a certain extent of lateral motion. At that between the carpus and fore arm there is a very extensive hinge-like motion of flexion and extension, as well as a wide lateral motion.

The general arrangement of the bones of the human upper extremity is adapted to a far more extensive and varied set of movements than exists in the corresponding member of any other animal; they have all relation to the office of the hand, as an instrument not of support, but of prehension, and that in its most perfect form. In this view they are fully considered in the article MAN.

Each of the Lower Extremities is formed by a Femur, Tibia, Fibula, Patella, Tarsus, Metatarsus, and Toes.

Fig. 24.

The Femur, or Thigh-Bone (*fig. 24, A*) is the largest of the body. It articulates with the acetabulum of the Os Innominatum by its head (1), which forms rather more than half a sphere, and is smooth, except at its summit, where there is a depression for an interarticular ligament. It rests upon a narrower part, the Neck (2), which descends obliquely to the summit of the shaft, and is at its base somewhat expanded. It is here set between two strong processes called Trochanters, by which the shaft is surmounted; and its base is bordered by two oblique lines, named Intertrochanteric, which pass on either surface of the bone, from one to the other Trochanter. The Greater Trochanter (3) is the uppermost, and lies at the outer part of the bone; it is thick, rough, and strong, and gives attachment to the great muscles of the buttock. Behind it is a deep depression, the Digital Fossa, in which the obturator and other muscles to rotate the thigh outwards are attached. The Lesser Trochanter (4) is on the inner aspect of the femur, and also gives a point of insertion for muscles. At the level of the Trochanters the shaft is flattened both behind and before, but below them it is round and nearly cylindrical, till, within one-fourth of its length from the lower end, it expands, and again becomes flattened. The shaft (5, 5) of each femur is directed rather inwards, and is slightly arched forwards; its axis makes, with that of the neck and head, an angle of about 120°; its surface is everywhere smooth, except behind, where there is a prominent line, the Linea Aspera, running along the middle, and at either end dividing into two, which above go each to one of the trochanters, and below each to one of the condyles. These condyles are the processes in which the lower expanded part of the femur terminates. The inner condyle (6) is the narrower, and descends lower than the outer (7), which is the broader and stronger. Their articular surfaces are united in front at a concave pulley-like surface (8), over which the patella lies: below it they diverge, and at the back of the femur are separated widely on two very convex prominences, between which there is a deep and rough fossa, in which the crucial ligaments of the knee-joint are fixed. On the sides of the femur, just above the lower border of the condyle, are eminences, the Tuberosities (9, 9), to which the external and internal lateral ligaments respectively are attached.

The Tibia, or Shin-Bone (*fig. 24, B*), is placed on the front and inner

part of the Leg. Its upper part, or Head (1), is far larger than any other. Its upper surface is nearly oval, its greatest diameter being transverse; and it presents two slightly concave oval smooth surfaces (2, 2), on which the condyles of the femur rest. Between them is an eminence, named the Spine, which fits in between the condyles, and to which, as well as to rough surfaces before and behind it, the crucial ligaments and semilunar cartilages are fixed. Below and on the sides of the head are tuberosities, on which the lateral ligaments are inserted, and behind the external tuberosity is a smooth surface which articulates with the head of the fibula. In front, and a little below them, is the tubercle (4) to which the ligamentum patellæ is attached. Below this the body (5, 5) is triangular, and as it descends, becomes smaller; its outer surface is hollowed; its inner, which forms the skin, slightly convex; its posterior rounded. The outer border gives attachment to an interosseous ligament, which fills up the space between it and the opposed part of the fibula: the anterior is sharp and prominent, and is named the Crest. The lower or tarsal extremity is a little expanded, and has a somewhat quadrilateral form. Its outer aspect has a slightly concave surface, which is articulated immovably with the fibula; the inner is prolonged into a bluntly pointed process, the internal malleolus (6), which has the internal lateral ligament of the ankle fixed to its extremity, and a smooth surface on its outer side, which articulates with the astragalus. The anterior surface of this extremity is smooth where tendons pass over it; the posterior is flat; the lower or terminal surface (7) is quadrilateral and slightly hollowed; it rests on and is articulated with the astragalus.

The Fibula (*fig. 24, B*) is situated at the outer part of the leg, and is fixed immovably by the side of the tibia. It is long, very slender, for the most part three-sided, and enlarged at either extremity. The upper extremity or head (1) is the smaller; it is rounded, and on its upper and inner part has an oval smooth surface, with which it articulates with the outer tubercle of the tibia; the rest of its surface is uneven, for the attachment of ligaments and a tendon. The lower extremity (2) is longer and more pointed than the upper; it forms the external malleolus, or outer ankle, to whose extremity the external lateral ligament of the joint is attached, and whose inner surface is articulated with the astragalus; behind it is a deep groove, over which the tendons of some muscles of the leg pass to the sole of the foot. Above the malleolus, and on the inner aspect of the fibula, is a smooth surface, where it is united with the tibia.

The Patella, or Knee-Pan, has a somewhat triangular outline. Its narrowest part is below, and is fixed by the ligamentum patellæ to the tubercle of the tibia. Its anterior surface is slightly convex, and looks fibrous, being marked by the insertions of the tendons of the extensor muscles of the leg; the posterior is smooth, and divided by a ridge into two parts, of which the outer is the larger, and which are adapted to the pulley-like surface between the condyles of the femur.

The Tarsus is composed of seven bones, namely, the Astragalus (1), Os Calcis (2), Navicular (3), Cuboid (4), Internal (5), Middle (6), and External (7) Cuneiform Bones. These are set together so that they cannot be moved by any slight force, and yet are possessed of considerable elasticity. The Astragalus is that on which, through the Tibia, which rests upon its upper quadrilateral surface, the weight of the body first falls. With the Tibia above, and the two malleoli on either side of it, it forms the ankle-joint, a hinge with a limited lateral motion. Its lower part rests, with two surfaces of contact, on the os calcis, whose hinder prominent part (8) forms the heel; and its anterior portion, or head, is received in a cavity, formed by the navicular bone in front, part of the os calcis behind, and a very strong ligament below and between them. This cavity is at the summit of an arch which the tarsus and metatarsus together contribute to form, and of which the supports are the os calcis behind and the ends of the metatarsal bones before. It is indeed a double arch, for it has at the sole a concavity, both from before backwards and from side to side; and the strength with which its several parts are joined is so great, that few accidents are rarer than a fracture or dislocation of any of the bones of the tarsus.

The rest of the bones of the Foot, including those of the Metatarsus (9, 9) and the Toes, are in number, arrangement, and form very similar to the Metacarpus and the Phalanges of the Fingers. The metatarsal bones however are longer, more slender, and set more closely side by side than the metacarpal; and the Phalanges are all much shorter, and (except the two of the great Toe) smaller. Their movements are in general the same as those of the fingers, but less extensive; neither is there any adaptation for so free a movement of the first toe as of the thumb.

There are some supplemental bones of the skeleton, which need but just be mentioned. These are the Sesamoid and the Hyoid Bones. The former occur within the substance or in the course of tendons which are much exerted; the patella is the largest of them; the number and existence of the others are not certain, but there are almost always two at the first joints of each of the thumbs and great toes; they are small, oval, or round, and rough on all their surfaces, except that by which they articulate with the bone on which they lie. The Hyoid Bone is that on which the larynx is suspended, and the base of the tongue fixed; it is not articulated, except by long liga-

ments, with any other of the bones. [LARYNX; TONGUE.] In relation to many points in this article, the following articles may be consulted: ARTICULATION, BONE, VERTEBRA, LOCOMOTION IN ANIMALS, MAX.

SKENEÆ, a genus of Gasteropodous *Mollusca*, named after Dr. Skene. The shell is very small, flat, and with few whorls. It is deeply umbilicated; the mouth is entire, circular, not quite connected with the body whorl; operculum rather spiral. The animal is nearly like that of *Rissoa*, and has large eyes. The species are few, and are found generally on the roots of *Corallina officinalis*.

SKIMMER. [RYNCHORA.]

SKIN. The Skin, or Dermo, is the outer covering of the body; and having to serve at once as a defence for the more deeply seated structures, as an organ of touch, and as an apparatus for secretion, it is one of the most compound of all the tissues.

It is composed of two chief parts:—a vascular basis named Cutis, and a superficial layer named Epidermis, or Cuticle, which is not vascular. The cutis is made up for the most part of fibres and laminae, like those of common cellular tissue. They are much more densely woven near the surface than in the deeper part of the skin: in the former they constitute a very tough and elastic compact membrane; in the latter they are arranged in irregular large cells, which in moderately stout persons are filled with fat, but in the emaciated are collapsed, and form a loose flocculent white tissue. This general form of structure prevails through the whole skin; but in different parts of the body, and still more in different persons, the density and thickness of its layers, the size of the cells, the quantity of fat which they contain in the deeper parts, and the fineness or coarseness of the tissue composing them, vary considerably.

The external surface of the skin presents a variety of wrinkles. The larger of these are produced by the action of muscles, which in many parts throw the skin into folds; others result from its loss of elasticity in old age, and the removal of the fat beneath it; and again others, which are seen most plainly on the palms and the balls of the fingers, and on the corresponding parts of the foot, run in very close parallel arches, and indicate the arrangement of subjacent rows of sensitive papillæ, with which the whole surface of the skin is beset, and which in the parts just named, and in some others, are arranged in regular double lines. In their most developed state, on the balls of the fingers for example, the papillæ are very fine conical processes, standing somewhat obliquely, and so densely set, that their summits form a seemingly smooth surface. On these parts each elevated line which one sees on the surface has beneath it two rows of papillæ; for when looked at closely, each such ridge shows on its summit a little furrow dotted with minute apertures, and which fits into the space between the rows of papillæ. Over the rest of the body the papillæ are much smaller, and are irregularly arranged. Everywhere, however, they are the most vascular part of the skin, each papilla receiving a distinct loop from the subjacent network of bloodvessels. It is in them also that the greater part of the very numerous nerves of the skin terminate; for though every part of the skin is sensitive, yet the papillæ are so in the highest degree, and are the chief instruments by which the sense of touch is exercised. [SENSES; NERVOUS SYSTEM.] It is through their being so much developed, that the tips of the fingers are adapted for the perception of the finest impressions of the sense; though even they have less delicate perception than the tip of the tongue, on which similar but larger and more pointed papillæ are set.

The chief secretory apparatus of the skin consists of the perspiratory glands, which are disposed over its whole extent, but, like the papillæ, are largest and most numerous in the palms and soles. By looking on the surface of the cuticle covering these parts, one may see, especially on a warm day, or when perspiring freely, a number of minute orifices between and upon the tops of the arched ridges already described. These are the orifices of the glands by which the perspiration is secreted, and sometimes one may squeeze through them a drop of the clear crystal fluid which the glands produce. Each orifice leads to a fine tube of somewhat less diameter than itself, which passes down through the epidermis, and into the deeper parts of the skin, making on its way several spiral turns, and ending in a slightly enlarged closed sac. In the sole, each such tube makes from 15 to 20 spiral turns; in the palm, from 6 to 10; in other parts, fewer: in the right hand the spiral turns are made from left to right; in the left, from right to left. There are about 25 of these orifices in a square line of the surface of the tip of the fore-finger; and about 75 in the same space between the bases of the fingers: taking therefore the whole superficies of the body at 14 square feet, it is probable that, as Eichhorn calculated, there are not less than ten millions of the glands scattered through the skin.

It is in them that the perspiration is being constantly formed, though it most generally passes away as fast as it is produced in an invisible vapour, and during health collects in the form of sweat only when it is very rapidly formed, as during active exercise, or when the surrounding atmosphere is already saturated with moisture. The fluid of the perspiration is composed of water, with very small quantities of animal and saline matter, some free lactic acid, nitrogen, and carbonic acid. By thus removing carbonic acid from the blood, the skin is, next to the lungs, the most important and essential excretory

organ of the body. Experiments have in fact proved that animals prevented from perspiring die of suffocation as certainly, though not so rapidly, as when their respiration is obstructed. The quantity of perspiration secreted amounts to about two pounds in 24 hours; but it is liable to considerable variations, according to the habits of the individual, the state of the atmosphere, the activity of other glands, such as the lungs and kidneys, and other circumstances.

Another secretion from the skin is that of the oily sebaceous matter by which its surface is always kept in a slight degree greasy, so that water adheres to it only in drops, and does not easily soak into the substance of the epidermis. The sebaceous glands by which this secretion is produced, as well as the hair-follicles on which they are almost always attendant, are described in the article HAIR.

The loss of fluid by these secretions from the skin is in some measure compensated by the absorption which it also exercises. It is uncertain how much, if any, of the vapour of the atmosphere around us is thus imbibed; but it is certain that the skin absorbs fluids placed for a short time in contact with it, and this so rapidly, that (especially after long fasting) a perceptible increase of weight is observed after a person has been immersed in a bath. The obstacle to a more constant and considerable absorption of fluid is the nearly impenetrable layer of epidermis; and hence the substances most rapidly absorbed are those which most easily pass through it, such as water, after having been imbibed into its deepest layers, vapours of sulphureted hydrogen, hydrocyanic acid, &c., oils rubbed upon it, or corrosives which destroy its texture.

Besides its secretions, there are produced from the vessels of the skin materials of which are formed certain appendages for its protection and other purposes, such as the cuticle, the hair, and the nails.

The cuticle, or epidermis, is an insensible and non-vascular membrane, which is laid over the whole of the external surface of the body in a layer, the thickness of which is varied according to the protection required for the wellbeing of the subjacent cutis. The under surface, which lies next to the cutis, is accurately fitted into all its irregularities, and sends prolongations down into the interior of all its glands and follicles; the outer surface, which is exposed to friction, is comparatively smooth. The epidermis is composed of several layers of cells: of the two layers into which it may commonly in an ordinary dissection be split, the lower is called Rete Mucosum, or Rete Malpighii; the upper and outer, more particularly, Epidermis. In the deeper layers the epidermis is composed entirely of minute polygonal cells, adhering by their edges, and containing nuclei and a thin fluid; in the layers nearer the surface are cells of the same kind, but larger and flatter; and those on the very outer surface are dry and scale-like; they have lost almost all trace of form, and becoming loose, are removed by friction at exactly the same rate as, under ordinary circumstances, new cells are produced at the surface next the cutis. Thus the epidermis is subject to constant and rapid change: its cells, as fast as they dry and are removed in the form of scurf from its exterior, being replaced by new ones at its interior; and thus, whatever waste (within certain limits) it is subject to, its thickness is not diminished, but rather, as the waste is increased, so is its thickness, till it attains that degree, which is competent to the protection of the subjacent cutis; as any one may see in the palms of his hands, soon after he has begun to occupy himself in a more than usually laborious handicraft.

The epidermis is the seat of the characteristic national colours of the skin, as well as of the colours of freckles and other superficial marks. In dark-complexioned races, especially in negroes, it is very thick, and its cells are filled with minute black or otherwise coloured pigment-granules, many of which also lie loose among them. [ALBINO; PIGMENT.] The thickness of the epidermis in these tribes renders it less penetrable by the rays of heat; and it is hence (and not on account of its colour, which would have an opposite effect) that a negro can bear the exposure of his skin to a degree of solar heat which blisters that of a European.

The nails are thin laminae of horny tissue, produced by the cutis on the back of the ends of the fingers and toes. Under each of the more perfect of the nails, such as those of the fingers and the great toe, the cutis has a peculiar structure, called the matrix of the nail, composed of large sharply-pointed and very vascular papillae, which at the root are arranged irregularly, but at the body of the nail are placed in close-set rows or longitudinal ridges. By all this vascular surface the substance of the nail is produced in minute cells, which subsequently coalesce and form the dense, obscurely fibrous, and transparent mass of the body of the nail. The crescentic opaque part at the root of the nail owes its whiteness in part to its own substance, which in the deeper layers is softer and more opaque than in those of the body, and in part to the surface beneath it being less vascular than the rest.

The under surface of the nail is grooved or otherwise marked in correspondence with the matrix, to which it closely fits; the outer surface, exposed to friction, is comparatively smooth, though still it presents traces of the ridges in which, when it was at the under surface, it was formed; for the nails are produced in the same method as the cuticle; as fast as their exposed surfaces or their ends are worn away, they are replaced by layers growing from the matrix; and the whole mass of the nail, growing at once from below its body and from its root, is constantly pushed forwards and thickened, at the

very same rate as its free extremity is cut or worn down, and its body thinned by friction.

SLATE. By some geological writers the laminar structures which prevail in many stratified and in some metamorphic rocks are called slaty or schistose; but, in consequence of the progress of investigation, one of these structures, locally superinduced in deposited strata, which is characterised by planes of cleavage generally meeting those of deposition at considerable angles, is specially called the slaty structure. If, in the diagram below, *c*, *s*, *l*, represent in section a series of

deposited beds of clay (*c*), sandstone (*s*), and nodules of limestone (*l*), all dipping, as the arrow *S* (south) indicates, at 20°: the lines which cross these beds at oblique angles, and are more highly inclined, as in the arrow *K* = 60°, are the edges of innumerable parallel planes of cleavage, which are continuous through the finely argillaceous beds *c*; more or less twisted in and about the limestone nodules *l*; more or less interrupted by the arenaceous beds *s*, or represented therein by lines more nearly rectangled to the plane of deposition. The law here indicated of the want of coincidence in the planes of cleavage and deposition is almost universally observed in nature. Nearly horizontal strata are crossed by inclined cleavage; highly inclined strata are traversed by nearly vertical cleavage. In strata which dip different ways from an axis or to an axis, the cleavage planes are sometimes found to be parallel throughout the mass on both sides of the axis; and even where strata are variously contorted, they are frequently dissected through a great part or the whole of their mass by cleavage planes passing in one direction. Hence the conclusion is obvious that this slaty structure, this monohedral symmetry (if we may not call it crystallisation), is the fruit of a general cause acting subsequently to the deposition and disturbance of the strata, capable of pervading and re-arranging the particles so as to polarise and systematise their mutual attractions, but not to fuse them together, destroy their original distinctness, or obliterate the evidence of their original condition. This force was so general, that along many miles of country, as, for example, in the whole Snowdonian chain, one particular direction (north-north-east), in North Devon and Pembrokeshire another (nearly east and west), is found to prevail more or less distinctly in all the rocks; though, as before observed, arenaceous and pebbly beds are least influenced by it, and limestones are unequally and variously affected.

This dependence of the slaty structure on the nature of the rock is sometimes very positively pronounced, as in some classes of rock the cleavage does change and even reverse its inclination where contortions prevail. (This is very observable in some cases of cleavage in the old red-sandstone of Pembrokeshire.) On a first view it appears to be equally dependent on geological time, since it is principally among the older strata that it is well exhibited on a large scale; but on this head doubt arises, when we find the Silurian rocks, which are not slaty at Ludlow, become so near Llandovery; the old red-sandstone slaty in Pembrokeshire and not so in Monmouthshire; the mountain limestone shales slaty near Tenby and not so in Yorkshire; the lias shales slaty on the northern slopes of the Alps, but not so in England.

There are then local conditions which influence the development of slaty cleavage, and it is essential to a general solution of the problem which this structure involves, that these conditions should be determined. Proximity to rocks of igneous origin has been freely appealed to for this purpose; but this appears an insufficient and not often applicable cause. The most general condition which has occurred to our observation is the fact of remarkable displacement of the strata on one or more anticlinal or synclinal axes; and it is of consequence to this inference to remark that very often, approximately or even exactly, the horizontal edge ('strike') of the inclined cleavage planes coincides with the axis of movement (and therefore with the strike) of the stratification. Pressure in some peculiar application appears to us to

be indicated by all the phenomena as the grand agent in the production of slaty cleavage. Only one tolerably successful effort has been made experimentally to reproduce this structure by art. Mr. R. W. Fox has caused electrical currents to traverse a mass of moist clay, and has observed in consequence the formation of numerous fissures, more or less similar to slaty cleavage, in planes parallel to the vertical bounding surfaces of the mass, and at right angles to the electrical currents. The exact application of this experiment is not understood. Perhaps however, conjoined with the admission that the great movements of strata, by which apparently slaty cleavage was determined, depended on disturbed equilibrium of internal heat, which might, or rather must, have developed electrical currents, this solitary experiment may be the commencement of a right mode of more extensive inquiry embracing the many circumstances of chemical nature, stratified arrangement, disturbed position, and proximity of igneous rocks, which must all be included in a good theory of slaty cleavage.

For economical purposes there appears little chance of obtaining in the British Islands good Slate (properly so called) from any but the ancient argillaceous strata superposed on mica-schist and gneiss, and covered by old red-sandstone or mountain limestone. From these strata in Scotland, Cumberland, Westmoreland, Yorkshire, Charnwood Forest, North Wales abundantly, South Wales, Devonshire, Cornwall, the north and south of Ireland, slates of various value are dug. The thin flagstone of the coal formation in many parts of England and Wales the laminated sandy limestone of Stonesfield, Collywiston, &c., which are often called slates, and are extensively used in roofing, are all obtained by natural partings parallel to the stratification. True slate is split by wedges from the apparently solid rock along planes often no more discoverable than those of a real crystal. In colour it is purple, blue, green, yellowish, or almost white, or striped across the planes. In some slates (west of Scotland, Ingleton, &c.) crystals of cubical iron pyrites are scattered. Much of the Cumberland slate appears full of fragments (Borrowdale), and some contains chistolite (Skiddaw).

In the United States, a good material is obtained in Maine at Barnard, Piscataquis, Kennebec, Bingham, and elsewhere; also in Massachusetts, in Worcester county, in Boylston, Lancaster, Harvard, Shirley, and Pepperell; in Vermont, at Guilford, Brattleborough, Fairhaven, and Dummerston; in Hoosic, New York; on Bush Creek and near Unionville, Maryland; at the Cove of Wachitta, Arkansas. At Rutland, Vermont, is a manufactory of slate pencils, from a greenish slate.

These slate rocks are also used for gravestones in New England cemeteries. It is however liable to fall to pieces.

Drawing Slate is a finer and more compact variety, of bluish and purplish shades of colour. The best slates come from Spain, Italy, and France. A good quality is quarried in Maine and Vermont, United States.

Novaculite, Hons-Slate, or Whet-Stone, is a fine grained slate, containing considerable quartz, though the grains of this mineral are not perceptible. It occurs of light and dark shades of colour, and compact texture.

Argillite is a general term given to argillaceous or clay-slate rocks. Many shales or argillites crumble easily, and are unfit for any purpose in the arts, except to furnish a clayey soil.

Alum Shale is any slaty rock which contains decomposing pyrites, and thus will afford alum or sulphate of alumina on lixiviation.

Bituminous Shale is a dark coloured slaty rock containing some bitumen, and giving off a bituminous odour.

Plumbaginous Schist is a clay slate containing plumbago or graphite, and leaving traces like black lead.

The *Pipestone* of the North American Indians was in part a red claystone or compacted clay from the Coteau de Prairie. It has been named *Callinite*. A similar material, now accumulating, occurs on the north shore of Lake Superior, at Nipigon Bay. Another variety of pipestone is a dark grayish compact argillite; it is used by the Indians of the north-west coast of America. (Dana.) [AGALMATOLITE; MICASCHIST.]

SLEEP, the periodical repose of the organs of the senses, and of the greater number of the intellectual faculties and voluntary movements. The above indeed is by no means a satisfactory definition; but it is, as with life, far easier to describe its phenomena than to define its nature.

True sleep is peculiar to the *Mammalia* and to Birds. The lower animals indeed rest from time to time, and withdraw themselves from the external world, but having no external eyelids, they cannot exclude all influence from without. Fish conceal themselves behind a stone or near the bank of a river; crocodiles hide themselves in the mud; and tortoises creep into holes. The higher animals likewise usually seek out some place of retirement to sleep in, and dispose themselves in a posture which either is maintained with little muscular effort, or is favourable to the preservation of warmth.

The approach of sleep is announced by diminished activity of mind and loss of the power of attention. The senses become blunted to external impressions, and we feel an unconquerable desire for stillness and repose. Our ideas grow more confused—our sensations more obscure—our sight fails us—and if our ears still perceive sounds they are indistinct, and seem as though distant. The eyelids close,

the joints relax, we instinctively assume an easy position, and fall into a sleep, which at first is deep, then soft and gentle, and becomes gradually less sound as the time for waking approaches.

Physiologists are accustomed to distinguish what are termed the organic or vegetative from the animal properties of living beings. By the former are understood development, growth, excitability, &c., those powers in short which are common to plants and animals; by the latter, those properties which are peculiar to animals, such as sensation and voluntary motion. During sleep the organs of vegetative life continue to discharge their functions with scarcely less activity than in the waking state. Their repose is independent of sleep, and occurs at very different times. The heart rests between each pulsation, the muscles of expiration and inspiration are in a state of alternate action and repose, and the peristaltic motions of the intestines have their distinct periods of remission. The pulse and respiration however become slower during sleep, and digestion seems to go on then less perfectly than in the waking state. The temperature of the body sinks during sleep, owing to the diminished nervous energy, and to the same cause may be ascribed the increased susceptibility of persons to rheumatism and other effects of cold when asleep.

Not only are the functions of organic life little affected by sleep, but even those of animal life are not in a state of complete repose. It would not be possible to make a dead body remain in those postures which we assume when asleep, and our eyelids are not closed except by muscular action. Some animals sleep standing, as the horse; birds do so also, sometimes standing on one leg. When very weary, we sleep even in the most constrained positions; soldiers have been known to sleep while marching, postillions on horseback, and fiddlers at a fair have continued to play even when through weariness they have fallen asleep. The numerous instances of somnambulism on record show how high a degree of activity of the animal functions is compatible with sleep.

Animals in general require less sleep than man: thus, for instance, four hours are sufficient for the horse. Those animals whose blood circulates very rapidly, whose motions are peculiarly euergetic, and their senses very acute, usually sleep more lightly, and for a shorter time than others. The timid herbivorous animals sleep less, and less profoundly than the bolder *Carnivora*. In man the want of sleep varies at different ages; the new-born infant sleeps almost continually, while persons in middle life can do with less sleep than children or very old persons, and women require less sleep than men. From six to eight hours a-day are usually passed in sleep, but habit exercises a great influence in determining the amount of repose required. John Hunter and Frederick the Great did not sleep more than four hours daily, while some sluggish persons spend nearly half their time in sleep. In extreme old age much sleep sometimes becomes necessary. De Moivre, when eighty-three years old, was awake only during four hours out of the twenty-four; and Thomas Parr, towards the close of his life, was almost constantly asleep. Children sleep very soundly, old persons are easily disturbed, men sleep more profoundly than women, and sleep is always sounder after considerable weariness.

There are some conditions which favour the occurrence of sleep. Stout and full-blooded persons, and those of an excitable but easily exhausted frame, require more sleep than such as are thin, or who, though equally excitable, are more energetic, and less easily tired. Abundant food induces sleepiness, and also wine and other stimulants. A class of medicines are known by the name of narcotics, whose peculiar action is to induce sleep. Ease and quiet of mind conduce to it, but the weariness of hopeless grief is likewise followed by sleep. Certain external causes favour sleep, such as the warm bath or friction of the surfaces of the body. Extreme cold is a powerful and most dangerous narcotic; it induces a sleep from which there is no waking. Such a sleep it was which nearly proved fatal to Dr. Solander, when with Sir J. Banks in Tierra del Fuego.

We have not yet noticed one very important character of sleep—its periodical return once in every twenty-four hours. The idle person sleeps as well as the diligent who has passed his time in exerting his powers of mind or body. Sleep usually occurs at night-time, and we are awake during the day; but the day may become the time for sleep, and night for watching, if a person's occupation so require. Many animals sleep during the day, and watch or pursue their prey at night. We cannot then regard the periodical return of sleep as dependent on the simple alternation of day and night, or merely as the result of bodily fatigue, since it is known that extreme weariness will prevent sleep. The alternation of sleep and waking is essentially connected with something in the nature of animals, to which there are many analogies. The succession of the seasons and of day and night, the ebb and flow of the sea, the daily variations in the electricity of the air, in the rise and fall of the barometer, and the regular declination of the magnetic needle eastward and westward, at different hours, illustrate the same law of periodical action which is displayed in the unvarying alternation of sleep and waking. "We may," says Müller, "regard sleep and the waking state as the result of a species of antagonism between the organic and the animal life, in which the animal functions, governed by the mind, become free to act, while at other times they are repressed by the organic force acting in obedience to a law of creative nature. In sleep, when the animal functions entirely or for the most part cease, the organic processes are almost

the only ones which continue, and during that state even the organs of animal life are rendered capable of renewed action by the organisative force which proceeds without the consciousness of the animal, though accordant with a well-constituted plan and with reason."

Little need be said of the uses of sleep. 'Nature's soft nurse,' it invigorates body and mind when worn out by toil, and the occurrence of sleep in the course of a disease is one of the most favourable signs of returning health. After a night's sleep we are nearly an inch taller than before; the intervertebral cartilages, which had been compressed by bearing the weight of the body during the day, having regained their natural form and proportions. The powers exhausted by our intercourse with the external world, recover themselves during sleep, and our senses in the morning are alive to all impressions. It is however pre-eminently the rest of the brain, which, when fatigued by the constant action of the mind, becomes incapable of continuing that action, just as the eye, if long fixed upon one spot, ceases to perceive any object distinctly. [NERVOUS SYSTEM.]

Since then sleep is not a mere torpor of the system induced by fatigue, long watching, or any external cause, but a natural state whose periodical recurrence is essential to the harmonious performance of our functions, it need excite in us no surprise to find that in certain animals this condition lasts for a long time, even for months; and that in it the activity of the organs of animal life is suspended more completely than in diurnal sleep. To this state the name of Winter Sleep, or Hybernation, is applied. Hybernation occurs in some *Mammalia*, in all the *Amphibia*, and in some of the Molluscos and Insect tribes. Birds do not hybernate, and the vulgar notion with reference to the sleep of the swallow in winter is erroneous. Hybernation is either perfect or imperfect. In the former, of which the marmot affords an instance, the lethargy is profound and undisturbed by any sense of thirst or hunger, and the animals do not awake until the period of sleep is completely past. In the latter, intervals of wakefulness occur, during which the creatures rouse themselves and seek for food, as in the case of many insects and spiders, also the hedgehog, bat, and dormouse. The time during which hybernation continues varies much: in some animals it lasts only four months, in others for five or six; but almost all awake either in March or April. The situations which animals select for hybernation, and the position in which they await it, differ, as might be expected, in accordance with their various habits, but all seem to subserve one great purpose—the preservation of a moderate and equable temperature. Most creatures hybernate in solitude, but some, as the marmot, pass the winter in company.

The approach of winter-sleep is not sudden, but it comes on gradually; the activity of the animals diminishing as their sense of hunger grows less keen. In some animals, as in the hedgehog, a diminution or total loss of appetite precedes hybernation for some weeks. When hybernation is perfect, the senses become so completely blunted, that severe wounds and electric shocks are insufficient to rouse the animal.

The phenomena of organic life go on far more sluggishly during hybernation than in diurnal sleep. The pulsations of the heart sink to a fourth or even a tenth of their natural frequency. The respiration becomes slow, intermits frequently and for a long time, or even becomes altogether imperceptible. An animal in this condition, if placed in a pneumatometer, will produce no change in the air which it contains, or may be kept for a considerable time in irrespirable gases without sustaining any inconvenience. The temperature of the body depends on the activity with which respiration and circulation are carried on; hence, during hybernation it sinks greatly, and in some animals is not higher than that of the surrounding atmosphere.

Hybernation is not mere stupor from cold; all animals may be hibernated by cold, but those which hybernate are comparatively few in number. A moderately low temperature indeed is favourable to hybernation, but instinct teaches the animals to defend themselves from the cold, and their death results from exposure to its severity. Suspended animation from cold is a morbid state; hybernation and sleep are preceded by similar phenomena, and both terminate alike, after a certain time, in renewed activity.

If, lastly, we inquire what uses are answered by winter-sleep, we shall see that it is a provision for the maintenance of life at a season when those animals in which it occurs would be unable to obtain their natural food. It serves likewise for their protection against a degree of cold to which they could not bear to be exposed. Nor is it merely against extreme cold that annual sleep and the instinctive preparations of animals for that condition supply a defence, but extreme heat is followed in some animals by a lethargy similar to hybernation. Thus the Tanrec, or Rat of Madagascar, sleeps during the height of summer. Changes in the system generally, and renewed activity of the various functions, follow hybernation, as they do diurnal sleep. It would lead us into discussions beyond our limits, if we were to examine the various peculiarities of hibernating animals, or to inquire into what may be termed the proximate cause of annual sleep. [HEAT, ANIMAL.]

The revolutions of the seasons produce changes in Plants not unlike those which we have just noticed in hibernating animals. There is however a still closer analogy between diurnal sleep and the so-called Sleep of Plants, a condition first discovered by Linnæus to be general, though some of the phenomena had long been noted in the tamarind-

tree, and in some leguminous plants with pinnated leaves, natives of Egypt.

The attention of Linnæus was called to this phenomenon by the following circumstance:—Having sown some lotus seeds, he watched the progress of the plants, and at length discovered upon one of them two flowers. When evening came, he could not find the flowers again, and supposed that some one had plucked them. On the following morning he again observed them, and they once more disappeared at evening. He then examined the plants with care, and saw that at evening the leaflets had approached each other, and thus concealed the flowers from view. Struck by this fact, he took a lantern in his hand and visited the flower-beds, when to his surprise he found the appearance of all things changed, and thus discovered the sleep of plants.

As night approaches, flowers close, the leaves of plants become more erect and fold themselves together, while vitality seems to retire from the periphery. Thus, during sleep the leaves of the sensitive-plant lose their peculiar sensibility, which retires to the petiole. With the approach of night too an important change takes place in the functions of plants, for instead of exhaling oxygen and absorbing carbon from the atmosphere, as in the daytime, their action at night is directly the reverse.

The sleep of plants usually occurs at night time, owing to the withdrawal of the stimulus of light, to which they are subjected during the day. The experiments of De Candolle indeed have proved that by producing artificial day and night it is possible to change the time for the sleep and waking of plants. There must however be some cause of sleep more intimately connected with their organism than the mere withdrawal of light; for not only are there plants which, like certain animals, sleep through the day and are awake at night, but it has been ascertained that the leaves of plants kept constantly in the dark open and close at regular intervals, as during sleep. [MOTIONS OF PLANTS.]

SLEEP OF PLANTS. [SLEEP.]

SLEEPER. [ELEOTRIS.]

SLO'ANEA, a genus of Plants belonging to the natural order *Tiliaceæ*, named by Plumier in honour of Sir Hans Sloane. The leaves are large and alternate, the flowers are large, and the fruit as big as chestnuts. The trees are not known to be applied to much use, with the exception of *S. dentata*, of which the wood is sometimes employed for making canoes of a single piece. The inner bark is astringent, and prescribed in dysentery. The fruit is eaten.

SLOE. [PRUNUS.]

SLOTH. [BRADYPUS.]

SLOW-WORM. [BLIND WORM; ORVET; SAURIANS; SCINCIDÆ.]

SLUG. [LIMAX; GASTEROPODA.]

SLUGS, SEA. [NUDIBRANCHIATA.]

SMARAGDITE. [AMPHIBOLITE.]

SMEATHMANIA, a small but beautiful genus of Plants belonging to the natural order *Passifloraceæ*. The genus possesses a 1-leaved nectarium, which is urceolate and surrounding the base of the stamens; the stamens are numerous, distinct, and seated on a short column with incumbent anthers; the stigmas are peltate and 5 in number; the capsule is inflated, and 4-5-valved. The seeds are dotted. All the species are upright shrubs, with white showy axillary flowers, and are natives of Sierra Leone. Three species are recorded, *S. pubescens*, *S. levigata*, and *S. media*.

SMELL. The essential part of the organ of smell consists of the expansion of the olfactory nerves, the first or most anterior of the nerves from the brain, whose minutest branches are distributed just beneath the mucous membrane of part of the nose. [NOSE.]

The olfactory nerves descend from the under surfaces of the olfactory bulbs [BRAIN] through the foramina of the cribriform plate of the ethmoid bone. They are very numerous, and are densely distributed in bundles and tufts in the mucous membrane covering the upper part of the septum, the under surface of the cribriform plate, and the inner surfaces of the superior and middle turbinated bones, and of the cells immediately adjacent to them.

All that is necessary for the perception of an odour is that the scented particles (without undergoing any such changes as light does in arriving at the retina, or sound on its way to the auditory nerve) should come in contact with the surface under which the olfactory nerves lie, with the force of rather more than an ordinary inspiration. If the medium containing the odour be at rest, or be only gently forced against the membrane, no impression is produced.

In different animals the sense of smell is adapted chiefly to that class of substances on which they feed. The *Carnivora*, for example, have an acute sense of the odour of animal substances, but, so far as we can discern, none for that of vegetables; and, on the other hand, *Herbivora* are as clear in their perception of the latter, and as nearly insensible to the former. Man, as his food is mixed, so also is his sense of smell adapted to both classes of substances, though for each less acute than that of the animals that feed exclusively on the one or the other. In the choice of food, which is the main object of the sense of smell, man generally, though almost unconsciously, and animals always, exercise the precaution of smelling, and they instinctively form a judgment according to the impression received. In eating also, much of that which is commonly attributed to the

sense of taste depends on the odour of the food carried from the mouth to the nose. In eating cinnamon, for example, or any similar aromatic substance, if we close the nostrils, we perceive no flavour, and, except for the stinging of the tongue, might imagine ourselves eating a tasteless wood. And, in like manner, we often mistake for those of odour the impressions made by substances on the nerves of common sensation with which the lining membrane of the nose is abundantly supplied; for example, in smelling ammonia, vinegar, and other acrid substances, the impression which we regard as their odour is compounded of that and of the irritation of the nerves of common sensation; and the nose of an animal whose olfactory nerves are destroyed is hardly less sensible to this latter irritation than that of one in which the nerves are entire. Facts of this kind have led to the error of supposing that the olfactory are not the only nerves of smell; they only prove that the sense of smell has a more limited range than is commonly supposed. The same substances, ammonia and the like, which irritate the common sensitive nerves of the nose, act in the same manner on the eye or any equally delicate part; but in the nose alone is this irritation accompanied by any peculiar sensation of odour by which one such substance can be distinguished from another. This perception of odour, independently of irritation, is the proper function of the olfactory nerves, which are thus strictly nerves of peculiar sensation, of the same class with the optic, auditory, and gustatory. [NERVOUS SYSTEM.]

SMELT. [SALMONIDÆ.]

SMERDIS. [ERICHTHUS.]

SMEW. [DUCKS.]

SMILACEÆ, *Sarsaparilla*, a small natural order of Plants belonging to Lindley's class of Dicotyledons. There has been much difference of opinion amongst botanists with regard to the position of *Smilax* in the natural system, as well as the number of genera that ought to be admitted into the order *Smilacaceæ*. Lindley has placed two genera, *Smilax* and *Ripogonum*, in this order, which possesses the following characters:—Flowers hermaphrodite or dioecious; calyx and corolla confounded, inferior 6-parted; stamens 6, inserted into the perianth near the base, seldom hypogynous; ovary 3-celled, the cells 1- or many-seeded; style usually trifid; stigmas 3; fruit a roundish berry; silumen between fleshy and cartilaginous; embryo usually distant from the hilum. They are mostly herbaceous plants, with a woody stem, and a tendency to climb. Their leaves are reticulated. This last character separates the order from *Liliaceæ* and its allied orders, with which it otherwise closely agrees.

Smilax is found in most parts of the world, especially in Asia and America. [SMILAX.]

SMILAX, a genus of Plants which gives its name to the natural order *Smilacaceæ*. The name occurs in Greek authors, as Theophrastus and Dioscorides, and is applied to several different kinds of plants, as the yew-tree; a species of *Phacelus* or *Convolvulus* (*Συλάξ-ραχέα*) is *Smilax aspera*, which belongs to the present genus. *Smilax* is characterised by having a 6-leaved corol-like perianth, with six stamens inserted into their base; the anthers are linear and fixed by the base; ovary 3-celled; ovules solitary, in each cell affixed to the apex; style very short; stigmas 3, spreading; berry 1-3-celled, 1-3-seeded; seeds globular; testa membranaceous, whitish; hilum large and coloured; albumen cartilaginous; embryo very small, remote from the hilum. The species form evergreen climbing shrubs, of which a few are found in temperate, but the majority in warm and tropical regions of both hemispheres, extending south to Australia, and north to Japan, North America, and the south of Europe. The species have fibrous or tuberous roots; stems often prickly; leaves alternate petiolate; cordate or hastate, nerved, reticulate, venose, conchiferous stipules between the petioles; flowers sessile on a globular receptacle; subcapitate pediculate and umbellate.

Though the original species (*S. aspera*) of this genus is an inhabitant of the south of Europe, those now most celebrated for yielding the different kinds of *Sarza* or *Sarsaparilla* are natives of South America. But *S. aspera* still continues to be employed for medicinal purposes in the south of Europe, where it is called *Sarsaparilla Italica*, but there is no truth in the statement of its being the plant yielding Indian *Sarsaparilla*, which is *Hemidesmus Indicus*. Another celebrated species is the *Smilax China*, which has a tuberous root abounding in fecula, and therefore probably useful as a demulcent, though the Chinese esteem it invigorating, and ascribe to it other virtues. It is remarkable that two Indian species, which, like the Chinese species, have tuberous roots, should be called in Sihat Hurina-Shook-China and Goota-Shook-China. These are *Smilax glabra* and *S. lanceifolia*, and their roots cannot be distinguished from the China root, or *Chob. chenna*, as it is called in India. A similar species is common in the southern parts of North America, and has been called *Smilax Pseudo-China*, though there is reason to believe that more than one species may be confounded under this name. *S. glyciphylla* is an Australian species, which has received its specific name from the sweetish taste of its leaves, and has been called Sweet Tea from its employment in the form of infusion, and is probably alterative and diaphoretic, as well as slightly tonic. It is probable that some of the species found in the Old World will be discovered to be possessed of virtues equal to the American species. Some of the Indian species were sent some years ago by Dr. Gibson, superintendent of the East India Company's

botanogarden near Poona, to the Medical Board of Bombay, for trial in the hospitals of that presidency. [SARSAPARILLA, in ARTS AND SC. Div.]

SMILLIUM, a genus of *Ranacææ*. [CIRCEPEDIA.]

SMITHIA, a genus of Plants belonging to the natural order *Leguminosæ*, named in memory of Sir James E. Smith. It consists of small plants with inconspicuous flowers, but the leaves are remarkable for their apparent sensibility on being touched, in which they resemble the Sensitive Plant. The genus is nearly allied to *Aschynomene* and to *Lourca*. The calyx is bipartite, the corolla papilionaceous, the stamens in two equal bundles, the legume transversely articulated, plicate, and inclosed within the calyx. The species are found in warm parts of the world, as in Australia and the plains of India, in the rainy season.

SMITHSONITE. [ZINC.]

SMOOTH-HOUND. [SQUALIDÆ.]

SMUT. [FUNGI; UREDO.]

SMYRNIUM (*Συμπριον*), a genus of Plants belonging to the natural order *Umbellifereæ*. It is known by its obsolete calyx; lanceolate or elliptical, entire, acuminate petals, inflexed at the point; didymous fruit, contracted at the side. The half-fruits are almost globose and reuniform, with three fine prominent ridges on the back, and two on the side, but almost obliterated; the channels with many vittæ; the seed is involute; the species are upright smooth biennials with fleshy roots, various leaves, terminal umbels, and variable involucres. The flowers are yellow or yellowish-green, and they are frequently polygamous.

S. Olusatrum, Common Alexanders, has a taper stem; the leaves of the stem are ternate, with ovate serrated-segments, and very short involucels. It is a native of the middle and south of Europe in humid places. It is found in Great Britain, and is observed most frequently near the coast, although not confined to such a locality. This plant was formerly much eaten in Europe both as a salad and potherb, on which account, and the black colour of its stalks and leaves, it derives its specific name *Olusatrum*, from 'olus' and 'ater.' Ray says that this is the *Herba Alexandrina* of Italy and Germany, whence our name Alexanders. It is supposed to have been originally brought from Alexandria. It flowers in May, and the whole plant dries up by the middle of July, but remains laden with large black seeds.

S. perfoliatum, Perfoliate Alexanders, has the stem angularly winged above, with ovate-cordate toothed leaves, which embrace the stem. This plant was obtained in Greece by Dr. Sibthorp, and is also an inhabitant of Spain, Italy, and Dalmatia. It is the *Smyrniun Dioscoridis* of Sprengel; and Sir J. E. Smith was of opinion that this species is the true *Σύμπριον* of Dioscorides, with whose description it remarkably agrees. [*Flora Græca*, p. 289.]

SNOW, water precipitated from the atmosphere in a frozen condition. It assumes very beautiful crystalline forms. When large solid pieces of water are thus precipitated, they are called hail. [WATER, in ARTS AND SC. Div.] Snow often exhibits under the microscope organic beings. This is more especially the case with Red Snow. [SNOW, RED.]

SNOW-BALL-TREE. [GELDER-ROSE; VIBURNUM.]

SNOW-BERRY. [CHIOCOCCA.]

SNOW-BUNTING. [EMBERIZIDÆ.]

SNOW-FLAKE. [LEUCOJUM.]

SNOW, RED. The occasional occurrence of snow coloured red has for a long time created great interest, and it is only since the increased use of the microscope that it has been discovered that this curious phenomenon is entirely due to organic bodies for its existence.

It appears that this phenomenon did not escape the observant eye of Aristotle, and he mentions that living beings found in old snow had frequently a reddish colour, which he supposed they derived from the snow. ('Hist. Anim.,' v. cap. 19.) This observation of Aristotle's however does not appear to have excited any attention, and no other writer mentioned the occurrence of red snow till 1760, when Saussure discovered it on the Brevent and other mountains, but more especially on the Saint-Bernard, where it existed in great abundance. He made some chemical analyses of this snow, and came to the conclusion that it was of vegetable origin, and probably consisted of grains of pollen mixed with the snow, such a cause having been known to discolour rain, producing what was called a 'sulphur shower.' (De Sauss., 'Voyage,' ii. p. 646.)

It was not however till the year 1819, when our countryman Captain

Ross returned from his arctic expedition, that this substance was accurately examined with a view to the discovery of the origin of its peculiar colour. Whilst in Baffin's Bay, 75° 54' N. lat., 67° 15' W. long., Captain Ross discovered a range of cliffs covered with snow of a crimson colour. The cliffs were about 600 feet high, and were coloured for the extent of eight miles. According to Captain Ross, the party he sent on shore "found that the snow was penetrated even down to the rock, in many places to a depth of 12 feet, by the colouring matter, and that it had the appearance of having been a long time in that state."

In the Appendix to the account of Captain Ross's polar expedition, Mr. Robert Brown described the colouring-matter of this snow as dependent on a species of unicellular plants belonging to the family of *Algae*, and pointed out its resemblance to the *Tremella cruenta* of 'English Botany.' At the same time some of the red snow water brought from Baffin's Bay was sent to Francis Bauer, who published the results of a very careful examination of it under the microscope, in the seventh volume of Brande's 'Journal of Science and Arts,' accompanied with several drawings. He found that the water contained a number of opaque or red spherical globules, which were heavier than the water, forming a sediment at the bottom of the bottle, and also of some transparent vesicular bodies which floated about in the fluid. On examining the red globules, he found them possessed of a pedicel resembling that of some species of *Uredo*, and regarded them as a species appertaining to this genus. He subsequently observed that many of the globules were attached to a gelatinous matrix presenting a cellular and articulated character. On exposing the water with the globules for some days to the air, he found that they lost their colour, and that on the sides of the vessel were developed new portions of the gelatinous matrix, which were covered with small globules, which he looked upon as young *Uredos*. He also found that on comparing the chemical analysis of the *Uredo fatida* with that of the red snow, they in a great measure agreed, and hence he came to the conclusion that the colouring-matter of the red snow was a fungus belonging to the genus *Uredo*, and to which he gave the name *U. nivalis*. [*Protococcus*; *Hæmatococcus*.]

But the question was not thus set at rest. In 1823 Baron Wrangel gave an account of a plant of a red colour, which he called *Lepraria Kermesina*, and supposed to be identical with the long-disputed *Byssus Isolitus* of Linnaeus. This plant was obtained from the surface of white limestone rocks, forming over them a thin red crust, and was also found contained in the rain-water remaining on the limestone. During the same year Professor Agardh of Lund, who had previously suggested the identity of this plant and that of red snow, received specimens of the *Lepraria* from Baron Wrangel, and also of the *Uredo nivalis* of Bauer from England, and he came to the conclusion, after a very minute examination, "that the two plants were actually one and the same species." "We must conclude," says Agardh (Greville's 'Scottish Cryptog. Flora—*Protococcus*,' p. 15), "that the *Uredo nivalis* and the *Lepraria Kermesina* are alike called into existence by the gradual melting of the snow, and the intensity of light in their relative situations; and that they are neither washed down from the rocks, as some persons believe, nor are precipitated from the atmosphere, as might be inferred from the accounts transmitted by the Italians."

The plants which Agardh had thus identified, he could not consider, with Bauer, a fungus, or, with Wrangel, a lichen, but, from its analogy to some of the *Algae*, he placed it in his 'Systema Algarum,' in that family under the name of *Protococcus nivalis*.

Protococcus nivalis, Greville (*Gleicococcus nivalis*, Shuttleworth).

a, mature globules mixed with younger ones (1) lying on a mass of gelatine; b, mature globules, some burst, with granules lying on the gelatine; c, granules; d, globules after discharging their granules; e, full-sized globules.

In 1825 the subject was taken up by Dr. Greville of Edinburgh. He had received specimens of the plant of red snow from the polar regions, and also from the island of Lismore in Scotland. From this latter situation it was sent to Dr. Greville by Captain Carmichael, who says:—"It occurs in abundance on the borders of the lakes of

Lismore, spreading over the decayed reeds, leaves, &c. at the water's edge, but in greater perfection on the calcareous rocks within the reach of occasional inundation; and what is rather remarkable, it seems to thrive equally well whether immersed in water or exposed to the dry atmosphere. It is to be found more or less at all seasons of the year." The specimens were immersed in water, and then examined by the microscope. In every instance Dr. Greville observed a gelatinous substratum varying in thickness, colourless, diffuse, without any border. Upon this gelatine rested a vast number of minute globules, the colour of fine garnets, exactly spherical, nearly opaque, yet very brilliant, and nearly equal in size. In the full-sized globules granules were detected in the interior, which gave to the surface a reticulated appearance. When mature, they burst, and the granules escaped, to the number of six, eight, or more, and the membrane only of the globule was left behind, buoyant and colourless. The globules or granules were never observed to move. Dr. Greville at first doubted the propriety of referring his plant to Agardh's genus *Protococcus*, as in his definition Agardh had not mentioned any gelatinous substratum, which was so evident in his own specimens. He however determined on keeping up the genus with an amended character. Agardh's definition of *Protococcus* is merely, "plants with aggregated, not mucous globules." To this Greville added, "globules containing granules seated on a transparent gelatinous mass."

In the same year Sir William Hooker, in the 'Appendix to Parry's Second Voyage to the Arctic Regions,' described, under the name of *Palmella nivalis*, the plant of the red snow collected in that expedition. Sir William Hooker referred the plant to this genus, as it only differed in its globules being seated on a gelatinous mass, instead of being immersed in it.

From this time to 1838 a variety of memoirs and observations upon the red snow were published, chiefly on the Continent, by Kunze, Unger, Martius, and other observers, but no new matter of any importance was elicited.

We now come to another and very important point in the history of red snow. Hitherto all the examinations had been made on old specimens of the red snow, most of them removed at a great distance from the spots on which they were originally found. In August, 1839, Mr. Shuttleworth, an English gentleman resident in Switzerland, being at Grimsel, understood that there was red snow in the neighbourhood, and having a microscope with him, made observations on the recently procured snow. Having melted the snow and placed some of the red matter on the field of the microscope, he was surprised at finding, instead of the immovable globules of an *Alga*, an immense number of exceedingly active animalcules, not of one form only, but of various sizes and forms. The results of this examination he has given in an interesting paper accompanied with drawings, in the 'Bibliothèque Universelle de Genève,' for February, 1840. The following are the forms of *Infusoria*, which he was enabled so to detect:—1. An animalcule belonging to Ehrenberg's genus *Aetasia*, which he called *A. nivalis*. 2. An animalcule, red inside, with a transparent carapace, belonging to the genus *Gyges* (*G. sanguineus*, Sh.). 3. One much smaller than the other two, moving, but resembling the globules of *Protococcus*. 4. One belonging to the genus *Volvox*. Several other uncoloured species were found, but they were considered accidental. In addition to the animalcules, Mr. Shuttleworth found bodies which he took to be true plants, and referred to the *Protococcus nivalis* of Agardh and the *P. nebulosus* of Kützing.

In 1840 Professor Agassiz of Neuchâtel made a visit to the glacier of Aar, having taken with him a microscope. He confirmed the researches of Shuttleworth, having found all the animalcules mentioned by him, and added four others to the list. Three of these are comparatively unimportant, but to the fourth great interest attaches, as he supposes that the ova of this animal are the globules which have been taken for a plant, and called *Protococcus*, &c. This animalcule is the *Philodina roseola* of Ehrenberg. It was found abundantly in the lower glacier of the Aar. It has a much higher organisation than the other animalcules, and contains in its inside a number of red globules, which may be distinctly seen through its transparent body. These globules are its ova, which, on being deposited, precisely resemble the globules of *Protococcus* as figured by Shuttleworth and others.

In the various papers referred to above, no mention is made of snow of any other colour than red. Martius however, a naturalist who accompanied the French expedition to Spitzbergen, mentions having found in one instance a field of green snow. It was accompanied however with the *Protococcus* giving a red colour. From many observations Martius arrived at the conclusion that the red globules of the green snow are identical with those of the red snow, and that the green snow (*P. viridis*) and the red snow (*P. nivalis*) are one and the same plant, only in different stages of development, but that it is difficult to state which is the original. The late Professor Meyen (Taylor's 'Ann. Nat. Hist.', August, 1841) remarks on this statement, that these *Protococci* are not plants, but animals, the *Euglena sanguinea* and *E. viridis* of Ehrenberg. The reason of their being so often taken for plants is, that they naturally pass a great portion of their existence in a passive state, only occasionally under favourable circumstances starting into activity. When they do this, their spherical

form is changed, and they become the elongated beings described and figured by Ehrenberg.

From these researches it is very evident that red snow is not dependent on one form of organic existence, but that several species of plants and animals contribute to its production. It may however be remarked that it is probable that a species of plant is first developed, and it is not impossible that all the forms of animalcules described, except *Philodina*, may turn out to be forms of the same species of plant.

SNOWDROP. [GALANTHUS.]

SOAP-BERRY. [SAPINDUS.]

SOAPSTONE. [STEATITE.]

SOAPWORT. [SAFONARIA.]

SOAPWORTS. [SAPINDACEÆ.]

SOCOTRINE ALOES. [ALOE.]

SODA. [SODIUM.]

SODA ALUM is a Mineral occurring in white fibrous masses. The outer fibres opaque by decomposition, internally transparent, and exhibiting a glossy or silky aspect. It is not scratched by the nail. Specific gravity 1·88. It is found at San Juan in South America. Its analysis by Thomson gives—

Sulphuric Acid	33·5
Alumina	12·0
Soda	7·5
Water	42·0
	—100;

with a little silica, lime, iron, and manganese.

SODA'DA, a genus of Plants named from 'Sodad,' the Arabic name of a shrub found in Egypt, as well as everywhere in the province of Yemen in Arabia. It was considered by Forskal, the discoverer, to be a distinct genus belonging to the natural family of *Capparidaceæ*. It is now arranged only as a sub-genus under *Capparis* [CAPPARIDACEÆ], distinguished by having concave leaflets of the calyx, atamens indefinitely numerous, berry ovate. It requires mention only as the unripe fruit is cooked, and forms an article of diet among the Arabs. The same plant is known in Egypt by the name Hembac. It forms a shrub with thorny nearly leafless branches.

SODALITE, a Mineral occurring crystallised and massive. Its primary form is the cube, but it is usually met with in rhombic dodecahedrons, parallel to the planes of which it is cleavable. Fracture conchoidal, uneven, with a vitreous lustre. Hardness sufficient to scratch glass easily. Colour white, gray, grayish-green, and green. Streak white. Lustre vitreous. Transparent, translucent. Opaque. Specific gravity 2·295 to 2·37.

Massive varieties amorphous. Structure granular, compact.

When heated by the blow-pipe, the edges are rounded with difficulty, and without any other alteration. With borax dissolves into a colourless transparent glass with great difficulty. It is found in Greenland, in Mount Vesuvius, and in Siberia. An analysis of the Vesuvian mineral by Arfwedson gave—

Silica	35·99
Soda	26·55
Alumina	32·59
Muriatic Acid	5·30
	—100·43

SODIUM, a Metal, the base of the alkali Soda. It was discovered at the same time with potassium by Sir Humphrey Davy. It oxidises so readily when exposed to the air, or any substance containing oxygen, that it is never found free in nature. Soda, the oxide of sodium, occurs naturally in combination with sulphuric acid, nitric acid, carbonic acid, and boracic acid. [GLAUBER SALT; GLAUBERITE; BORON; SODALITE.]

Sodium, in combination with chlorine, forms Chloride of Sodium, or Common Salt, the principal ingredient in sea-water.

Sea-water contains 32 to 37 parts of solid substances in solution in 1000 parts of water. The largest amount in the Atlantic, 36·6 parts, is found under the equator, away from the land or the vicinity of fresh-water streams; and the smallest in narrow straits, as Dover Straits where there are only 32·5 parts. In the Baltic and the Black Sea the proportion is only one-third that in the open ocean. Of the whole, one-half to two-thirds is common salt (chloride of sodium). The other ingredients are magnesian salts, chloride and sulphate, amounting to four-fifths of the remainder, with sulphate and carbonate of lime, and traces of bromides, iodides, phosphates, and fluorides. The water of the British Channel affords—water 964·7 parts in 1000, chloride of sodium 27·1, chloride of potassium 0·8, chloride of magnesium 3·7, sulphate of magnesia 2·30, sulphate of lime 1·4, carbonate of lime 0·03, with some bromide of magnesium, and probably traces of iodides, fluorides, and phosphates. The bitter taste of sea-water is owing to the salts of magnesia present.

The waters of the Dead Sea contain 200 to 250 parts of solid matter in 1000 parts (or 20 to 25 per cent.), including 7 to 10 per cent. of common salt, the same proportion of magnesian salts, principally the chloride, 2½ to 3½ per cent. of carbonate and sulphate of lime, besides some bromides and alumina. The density of these waters is owing to this large proportion of saline ingredients. The brine-springs of England and America are well known sources of salt. Many of the

springs afford bromine and iodine, and large quantities of it are manufactured for making Daguerreotype plates and other purposes.

Chloride of Sodium crystallises in cubes, and its presence in water or the secretions of animal bodies may easily be detected by evaporation, and submitting the crystals to the microscope. Salt is originally associated with gypsum and clay, and sandstone (New Red-Sandstone). It is necessarily a constituent to a greater or less extent of all deposits formed from the bed of the ocean. It occurs in extensive beds in Spain, forming hills 300 or 400 feet high; also in Poland, the Tyrol, Bavaria, Salzburg, Upper Austria, Stiria, Hungary, Transylvania, Wallachia, Galicia, Upper Silesia; at Vic and Dienze in France; at Bex in Switzerland; in Cheshire, England; in Africa, Persia, India, China and Asiatic Russia, in South America, in Peru and the Cordilleras of New Granada.

The most remarkable deposits are those of Poland and Hungary. The former, near Cracow, has been worked since the year 1251, and it is calculated that there is still enough salt remaining to supply the whole world for many centuries. The deep subterranean regions are excavated into houses, chapels, and other ornamental forms, the roof being supported by pillars of salt; and when illuminated by lamps and torches they form objects of great splendour.

The salt is often impure with clay, and is purified by dissolving it in large chambers, drawing it off after it has settled, and evaporating it again. The salt of Northwich (in Cheshire) is in masses 5 to 8 feet in diameter, which are nearly pure, and it is prepared for use by crushing it between rollers.

Beds of salt have lately been opened in Virginia in Washington county, where as usual it is associated with gypsum. The Salmon Mountains of Oregon also afford rock-salt.

Salt-beds occur in rocks of various ages: the brines of the United States come from a Red-Sandstone below the coal; the beds of Northwich, England, occur in Magnesian Limestone; these of the Vosges in marly Sandstone beds of the Lower Secondary; that of Bex in the Lias or Middle Secondary; that of the Carpathian Alps in the Upper Oolite; that of Wieliczka, Poland, and the Pyrenees, in the Cretaceous Formation or Upper Secondary; that of Catalonia in Tertiary: and moreover there are vast deposits that are still more recent, besides lakes that are now evaporating and producing salt depositions.

Vast lakes of salt-water exist in many parts of the world. Lake Timpaugos, or Youta, called also the Great Salt Lake, has an area of 2000 square miles, and is remarkable for its extent, considering that it is situated towards the summit of the Rocky Mountains at an elevation of above 4000 feet above the sea. The state of California abounds in salt hills and lakes. In the north of Africa large lakes and hills of salt abound, and the deserts of Africa are frequently found covered with an efflorescence of salt.

Carbonate of Soda, or Natron, occurs in white efflorescent crusts, sometimes yellowish or grayish. It is abundant in the soda lakes of Egypt, situated in a barren valley called Bahr-bela-ma, about 30 miles west of the Delta. Also in lakes at Debreczin in Hungary; in Mexico, north of Zacatecas, and elsewhere. It is sparingly dissolved in the Seltzer and Carlsbad waters.

Trona is a Sesquicarbonate of Soda. In the province of Suckena in Africa, between Tripoli and Fezzan, it forms a fibrous layer an inch thick beneath the soil, and several hundred tons are collected annually. At a lake in Maracaibo, 43 miles from Merida, in South America, it is very abundant.

It is mostly obtained for commercial purposes from chloride of sodium by the addition of charcoal.

Nitrate of Soda is found native, in the district of Tarapaca, in South America; the dry pampa, for an extent of 40 leagues, is covered with beds of this salt, mixed with gypsum, common salt, sulphate of soda, and remains of recent shells. It is found in other parts of the world, and is used for many of the purposes to which nitrate of potash is put, especially in making nitric acid.

(Dana, *Manual of Mineralogy*.)

SOJA, a genus of Plants belonging to the natural order *Leguminosæ*. *Soja hispida* (Moench), *S. Japonica* (Savi), the *Dolichos Soja* (Linn.), is a native of Japan and the Moluccas, and abundant in the peninsula of India, though probably introduced there. The seeds resemble those of the haricot, French or kidney bean, and are used by the Chinese to "form a favourite dish, called 'ten-hu,' or 'tau-hu,' which looks like curd, and which, though insipid in itself, yet with proper seasoning is agreeable and wholesome." The Japanese call the seeds 'Miso,' and put them into soup, of which they sometimes partake three times a day. They likewise prepare with them the sauce termed 'Soija,' which has been corrupted into 'Soy.' Soy is only sparingly used as a sauce in this country. It has the character of being a useful stomachic, but not more so than any of the other condiments when used with moderation.

SOLA, frequently *Shola*, is the name of a Plant common in moist places, and in the rainy season in many parts of the plains of India. It belongs to the genus *Aschynomene*, and has been called *A. aspera* by Linnæus, from the lower part of the stem being rough and scabrous, as well as the legumes. It has been called *A. lagenaria*, both by Loureiro and Roxburgh. The plants are remarkable for their light and spongy texture, and seem indeed to be composed almost entirely

of pith. On this account the thicker stemmed plants are collected in the dry mouths and the light substance applied to a variety of uses, as for making some kinds of toys, and the floats of fishermen's nets; cut into thin slices and pasted together, they are much employed for making hats, which, being light and having broad brims, are well suited for protecting the head from the influence of the powerful Indian sun, especially if a handkerchief be put loosely into the crown of the hat. This substance has also been employed for lining drawers of natural history, and in its texture very much resembles the substance called rice-paper, which is the pith or stem of a Malvaceous plant cut into thin slices.

SOLAN GOOSE. [DUCKS.]

SOLANA'CEÆ, a natural order of Plants belonging to the dicarpous group of Monopetalous Exogens. This order is composed of herbs or shrubs, rarely of arborescent plants, with colourless juices, round or irregularly angled stems or branches, sometimes armed with thorns or prickles; their leaves alternate, simple, entire, or lobed. The inflorescence is variable, mostly axillary, sometimes terminal; pedicels without bracts, and the flowers regular and united. The calyx is 5-parted, persistent, inferior; corolla monopetalous, hypogynous, 5-cleft or 4-cleft, regular, deciduous, plaited or imbricated in æstivation; stamens inserted upon the corolla, as many as the segments of the limb, and alternate with them; anthers bursting, mostly longitudinally, sometimes by pores at the apex; ovary 2- or 4-celled, style continuous, stigma simple; fruit either a capsule, with a double dissepiment parallel with the valves, or a berry with a placenta adhering to the dissepiment; seeds numerous, sessile; embryo straight or curved, lying in fleshy albumen; radicle next the hilum.

This order is most closely allied to *Scrophulariaceæ*, but is distinguished by Brown from that order by the possession of a curved or spiral embryo, a plaited æstivation of the corolla, and the flowers being regular, with the same number of stamens as lobes. From the occurrence of many species in this order with a straight embryo, but with the other characters of *Solanaceæ*, Lindley, with Bartling and others, is inclined to look upon this as a secondary point, and a plaited corolla and symmetrical flowers to constitute the real character of this order. *Solanaceæ* and *Scrophulariaceæ* are however so nearly allied that scarcely any limits exist between them. They may be considered as the connecting groups of two larger masses of plants, of which one has a tendency towards regular flowers and symmetrical stamens, and the other a tendency towards irregular flowers and didynamous stamens.

The plants of this order are natives of most parts of the world, without the arctic and the antarctic circles, and especially within the tropics.

Nicotiana glauca.

a, cutting, showing alternate leaves and monopetalous flowers; b, transverse section of capsule with many-seeded placenta; c, pistil; d, fruit; e, seed, with straight embryo surrounded with albumen.

This order is one of the most important and interesting in its class, from its bringing together plants of the greatest utility, yet possessing apparently opposite properties. It is a great advantage of a natural system that it brings together not only plants that are allied in structure, but in properties also; but this order seems to form an exception. The Deadly Nightshade, the esculent Potato, the pungent Capsicum, the mild Tomato, the wholesome Egg-Plant, and the poisonous Tobacco, are all found here. They will all however, on close examination, be found to possess the same properties in a greater or less degree. The potato, the tomato, and egg-plant possess, when uncooked, in a mild

degree, the properties of the Nightshade, the Stramonium, and the Henbane, confirming the remark of De Candolle, "that all our aliments contain a small proportion of an exciting principle, which, should it occur in a much greater quantity, might become injurious, but which is necessary as a natural condiment." In fact, when food does not contain some stimulating principle, we add it in the form of spices. Many of the plants of this order are used in medicine, amongst the most valuable of which are Henbane [*HYOSCYAMUS*], Deadly Nightshade [*ATROPA*], Bitter-Sweet [*SOLANUM*], Stramonium [*DATURA*], and Tobacco [*NICOTIANA*]. The species of *Physalis* were formerly used in medicine, but are not now in repute in this country. *P. Alkekengi*, the Common Winter Cherry, is grown as an ornamental plant; and in Arabia, and even Germany and Spain, the berries are eaten as a dessert. *Lycium barbarum* is known in this country as Tea-Plant, and has been recommended as a substitute for the Chinese plant. The Calabash-Trees of the West Indies and the American continent are different species of *Crescentia*, which is often referred to this order. The fleshy pulp of the fruit of some is eaten, but in most species is deleterious. The most valuable part of the calabashes is their rind, which is tough, and it is applied by the negroes to a variety of purposes. Cups, mugs, bowls, basins, and sancepans, are made from them, and many other articles of household use. Cayenne-pepper [*CAPSIUM*] is the produce of this order, as well as the potato, tomato, and egg-plant [*SOLANUM*], which are used extensively as articles of diet.

SOLANDRA, a genus of Plants belonging to the natural order *Solanaceæ*, which has been thus named in compliment to Daniel C. Solander, LL.D. The name has been applied to other genera, but is now restricted to a small Solanaceous genus, which is remarkable for the beauty and great size of the flowers of its species, which are natives of Mexico, Jamaica, and Brazil, with a doubtful species in Ceylon, forming large scandent shrubs, with broad alternate leaves crowded at the extremities of the branches with the solitary extra-axillary or terminal flowers. The genus is characterised by having a sheath-like calyx splitting on one side, and 3-5 cleft at the apex. Corolla funnel-shaped and ventricose, with a plicate quinquefid limb and undulated lobes. Stamens 5; anthers versatile, opening longitudinally. Berry pulpy, covered by the split calyx, 4-celled, many-seeded. These, being highly ornamental plants, are cultivated in our hothouses, but, requiring moisture and much room, are difficult to flower. Sweet says the best way is to plant them in a loamy soil, and allow them to grow fast at first, till they have made a great many shoots; then keep them very dry till their leaves drop off, and they will produce plenty of flowers. The best way to have plants flower young is to take the cuttings from the flowering shoots.

SOLANOCRINITES. [ENCRINITES.]

SOLAN'UM, the name of one of the most extensive genera of Plants, the type of the natural order *Solanaceæ*. This genus is distinguished by the following characters:—Calyx permanent, 5-10-parted; corolla rotate; anthers oblong, connivent, opening by two pores at the extremity. Fruit a berry, subglobose, 2-celled, sometimes 3-4-celled. The species are herbs or shrubs, unarmed or prickly, rarely spiny. The leaves are entire, sinuated or lobed, mostly alternate.

Upwards of 400 species of plants belonging to this genus have been enumerated, including many with apparently very opposite properties. The esculent Tomato, the Egg-Plant, and the invaluable Potato, with the various species of poisonous Night-Shades, are found united so closely by botanical characters that it is impossible generically to separate them. The properties of these plants however do not differ in kind but in degree; and the berries and leaves, and even the tubers when uncooked, of the Potato, possess in a mild degree the narcotic properties of the poisonous Nightshades. Many of them have also very handsome flowers, and are much cultivated in our gardens and greenhouses. From the immense list of species belonging to this genus, we shall select for description a few of those that are used as medicines or food, or are much cultivated.

S. tuberosum, Common Potato, is known in the genus by its tuberous subterranean stem, herbaceous stems without thorns, unequally pinnate leaves with entire leaflets, and articulated pedicels. It is one of the plants for which we are entirely indebted to America. It is found native in the greatest abundance on the western coast of South America. Like most plants which are much cultivated, an abundance of varieties have been produced from the original plant, and in the leaves, colour of the flowers, shape, size, and colour of the tubers, it has a great tendency to depart from its normal character. [POTATO, in ARTS AND SC. DIV.] Two other species of *Solanum*, namely, *S. Valenzuela* and *S. montanum*, produce edible tubers, but they are little used.

S. nigrum, Common or Garden Nightshade. Stem herbaceous, without thorns; leaves ovate, bluntly toothed, and waved; umbels lateral, drooping. Throughout Europe it is a weed in cultivated ground, and is also found in Africa and Asia. It is common in gardens, fields, and waste places in Great Britain. It has white flowers, producing small berries of a black colour.

S. dulcamara, Woody Nightshade, or Bitter-Sweet. Stem shrubby, thornless, climbing, flexuous; leaves cordate, upper ones jagged; corymbs almost opposite the leaves. It is a native of Europe, Asia, and North America, in hedges and among bushes. It is plentiful in Great Britain. It has purple flowers and crimson berries, which

latter may be mistaken by children for red currants, a mistake that has sometimes been attended with fatal consequences.

S. Melongena, Egg-Plant, Mad Apple, or Jew's-Apple. Stem herbaceous, woody at the base, clothed with star-shaped hairs; ovate serrated leaves; flowering peduncles reflexed; fertile peduncle solitary, sterile ones racemose; calyx campanulate; corolla angular. It is a native of the East Indies, and also said to be of Arabia. This plant has purple flowers, and bears large smooth shining berries, which are the shape and size of a small hen's egg. Two varieties of this plant are recorded—the *S. M. ovigerum*, in which the stem, calyx, and leaves are without thorns; and the *S. M. esculentum*, in which these parts are more or less covered with thorns. Several sub-varieties of both these are recorded, varying in the shape and colour of the fruit. The berries are mostly of a white colour, but in some of the sub-varieties they are yellow, red, purple, and black. The fruit of this plant is used by the French and Italians in stews and soups. For this purpose the varieties used are the oval-shaped white, the globular-shaped white, and the purple or violet-coloured of both forms. In cultivating them they may be reared in hot-beds in a rich light soil, or in fine summers they will even produce their fruit in this country against a wall, if planted out in June after having been struck in a hotbed.

S. Sodomæum, Sodom Egg-Plant, or Apple of Sodom. Stem shrubby, diffuse; prickles straight, dilated at the base; leaves oblong-sinuate, shining above, and rather scabrous and prickly on both surfaces; lobes obtuse-angular; peduncles bifid. It is a native of the North of Africa and the south of Europe. The fruit of this plant is white, and about the size of a walnut. It is very subject to the attacks of an insect which deposits its eggs within the germen, and as the fruit enlarges, the larvæ of the insect, as in the case of many other fruits, destroy and pulverise the whole of the interior, whilst the rind is left unchanged and entire. When the fruit is gathered under these circumstances, it is crushed to pieces by the hand; or if conveyed to the lips, the mouth becomes filled with an ash-like powder, exceedingly bitter to the taste. To these berries remarkable properties have been assigned by Josephus, Tacitus, and others. Meadeville, an old English writer, says, speaking of the Dead Sea, "And there heyden growen trees that baren fulle faire apples and faire of colour to beholden, butte whose breake the one or cutteth the other in two, he shall find within them coles and cyndres." Milton finely alludes to this fruit in the lines:—

"Greedily they pluck'd
The fruitage fair to sight, like that which grew
Near that bituminous lake where Sodom flamed.
This more delusive, not the touch but taste
Deceived; they fondly thinking to allay
Their appetite with gust, instead of fruit
Chewed bitter ashes."

S. sanctum, Palestine Egg-Plant. Stem shrubby, tomentose; leaves ovate-repand, oblique at the base, clothed with heavy tomentum on both surfaces. Berries nearly globose. This plant is a native of Palestine; it is often found in collections of plants. There are several other species of *Solanum*, which, on account of the size, form, and colour of their fruits, are called Egg-Plants, as *S. Indicum*, the Indian Egg-Plant, &c.

S. Aethiopicum, Ethiopian Nightshade. Stem herbaceous; leaves ovate-repand, angular; peduncles usually 1-flowered, drooping. Berries torulose. It is a native of Ethiopia, China, and Japan. There are two varieties recorded: one, the *S. A. violaceum*, is a native of China, and the fruit is frequently eaten in that country as a dessert. It has a large spheroid oval berry of a red colour. The other variety is the *S. A. aculeatum*, having a prickly stem, and small yellow berries of the size of peas.

S. pseudo-quina, False Quina Nightshade. Stem shrubby, unarmed. Leaves oblongo-lanceolate, narrow, acute-entire, glabrous above, but with fascicles of villi in the axils of the nerves beneath. Racemes extra-axillary, short; calyx glabrous. This plant is a native of Brazil in the district of Curitiba, in St. Paul without the tropics. The Brazilians use this for the same purposes as the Quina, or Jesuits Bark. It is intensely bitter, and may with advantage be used as a substitute for that bark.

S. verbascifolium, Mullein-Leaved Nightshade. Stem shrubby; leaves ovate-oblong, acuminate, entire, tomentose, white beneath, without any leaves in the axils; corymbs nearly terminal, dichotomous; calyx semi-quinquefid. It is a native of Asia, America, and the tropical parts of Australia. This plant is frequently cultivated. Every part is covered with a powdery white tomentum. The flowers are white, and the berries are of the size of small cherries.

S. Lycopersicum of Linnaeus, Common Love Apple or Tomato. This, with some other of the older species of *Solanum*, now form the genus *Lycopersicum*, which is distinguished by possessing a calyx 5-6 parted; corolla rotate, 5-6-cleft; stamens 5; anthers conical, connate at their extremities by an elongated membrane, and dehiscing lengthwise inside; berry 2-3-celled; seeds villous. The present species is called *L. esculentum*; it has herbaceous pilose stems; unequally pinnate leaves; leaflets cut, attenuated at the apex, glaucous beneath; flowers many, united; berries torulose. This plant is a native of South America, but it is much cultivated and well known in the United

States of North America, and in France, Germany, and Italy. When ripe the fruit has an acid flavour, and is added to soups, sauces, &c. It is also used in confectionary as a preserve, and sometimes as a pickle. It is not often used in this country, but in Italy, near Rome and Naples, whole fields are covered with it, and scarcely a dish is served up into which it does not enter as an ingredient. In the cultivation of these plants the seed should be sown in March in a hot-bed, and when 2 inches high they may be pricked out into another hot-bed. In May they should be transplanted into a warm south border, where they may have the full sun, and the fruit may ripen quickly. The stem runs up 6 or 8 feet high, and should be trained to stakes or nailed up a wall or pales. The fruit begins to ripen in August, and may be gathered in October, and, when kept dry, will keep good till November. There are several varieties cultivated; the best are called the Large and Small Cherry and Pear-Shaped Red, and the Large and Small or Cherry-Shaped Yellow. The size of the fruit is seldom larger than a golden-pippin apple. (Don's Miller, vol. iv., p. 444.)

Several other species of *Solanum* are recorded as having medical properties. *S. Jacquinii* is considered by the native practitioners of India as an expectorant; *S. Bahamense* is used as a gargle for sore throat in the West Indies; *S. mammosum*, *S. paniculatum*, and *S. cernuum*, have the reputation of being diuretic and astringent.

(Lindley, *Flora Medica*, p. 512.)

SOLARIUM. [TROCHIDÆ.]

SOLASTERIÆ, or SOLASTERINÆ, a sub-family of *Asteriadae*, including those forms of Star-Fishes which have two ranges of suckers in each avenue. There are two British genera, *Cribella* and *Solaster*.

Cribella has only a few rays covered with spine-bearing warts; the intermediate apices porous; the avenues bordered by two sets of spines.

There are two species which are not uncommon on the shores of the British Islands, *C. oculata* and *C. rosea*.

Solaster (Fishes) has many rays studded over with bundles of spines; the avenues bordered by three sets of spines.

S. papposa, the Rosy Sun-Star, is common on the eastern coasts of Great Britain, where, on account of the number of its rays, it is called Ten-Fingers. It is of a deep red or orange colour. Another British species is *S. endeca*. [ECHINODERMATA.]

SOLDANELLA, a genus of Plants belonging to the natural order *Primulaceae*. Some of the species are slightly purgative.

SOLE. [PLEURONECTIDÆ.]

SOLEA. [PLEURONECTIDÆ.]

SOLECURTUS. [PYLORIDIA.]

SOLEMYA. [PYLORIDIA.]

SOLEN. [PYLORIDIA.]

SOLENA'CEA. [PYLORIDIA.]

SOLENE'LLA (Sewerby), a genus of *Mollusca*.

SOLENIDÆ. [PYLORIDIA.]

SOLENI'TES, a Fossil Plant from the Yorkshire coast. (Lindley.)

SOLE'NODON, a genus of Insectivorous *Mammalia* established by Brandt on a specimen sent from the island of Hispaniola by Jäger. The habit is generally between that of *Sorex* and *Didelphys*. Muzzle elongated, the snout smooth, produced, and with nestrils at the sides of its apex. Eyes minute. Ears large, rounded, nearly naked. Body hairy. Stern and upper part of the rump beset with a few very short silky hairs. Feet ambulatory, plantigrade, pentadactylous; claws falcate, those of the fore feet the longest. Testes inguinal (?) Tail long, smooth, and for the most part scaly. Dental Formula:—

$$\text{Incisors, } \frac{6}{6}; \text{ Molars (spurious) } \frac{6}{6}; \text{ true Molars } \frac{8}{8} = 40.$$

The skull of *Solenodon* is considerably elongated: the occipital, parietal, and temporal bones are moderately convex; and the condyles of the occipital are prominent. There is an obtuse crest on the sagittal suture, but none on the coalesced frontal bones. The internal pterygoid processes alone are conspicuous, thin, and joined by a suture with the perpendicular parts of the palatal bone. There is no bony bulla, and consequently the interior wall of the tympanic cavity is only closed by skin. There is no zygomatic arch. The coronoid process of the mandible is dilated and directed outwards. The angle of the mandible is dilated, subtrapezoidally rounded, and prominent above the condyloid part.

The two anterior upper incisor teeth are the largest, disjoined from the others, perpendicular, and unicuspid; the two anterior lower incisors are very short and very narrow; the two middle are the longest, and conical, and excavated on the internal surface with a rather deep triangular canal. Brandt remarks that the structure of the teeth manifests a greater similitude to that of *Mygale* than any other genus.

S. paradoxus has the sides of the head and neck dilute yellow-brown, mixed with ferruginous, and occasionally with gray. Abdomen and feet dilute yellow-brown, with hardly a mixture of gray. Space upon the breast between the anterior limbs dilute ferruginous, extended to the internal side of the feet, and anteriorly to the cubit. A similarly coloured space occupies the inguinal region, and also extends upon the anterior part of the legs. Upper part (dorsum) of the

muzzle, forehead, vertex, middle of the nape, and anterior part of the back, tinged with black-brown: the rest of the back black-brown, the colour (more diluted) extending towards the posterior part of the sides and towards the external surface of the thighs. The nasal and middle part of the scaly tail gray; the apical part white.

a, Skull of *Solenodon* (profile); *b*, seen from above; *c*, seen from below; *d*, mandible or lower jaw; *e*, anterior part of the intermaxillary bone, with the two anterior incisor teeth; *f*, anterior surface of an anterior upper incisor tooth; *g*, anterior parts of the mandible, with the four anterior incisor teeth; *h*, the crown of a second or middle incisor tooth of the mandible, seen on its internal surface, and exhibiting its triangular canal. (The foregoing figures are nearly of the natural size.) *i*, Teeth of the upper jaw seen laterally; 1 1, natural size; 2 2, magnified. (Brandt.)

Feet of *Solenodon*. (Brandt.)

a, anterior part of the anterior foot, seen on the dorsal or upper side; *b*, a similar view of the anterior part of the posterior foot.

NAT. HIST. DIV. VOL. IV.

Habits, &c.—Brandt remarks that nothing is known of the mode of life of this animal; but from the structure of the proboscis and claws, he concludes that it must burrow. The form of the nose and of the cribriform plate seems, he observes, to indicate a well-developed organ of smell.

The true place of this animal is, most probably, among the *Soriceide*

Solenodon paradoxus. (Brandt, 'Memoirs of the Imperial Academy of Sciences of St. Petersburg, 1832-33'.)

SOLETELLI'NA. [PYLORIDIA.]

SOLIDA'GO, a genus of Plants belonging to the natural order *Compositae*, the sub-order *Corymbiferae*, and the tribe *Asteroideae*. It has radiant heads of flowers, the florets of the ray pistilliferous, ligulate in one row; those of the disc tubular, with stamens and pistils, the receptacle rather alveolate, the involucre imbricated, with a few scales on the peduncle; the pappus pilose in one row; the fruit terete. This genus closely resembles *Aster*, from which it is distinguished by its pappus in a single row, and its terete fruit.

S. Virgaurea, Golden Rod, has an erect slightly angular stem, the leaves lanceolate, narrowed at both ends; the lower leaves elliptical, stalked, serrated; the raceme erect, simple, or compound; involucral scales lanceolate, acute; the fruit downy. This plant is a native of the woods and thickets of Great Britain, and was formerly much used in medicine. Its leaves and flowers are said to be aperient, and it has been employed for internal hæmorrhages. It is astringent and tonic.

SOLIP'ES, Cuvier's name for his third family of *Pachydermata*.

[PACHYDERMATA.]

SOLITAIRE. [Dodo.]

SOLITARY SNIPE. [SCOLOPACIDÆ.]

SOL'LYA, a genus of Plants belonging to the natural order *Pittosporaceae*. The genus is closely allied to *Pronaya* and *Billardiera*, and the species are highly ornamental plants, which are indigenous in Australia and Van Diemen's Land, with voluble stems, oblong alternate, shining, dark-green leaves, with the flower-stalks terminal, or opposite to the leaves, and bearing bunches of bright blue nodding flowers. *S. heterophylla* and *S. angustifolia* are two common species cultivated in our greenhouses, and were very common everywhere until the severe winter of 1837-38.

SOLOMON'S SEAL, the common name of the species of *Polygonatum*, a genus of Plants belonging to the natural order *Liliaceae*, and the sub-order *Asparageae*.

Polygonatum has the perianth tubular, 6-toothed, tardily deciduous; the ovary 3-celled; cells 2-ovuled; the stigma blunt, trigonous; berry with 1-seeded cells; the flowers not jointed to pedicel. There are three British species.

P. verticillatum has linear-lanceolate whorled leaves, with an erect angular stem. It is a rare plant in Great Britain.

P. officinale, Solomon's Seal, has leaves ovate-oblong, half-clasping, glabrous, stem angular; peduncles 1-2-flowered; filaments glabrous. It is the *Convallaria Polygonatum* of Linnæus, and has been confounded with the following. It is only found in Scotland.

P. multiflorum has leaves ovate-oblong, half-clasping, glabrous, alternate; stem round; peduncles one- or many-flowered; filaments downy. This plant is the common species known by the name of Solomon's Seal.

SOMATERIA. [Ducks.]

SOMERVILLITE, *Humboldtite*, is a Mineral occurring crystallised. Primary form a square prism. Cleavage perpendicular to the axis, very distinct. Colour pale dull brownish-yellow. Fracture uneven. Transparent, translucent. It is found in the cavities ejected from Vesuvius. Its analysis by Monticelli and Covelli gives—

Silica	43.96
Lime	31.67
Magnesia	8.83
Alumina	0.50
Protoxide of Iron	2.00
	—86.96

Kobell found 4.25 per cent of Soda.

SOMMITE. [NEPHELINE.]

SONCHUS (*Σύνchos*), a genus of Plants belonging to the natural order *Compositæ*; sub-order *Cichoraceæ*. It is characterised by a many-flowered head, involucre lubricated with scales, swelling at the base; receptacle naked; fruit transversely striated; pappus simple, sessile. The species are inhabitants of Europe, Asia, Africa, and America. De Candolle enumerates forty-five species, of which four are natives of Great Britain. They are not used in medicine, but some of them are cultivated in gardens.

The most common species is the *S. oleraceus*, the Common Sow-Thistle. It has a downy subumbellate flower-stalk; a glabrous involucre; lyrato-runcinate leaves, upper ones lanceolate sagittato-amplexicaul at the base, all dentato-ciliate. This plant is found commonly in waste places and cultivated ground all over the world. It has small yellow flowers and a conical involucre when in seed, and is greedily fed upon by many animals.

S. arvensis, Corn Sow-Thistle. Flower-stalks corymbose; involucre glandulose-hispid; leaves dentienlate, cordate at the base, oblongo-lanceolate, lower ones sinuato-runcinate. It is frequent in corn-fields in this country and the southern parts of Europe, and in Pennsylvania. Dr. Sibthorp found it in Greece, and was of opinion that it was the same plant as the *Σύνchos ἱερός* of Dioscorides.

SONNERATIA, a genus of Plants belonging to the natural order *Myrtaceæ*, so named by the younger Linnaeus in compliment to M. Sonnerat, well known by his 'Voyage à la Nouvelle Guinée,' and his 'Voyages aux Indes Orientales et à la Chine,' and who made known many new plants. The genus is characterised by having a 4-6-cleft campanulate calyx, adhering to the ovary at the very base; petals 4 to 6, alternating with the valvate lobes of the calyx; stamens numerous; styles filiform, with a peltate stigma; fruit baccate, appearing half-superior, many-celled; seeds numerous, nestling in a fleshy pulp, curved; the species form moderate-sized trees, with opposite leaves, which are entire, thick, and almost veinless; flowers usually solitary, large.

S. acida is the best known species, being the Pagapate of Sonnerat, and the Blatti of Rheede, which has an acid eatable fruit. The branchlets tetragonal; leaves oval, oblong; calyx 6-cleft; petals 6; berry globose. The tree is forty feet high, and is a native of New Guinea and the Moluccas, as well as of the Malabar coast and of the delta of the Ganges.

S. alba is another species of the Moluccas, and *S. apetala*, a native of Ava, near Rangoon, as well as in moist situations along the Burmese coast.

SOPHORA, a genus of Plants belonging to the natural order *Leguminosæ*, said to be so named from an Arabic name (Sophera) of one of the species. These are ornamental shrubs and trees, found in central and tropical Asia, also in the warm parts of North America and the equinoctial and sub-tropical parts of South America. The genus is characterised by having a 5-toothed campanulate calyx; corolla papilionaceous; petals of the keel usually united together at their apex; stamens 10, distinct; legumes moniliform, without joints or wings, and containing several seeds; the leaves are impari-pinnate, usually exstipulate and terminal; the inflorescence is in racemes or panicles of yellow, white, or blue flowers. The species best known in England are *S. Japonica* and *S. Chinensis*, which, being from the northern latitudes of the countries from which they are named, are hardly enough to withstand the climate of England; and it has been proposed to engraft the Nepaul *S. velutina* on the *S. Japonica*. Being handsome trees, with both leaves and trees differing much from European trees, they are well adapted for standing singly in lawns. They are raised from layers, but also from seeds, and require a little protection when young.

SORBUS, a genus of Plants, comprising the Mountain-Ash, Rowan-Tree, and Service-Tree. [PRAUS.]

SORDAWALITE, a Mineral occurring massive. Its fracture is conchoidal. Colour grayish-greenish or bluish-black. Structure compact. Hardness 2.5 to 3.0. Brittle. Lustre vitreous. Opaque. Specific gravity 2.50 to 3.0. It is found near Sordawla in Finland, and at Bodenmais in Bavaria.

Its analysis by Nordenskiöld gives—

Silica	49.40
Alumina	13.80
Peroxide of Iron	18.17
Magnesia	10.67
Phosphoric Acid	2.68
Water	4.38

— 99.10

SORECIDÆ, the family of Shrews, or Shrew-Mice, comprising the genus *Sorex* of Linnaeus.

"The *Sorecidæ*," says Mr. Swainson, "like the bats, have the grinders furnished with conical points; but they are destitute of wings or lateral membranes, and they possess clavicles; they have no cæcum, and they all press the entire sole of the foot on the ground in walking. In their economy they are nocturnal, leading for the most part a subterraneous life, and deriving their principal support from insects: those that are natives of cold countries pass the winter in a lethargic state: their feet are short, and their motions, when on the surface of the earth, slow and feeble."

This family, according to Mr. Swainson, embraces the Shrews, Moles, and Hedgehogs, with the following characters:—

Muzzle lengthened, pointed. Legs short, feeble; feet pentadactylous. Lower incisors generally very long, pointing forwards. No lateral membranes. Mamms ventral. The family thus characterised includes the genera *Erinaceus*, *Lianus*; *Sorex*, *Linnaeus*; *Mygale*, *Geoff.*; *Scalops*, *Cuv.*; *Chrysochloris*, *Cuv.*; *Talpa*, *Linnaeus*; *Centetes*, *Cuv.*; and *Condylura*, *Desm.*

The *Insectivora* of Cuvier consist of the Hedgehogs (*Erinaceus*); the Tenrecs (*Centetes*); the Shrews (*Sorex* and *Scalops*); the Desmans (*Mygale*); *Chrysochloris*; *Talpa*; and *Condylura*.

The genus *Sorex* of Linnaeus is placed between *Talpa* and *Erinaceus*; and this article will be confined to the true Shrews (*Sorex*) and the forms which most closely approximate to that genus.

The geographical distribution of the forms of these *Soricidæ* is wide: examples of them occur in Europe, Asia, Africa, and America.

Sorex.—Upper incisors curved and toothed or notched at the base; lower incisors nearly horizontal, all much produced. Body covered with soft and velvety fur. Muzzle very much attenuated; ears short and rounded. Five toes with moderately strong claws on each foot. Tail generally long.

Dental Formula:—Incisors, $\frac{2}{2}$; Canines, $\frac{0}{0}$; Molars, $\frac{8-8}{5-5} = 30$.

Teeth of *Sorex*, from a large species taken in the Island of Mauritius. (Six times larger than nature.)

S. araneus, is the Musaraigne of the French; Toporango of the Italians; Murganbo of the Spanish; Splitzmaus and Zismaus of the Germans; Nabbmus of the Swedes; Næbmus and Musasækie of the Danes; and Llygodyn Goch, Chwistlen, and Llyg of the Welsh. It is reddish mouse-colour above, paler beneath; tail somewhat quadrangular, rather shorter than the body, not ciliated beneath.

Mr. Bell, whose description we have above given, states that he has ventured, after some consideration, to retain the name of *Araneus* for the Common Shrew of England, notwithstanding the doubts which have existed in the minds of many zoologists, and in which he had till lately participated. These doubts, he observes, have arisen from what he believes to be an erroneous statement of Geoffroy, who, in his paper on the Shrews, in the 'Annales du Muséum,' has given as a character of *S. araneus*, that the teeth are all white; and as Daubenton, in his memoir on the same subject, in the 'Mémoires de l'Académie des Sciences,' does not mention the colour of the teeth at all, the authority, he adds, of Geoffroy has been sufficient to produce considerable hesitation as to whether the *S. araneus* of the continental authors be identical with our Common Shrew, which has invariably brown teeth. "It seems however," says Mr. Bell in continuation, "to have been overlooked, that Daubenton, in his description of the Shrews in Buffon's 'Histoire Naturelle,' has set the question at rest, as far as regards the colour of the teeth; for, in describing the Musaraigne (*S. araneus*), he refers, for the account of the teeth, to his description of the Musaraigne d'Eau (*S. fodiens*); and we there find that the teeth of the Musaraigne are brown at the tips. Now, as he invariably speaks of this species without any adjunct to the name

in contradistinction to the Water-Shrew, there can be no doubt, as far as this character is concerned, that the continental and British animals may be identical; and there appears to be no reason, from any other characters, to doubt that such is the case. That more than one species have been confounded amongst the Common Shrews of this country, I have long entertained a decided prepossession; but I have not at present sufficient ground to warrant me in describing them as distinct. ('History of British Quadrupeds.')

Insects and worms are the food of the Common Shrew. Pennant states that it inhabits old walls, beaps of stones, and holes in the earth, and is frequently found near hay-ricks, dunghills, and similar places. The annual autumnal mortality among these animals, at which season (about August) they are so often found dead, has been observed by most, and satisfactorily accounted for by none, as far as we know. Pennant says, and Agricola, as we shall presently see, noticed the fact before him, that cats will kill but not eat them, being probably disgusted by their peculiar and somewhat musky smell; and the bodies of the dead Shrews have been observed to be marked by a nip near the loins, as if by the bill of some rapacious bird. Kestrels and Owls however are known to prey upon them, and the bones of the head have been found in the stomach of the Barn-Owl. Mr. Turner, of Pury St. Edmunds, detected among twenty casts from that owl, taken from a considerable mass, the skeletons of seven Shrews.

Shrews are very pugnacious; and Mr. Bell remarks that, if two be confined in a box together, a very short time elapses before the weaker of the two is killed and partly devoured; he also gives his reasons for supposing that Shrews fall victims to the rapacity of moles. The nest, which is framed of soft grasses and other plants, is generally found in a hole more or less shallow in the ground, or a dry bank, and is entered at the side, being, so to speak, roofed over. Here the female produces in the spring from five to seven little Shrews.

Among the ancients, the Shrew-Mouse had a very bad reputation. Thus Aristotle declares that its bite is dangerous to horses and other beasts of burden; and that it is more dangerous if the Shrew-Mouse be with young. The bite, he says, causes boils (*φλύκταιναι*), and these burst, if the Shrew-Mouse be pregnant when she inflicts the wound; but if she be not, they do not burst. ('Hist. Anim.' viii., 24.) Pliay states that the bite of the Italian Shrew-Mice is venomous:—"In Italia muribus araneis venenatus est morsus." ('Nat. Hist.' viii., 58.) With reference to this supposition, it is worthy of remark that the French apply the term *Musaraigne*, or *Musette*, to a disease of the horse, which manifests itself in a small tumour (anthrax) on the upper and internal part of the thigh, and is often accompanied by very severe symptoms.

Agricola, in his book '*De Animantibus Subterraneis*,' does not forget the ancient traditions of the Shrew's venom, and thus bands them on:—"The *Mus araneus*," says he, "took its name among the Latins, because it injects venom from its bite, like a spider." The Greek name, *Μυρμολογία*, he derives from the facts that it is of the size of a mouse, whilst it is of the colour of a weasel. In his description of the animal, he notices the termination of the teeth in both jaws in bifid points, whence, he remarks, animals bitten by it receive quadrifid wounds. He tells us that its bite in warm regions is generally pestiferous, but that in cold climates it is not; consoling those who may suffer by the not unusual assertion in such cases, that the animal itself, torn asunder or dissected and placed upon the wound, is a remedy for its own venom. Agricola states also that cats kill it, but abhorring this same venom, do not eat it.

This harmless little animal was also an object of fear and superstition to our ancestors. This is referred to by Mr. Bell in his '*History of British Quadrupeds*,' and also by White in his '*Natural History of Selbourne*.'

Common Shrew (*Sorex araneus*).

The other British Shrews are the Water-Shrew (*S. fodiens*, Pallas); and the Oared-Shrew (*S. remifer*, Geoffroy).

The Water-Shrew, whose habits are graphically described by Mr. Dovaston in '*Loudon's Magazine*' (ii.), appears to be the *Musaraigne d'Eau* of the French. The Oared-Shrew seems to have been first

published as British in Sowerby's '*British Miscellany*,' from a specimen taken by Dr. Hooker in Norfolk, under the name of *S. ciliatus*.

Under surface of hinder feet of Shrews. (Bell.)
a, Common Shrew. b, Water-Shrew. c, Oared-Shrew.

S. Indicus, *S. myosurus*, Pallas, the Musk-Rat of India, has much the same appearance in point of colour and the size of its naked ears as our Common Shrew, but is nearly as large as our common Brown Rat, and the tail is round and thinly furnished with hairs. This species diffuses a most powerful odour of musk, which impregnates everything that is touched by it. It has been alleged that even the wine in a well-corked bottle, over which the animal has run, has been rendered unfit for use in consequence of the flavour imparted to it. Cuvier states that this species is found throughout the East Indies and in a part of Africa, and that it is among the animals embalmed by the ancient Egyptians; but, according to others, it is *S. Olivieri*, Desm., which Olivier found in a mummy state in the catacombs of Sakkara.

Mygale.—Great lower incisors having between them two very small teeth. Muzzle in a very small and very moveable proboscis. Ears short. Five unguiculated toes on each foot united by a membrane. Tail long, scaly, compressed laterally.

Dental Formula:—Incisors, $\frac{2}{8}$; Canines, $\frac{0}{0}$; Molars, $\frac{10-10}{7-7} = 44$.

Teeth of the upper jaw of *Mygale moschata*. (F. Cuvier.)

M. moschata, *Castor moschatus*, Linn., appears to be the *Dæsmen* of the 'Fauna Suecica'; *Le Desman* of the French; the *Biesamratze* of the Germans; the *Wychozhol* of the Russians; and the *Muscovy* or *Musk-Rat* of the English.

Musk-Rat (*Mygale moschata*).

The tail is shorter than the body, scaly, nearly naked, contracted at its base, cylindrical, and convex in its middle, very much compressed vertically at its extremity; fur brown or dusky above, whitish-ash below. Total length, including the tail, about 15 inches, of which the tail measures 8 inches. It is found in the river Volga, and the adjacent lakes from Novgorod to Saratov.

This species does not appear to have been seen on dry land; and indeed it is broadly asserted that it never goes there, but wanders from lake to lake in fortuitous floods only. It is often seen swimming or walking under the water, and coming for air to the surface, where, in clear weather, it is apt to sport. Stagnant waters shut in by high banks are its favourite localities, and in such places it makes burrows

some twenty feet in length. Its principal food is alleged to consist of fish, leeches, and the larvae of water-insects; but fragments of roots have been found in its stomach. Its pace is slow; but it does not seem to be torpid in winter, at which season it is often taken in nets. The holes which it makes in cliffs and banks have the entrance far beneath the lowest level of the water, and the animal works upwards, never however reaching the surface, but only sufficiently high to secure itself from the highest rise of the river. Fish, as we have seen, forms part of its food; but the quadruped in its turn falls a victim to the Pike and *Siluri*, whose flesh becomes so impregnated with the flavour of musk in consequence, as to be not eatable.

From the region about the tail a sort of musk, resembling the genuine sort, is expressed; and the skins are put into chests and wardrobes among clothes, for the purpose of preserving them from moths. These skins were also supposed to guard the wearers of them from fevers and pestilence. The price at Orenberg for the skins and tails was formerly twenty copecs per hundred. They were so common near Nischnei-Novgorod, that the peasants were wont to bring five hundred each to market, where they sold a hundred of them for a rouble.

There is a species more than eight inches in length (*M. Pyrenaica*) inhabiting Tarbes, at the foot of the Pyrenees.

Scalops.—Muzzle pointed and cartilaginous; no external ears. Three toes on the anterior feet, which are short, wide, and armed with strong claws fit for burrowing; posterior feet feeble, with five toes. Tail short.

Dental Formula:—Incisors, $\frac{2}{2}$; Grinders, $\frac{10-10}{10-10} = 44$.

The above is the formula given by Sir John Richardson; but F. Cuvier (and he is followed by Lesson) makes the number 36, namely:

Incisors, $\frac{2}{4}$; Canines, $\frac{0}{0}$; Molars, $\frac{9-9}{6-6} = 36$.

We subjoin the teeth as given by F. Cuvier, but Richardson's description appears to be very carefully given, and his accuracy is well known.

Teeth of *Scalops*.

S. Canadensis, Cuv. (*Sorex aquaticus*, Linn.) is the Brown Mole of Pennant; the Shrew-Mole of Godman; the Mole of Lewis and Clarke; and the Musarnigne-Taupe of Cuvier.

The body is thick and cylindrical, like that of the Common Mole, without any distinct neck; limbs very short, being concealed by the skin of the body nearly down to the wrist and ankle-joints; fore extremities situated nearly under the auditory opening; the moveable snout almost linear, and projecting about $4\frac{1}{2}$ lines beyond the incisors, naked at its extremity, particularly above, thinly clothed with hairs below for about two-thirds of its length next the incisors; a conspicuous furrow extends nearly its whole length on the upper surface,

and beneath there is also a furrow, reaching half its length from the incisors, beyond which last the snout is transversely wrinkled beneath, and its small, flat, or truncated extremity is smooth and callous; the small oblong nostrils open in an inclined space immediately above this circular callous end. The eyes are concealed by the fur, and scarcely to be found in dried specimens. In most lights it is brownish-black; when blown aside it shows a grayish-black colour from the roots to near the tips. Such is the general colour over the whole body, but there is a slight chestnut-brown tinge on the forehead and about the base of the snout. On the throat the fur is shorter and paler. Length of head and body 7 inches 8 lines, and of tail 1 inch 6 lines. Such is, in substance, the accurate description by Sir John Richardson of this species.

It inhabits the banks of the Columbia River and the adjoining coasts of the Pacific, where it occurs in considerable numbers.

Sir John Richardson states that the Shrew-Mole resembles the common European Mole in its habits, in leading a subterranean life, forming galleries, throwing up little mounds, and in feeding principally on earth-worms and grubs. The individual domesticated by Mr. Titian Peale is described by Dr. Godman, who paid much attention to the manners of these animals, and who relates that they are most active in the early part of the morning, at mid-day, and in the evening, coming daily to the surface, when in their natural state, at noon. Then they may be taken by driving a spade beneath them and throwing them on the ground, but they are hard to be caught at any other time of the day. They burrow in a variety of soils, but in wet seasons they retire to the high grounds. Mr. Peale's shrew-mole fed largely on fresh meat, cooked or raw, drank freely, was lively and playful, followed the hand of its feeder by scent, burrowed for a short distance in loose earth, and after making a small circle returned for more food. It employed its flexible snout in a singular manner whilst it was eating, in order to thrust the food into its mouth, doubling it so as to force it directly backwards.

Shrew-Mole (*Scalops aquaticus*).

M. Lesson makes the *Scalops Pennsylvanica* the type of his genus *Talpaorex*, acknowledging however that it only differs from *Scalops* in its dental formula, which he gives thus:—

Incisors, $\frac{2}{4}$; Canines, $\frac{0}{0}$; Molars, $\frac{11-11}{6-6} = 40$.

It will be well for the student to bear in mind, with reference to the genus proposed by Lesson, Sir John Richardson's observations on the dentition of *Scalops* above noticed.

With regard to the question of the existence of True Moles in North America, the following remarks of the last-mentioned accurate and diligent author are also worthy of attention:—"From the great resemblance of the Shrew-Mole to the common one, they might be readily mistaken for each other by a common observer; and Bartram and others, who have asserted the existence of a species of the genus *Talpa* in America are on this account supposed, by later writers, to have been mistaken. There are however several true moles in the Museum of the Zoological Society which were brought from America, and which differ from the ordinary European species in being of a smaller size, and in having a shorter and thicker snout. Their fur is brownish-black. I could not learn what district of America they came from." ('Fauna Boreali-Americana')

Macroselides.—Muzzle narrow, ending anteriorly in a long and subcylindrical proboscis, having nostrils at its apex; eyes moderate; ears large and round. Body furry. Tail elongated, scaly, annulated, and furnished scantily with hairs. Feet distinct, plantigrade, and 5-toed; the claws scissorial; hind legs much shorter than the fore feet.

Incisors, $\frac{2}{2}$; Canines, $\frac{4-4}{4-4}$; Molars, $\frac{5-5}{5-5} = 40$. (Smith)

M. typicus.—Above brown, brightened by an intermixture of tawny; beneath whitish; extremities covered with a very short

whitish hair; ears within, scantily furnished with some of a similar colour, without, nearly bare; tail thinly clothed with a stiff short black hair; whiskers near the base of the prothoscis, each hair variegated black and white; claws short, black, compressed, and pointed. Length from nostrils to root of tail $4\frac{3}{4}$ inches; length of tail $3\frac{1}{2}$ inches. The colour of both sexes is nearly alike.

Skull and Teeth of *Macroselides typicus*.

a, upper surface of the skull, natural size; *b*, lateral parts of the same, natural size; *c*, lower jaw of the same, natural size; *d*, upper surface of the skull of the same, double the natural size; *e*, lower jaw of the same, double the natural size. (Smith.)

It inhabits the open country in the interior of South Africa, and is occasionally seen during the day about the roots of bushes or amongst brushwood, whence, upon being discovered, it instantly retreats to its natural and subterraneous habitation. ('Zoological Journal.')

This, or one of the species (but most probably this) seems to be the Elephant-Shrew of Pennant, and is thus described:—"Shrew with a very long, slender, and little nose; the whole animal of a deep brown-colour. Inhabits the neighbourhood of the Cape of Good Hope: called the Elephant, from its prothoscis-like snout: engraven from a drawing by Mr. Paterson." Pennant further remarks that this animal has been very ill represented by Petiver, in Table 23 of his 'Gnaphalacii Naturæ et Artis Decas tertia,' and truly so it is: but Pennant's figure is not much better. Petiver's description is: "9. *Mus araneus Capensis maximus*. Taken from a painting of Dr. Sherard's, now consul of Smyrna."

Macroselides typicus. (Reduced from Dr. Smith's figure.)

SOREX. [SORECIDÆ.]

SORGHUM, a genus of Grasses, said to be named from the Oriental name of one of the species, of which 'sorgo' is the Italian name. The species have sometimes been referred to *Holcus*, sometimes to *Andropogon*, but from their habit and uses they seem well entitled to be considered as a distinct genus, which may be characterised as having the flowers monocious, panicled; glume coriaceous, cartilaginous, 2-flowered; the upper flower hermaphrodite, the lower palea more or less deeply bifid and awned between the lobes, the upper often wanting. The species form tall grasses with succulent stems, and are found in the tropical parts of Asia, whence they have spread to the warm parts of Europe.

S. vulgare is the largest of the small cereal grains, and may be considered the representative of the Indian Corn (*Zea Mays*) in America, where it is usually called Guinea Corn, and in some works the Great or Indian Millet. The different kinds are usually called Joar in India, where they form principal objects of culture, and one of much more importance than would appear in Europe, as many of the inhabitants live as much upon these small or dry grains as upon rice. The Joar is the Durra of some Arab tribes, and the Zurrut of others; its Indian origin is indicated by the Persian name, Jawurs Hiudec. It is extensively cultivated throughout Asia, and appears to be the Tall Corn of the Chinese. It has been introduced into the south of Europe, where it is chiefly employed for feeding cattle and poultry, but it is also made into cakes. The flour is white, and a good deal resembles that of the Indian corn in nature. The species commonly sown in India are *S. vulgare* and *S. bicolor* (Kala-Joar). *S. cernuum* is a distinct species, which forms the principal food of the mountaineers of the Munnipoor district. *S. saccharatum* is also cultivated in many parts during the rainy and cold seasons, on land which is too high for rice. The stalks and straw of all are much valued as fodder for cattle, being cut into small pieces, commonly called Kurbee.

SORREL. [RUMEX.]

SORREL-WOOD. [OXALIS.]

SORUS, in Botany (from *σῶρος*, 'a heap'), a term applied to the collections of the sporangia or capsules which are found on the edges or the under surface of the fronds of ferns. In most instances, as in the *Aspidiaceæ*, *Asplenaceæ*, *Davalliaceæ*, &c., the sori are covered with a peculiar projecting portion of the epidermis, which is called the Indusium, and forms an important part in the systematic arrangement of these plants. In some instances, as in *Adiantum* and *Ceratopteris*, the substance of the leaf has a share in the formation of the indusium. It has been generally admitted that the indusium is the analogue of the bract in the higher plants, but Treviranus maintains that it is an entirely peculiar organ, and, according to this view, can it be looked upon as a mere extension of the epidermis. In looking for analogies between flowering and flowerless plants, Kölreuter supposed that the indusium represented the stamens.

The term Sorus is sometimes applied to mere collections of spores or granules, as seen in many *Algae*, of which *Delosseria alata* and *D. sinuosa* are examples.

SOUL-MANGA. [CINNYRIDÆ.]

SOULAMIA (Soulamion is the name of the tree in the Moluccas), a genus of Plants belonging to the natural order *Polygalaceæ*. It has 5 sepals, the 3 outer ones very small, the 2 inner large and concave; the petal is concave; the capsule samaroid, indehiscent, compressed, corky, emarginate, and 2-celled.

S. amara, Bitter Soulamia, is a shrub with crowded ovate leaves tapering to the base, quite entire, and veiny. It is a native of the Moluccas, and has white racemose flowers, the size of those of the vine. The fruit is compressed, thin at the edges, dry, with 2 seeds in

each cell resembling cucumber seeds, but smaller, each lying in a small cavity of the cell.

(Lindley, *Flora Medica*.)

SOUR-SOP. [ANONACEÆ.]

SOUSLIK, the name of certain Marmots with cheek-pouches (*Spermophilus*, F. Cuv.). [MURIDÆ.]

SOUTHERN-WOOD. [ARTEMISIA.]

SOW-THISTLE. [SONCHUS.]

SOY. [SOJA.]

SOYA, or SOWA, an Umbelliferous Plant cultivated in India. It is the *Anethum Sowa* of Roxburgh, of which the aromatic seed is much used by the natives in cookery, as well as for medicinal purposes; the green parts also are cut down, and sold in the bazaars, as the plant is used as a vegetable both by Mussulmans and Hindoos. The seeds are the 'shubit' of Avicenna, which is usually translated Anethum; by the Arabs it seems to have been considered the *Arghol* of Dioscorides.

SOYMIDA, a genus of Plants belonging to the natural order *Meliaceæ*, named by A. Jussieu from the Telinga name of the tree, which was referred to *Swidenia*, and called *S. febrifuga* by Dr. Roxburgh. This is a large forest-tree, a native of the mountainous parts of the Rajabundry Circars, and likewise of the jungly parts in general of the central parts of Hindustan. The genus is characterised by calyx 5-leaved, imbricate; petals 5, shortly clawed; stamen-tube cup-shaped, 10-lobed, each lobe bidentate at the apex; anthers 10, included within the tube and lodged between the teeth of the lobes; ovary 5-celled, seated on a broad disc; ovules numerous, pendulous from the centre of the cells; style short, stigma peltate, 5 cornered; capsule woody, 5-celled, 5-valved; seeds winged. The only species known attains a height of 80 feet, with abruptly pinnate leaves. The inflorescence is a large diffuse and terminal panicle.

This tree, which is called Rohuna in Hindustan, is particularly noted on account of its bark. This is of a dull red colour, of a fibrous nature, and astringent, and has been much employed in India for the cure of intermittent fevers.

SPADIX. [INFLORESCENCE.]

SPALAX. [MURIDÆ.]

SPANIEL, a variety of Dog. It is not at all improbable that dogs of this race were known to the Romans. Lieut.-Col. Hamilton Smith remarks that the Spaniel, *Canis extrarius* (l), is clearly figured on some of the later monuments, and seems to be identical with the *C. Tuscanus* praised by Nemesianus; and indeed the lines in the 'Cynegeticon,' beginning—

"Quin et Tuscorum non est extrema voluptas
Sempe canum, forma est illis licet obesta villos,"

with the allusion to their hunting qualities—

"Moresque almiu nareque sagaces"—

strongly favour that opinion. It may also be noted the Nemesianus in another part of the poem speaks of dogs—

"Quorum proles de sanguine manat Ibero."

The Spaniel appears to have been the companion of the Falconer at a very early period. In 'The Booke of Falconrie or Hawking' (1611), 'heretofore published by George Turberville, Gentleman,' we find among 'The Contents of this Booke,' 'A little treatise translated out of the Italian tongue, touching the diseases happening to Spaniels, with their Cures; and on turning to the page we come to 'A Treatise and discourse of the cure of Spaniels when they be any way over-heat; devised and written by M. Francesco Sforzino Vicentino, the Italian Gentleman-Falconer,' and beneath the title a cut, where stands the falconer, hawk on fist, hat on head, staff in hand, and pouch on side, in trunk-hose, and with bare-headed attendants, accompanied by two couple of Spaniels.

In the sporting prints engraved by Hollar after Barlow, a whole team of spaniels are introduced giving tongue in 'Partridge Hawking,' with the following lines at the bottom of the plate:—

"The fearful Partridge being sprung by quest
Of Spaniels from their pleasing food and rest,
The keen and bloody Hawke pursues; the Knight
Hath then his sport, and feasts on them at night."

And again in 'Fasant Hawking,' with the following quatrain:—

"The Fasant Cocke the woods doth most frequent,
Where Spaniels spring and perche him by the sent;
And when in flight, the Hawke with quickened speed
With 'a beake and savage talons makes him bleed."

Spaniels, apparently of a stouter breed, are also introduced in 'Hern Hawking' by the same hands, a circumstance worthy of remark, inasmuch as in the cut in 'The Booke of Falconrie,' with the superscription 'How to see a Hearon,' the mounted gentleman-falconer, who is covered, is attended by bare-headed domestics, and accompanied by a couple of grayhounds.

The author of the 'Sportsman's Cabinet' states that the race of dogs passing under the denomination of spaniels are of two kinds, one of which is considerably larger than the other, and known by the appellation of the Springing Spaniel, as applicable to every kind of game in any country, whilst the smaller is called the Cocker, or Cocking-Spaniel, as being more adapted to covert and woodcock shooting.

Dr. Caius, in his systematic table of British Dogs, makes the Fowlers consist of the Spaniel (*Hispaniolus*), Setter (*Index*), and Water-Spaniel or Fynder (*Aquaticus*); whilst under the title Lap-Dogs, the Spaniel Gentle or Comforter (*Melivus* or *Fotor*—the Maltese Lap-Dog), stands alone.

Pennant, in following out the tract of Caius, says, "The third division of the more generous dogs comprehends those which were used in fowling; first, the *Hispaniolus*, or Spaniel: from the name it may be supposed that we were indebted to Spain for this breed. There were two varieties of this kind, the first used in hawking, to spring the game, which are the same with our Starters. The other variety was used only for the net, and was called *Index*, or the Setter, a kind well known at present." [SETTER.]

The probability appears to be that all the varieties of the Spaniel, the small Water-Spaniel, the Cocking Spaniel, King Charles's Spaniel, and the Blenheim Spaniel, if that breed be not the true spaniel of King Charles I., are all the result of careful breeding from the large Water-Spaniel (not the Rough Water-Dog which some call a Water-Spaniel), which seems to have been the old Springing Spaniel.

It is no small proof of the merit of the Spaniel that it has kept its ground amid all the revolutions of sporting. 'A good spaniel is still a great jewel.' The companion of the hawk and net now attends the grayhounds, and it is indispensable in woodcock-shooting: apart from its excellent services in cover, there is no more lively field-shooting than that with a team of thoroughly well-bred spaniels broken never to give tongue, to range well, but not at a greater distance than fifteen or twenty yards from the gun, and never to chase either feather or fur. The sportsman's attention is always kept on the alert, and he who has accustomed himself to this style of shooting will generally be found to be a quick and sure shot.

Spaniels have a great share of intelligence and affection; these qualities, being combined with much beauty, make them highly prized as companions; and we have, in our day, the

"Spaniel, bred with all the care
That waits upon a favourite heir,"

Seventy pounds have been refused for one of these dogs.

The docility of the Spaniel is equal to its intelligence and feeling of attachment. A spaniel has been taught to wait at table, take away plates and fetch others, carry wine in a glass without spilling, and to hold the stirrup in his mouth for his master while he was mounting his horse. The spaniel given by Mr. Daniel, author of 'Rural Sports,' to the Hon. Mr. Greville, would, we are told, in addition to the common tricks which dogs trained to fetch and carry exhibit, bring bottles of wine from the corner of the room to the table by the week, with such care as never to break one, and was the 'boots' of the mess-room.

SPANISH FLY. [CANTHARIDÆ.]

SPAR, a word from the German 'Spath,' employed, combined with specific terms, in Mineralogy, to include a great number of crystallised earthy and some metallic substances, but chiefly the former. Thus calcareous spar is crystallised carbonate of lime; fluor-spar, fluoride of calcium; heavy spar, sulphate of barytes, &c. By miners the term is frequently used alone to express any bright crystalline substance; but in mineralogy, strictly speaking, it is never so employed.

SPAR, HEAVY. [BARYTES.]

SPARGANIUM (from *σπάργανον*, a bandage), a genus of Plants which with the genus *Typha* constitute the natural order *Typhaceæ*. The species are monœceous. The flowers are arranged in dense spherical heads. Both the barren and fertile flowers are composed of a single perianth with three leaves; the stamens are longer than the calyx, and the fruit consists of a dry drupe with one seed. The species are found commonly in ditches and marshes of the northern hemisphere. Three of these are common in Great Britain.

S. ramosum, Branched Bur-Reed, is known by its branched flower-stalk, triangular leaves, and linear stigma. This species was the only one of the genus found by Dr. Sibthorp in Greece, and appears to be the *Σπάργανον* of Dioscorides. It is an inhabitant of ditches, lakes, and stagnant waters, forming a handsome addition to their vegetation.

S. simplex, Unbranched Bur-Reed, is known by its simple stem; and the *S. natans*, Floating Bur-Reed, by its long linear floating leaves. They are both found in the same situations as the first.

SPARIDÆ, or SPAROIDEÆ, a family of Fishes belonging to the section *Acanthopterygii*, which are distinguished by the following characters combined, namely: the possession of a single dorsal fin, the anterior half of which is supported by spinous rays, and which is not divided, nor is it protected by scales; the operculum is spinous, the palate destitute of teeth, the branchiostegous membrane has five or six rays, and the pyloric appendages are few in number. The body is usually of an ovate form, and covered with large scales; the mouth is not protractile.

The species of this family feed chiefly upon the animals of small shells, *Crustacea*, &c., for crushing which their strong teeth are admirably adapted.

Guided by the structure of the teeth, Cuvier divides the family into four tribes. In the first the jaws are provided with teeth, which are rounded like paving-stones; in the second the teeth are conical

and pointed; in the third the teeth are minute and thickly crowded; and the fourth tribe have a series of trenchant teeth.

To the first of these tribes belongs the genus *Sargus*, where the incisors, or foremost teeth, are compressed, and have sharp-cutting edges; the molars are rounded, and form several rows.

Of this genus numerous species are described in the 'Histoire des Poissons' of Messrs. Cuvier and Valenciennes. Several are from the Mediterranean, and the others are chiefly from the coast of America, north and south.

The next genus, *Charanz*, is founded upon a single species, an inhabitant of the Mediterranean, which has sharp-cutting incisors, like the species of *Sargus*, but the molars are extremely minute, and form only a single row.

The third genus of the first tribe is *Chrysophrys*, which is distinguished from the *Sargus* by the incisors being conical, and usually four or six in number in front of each jaw; the molars for the most part are rounded, and form at least three rows on each side of each jaw, a character which serves to distinguish the present genus from *Pagrus*.

This genus is numerous in species, and these are almost entirely confined to the seas of the warmer and tropical parts of the Old World. The *Chrysophrys aurata*, a species which is very common in the Mediterranean, is also occasionally met with on our coast, as well as that of France.

The same remark applies to the *Pagrus vulgaris*, which is an example of the next genus, *Pagrus*, which differs from *Chrysophrys* in having only two rows of molar teeth on each side of the jaw. Several species of this genus are found in the Mediterranean, others inhabit the Indian seas, some again are found on the coasts of Australia and New Zealand; and the *Pagrus argyrops* is found on the North American coast.

The last genus of the first division is *Pagellus*, the species of which are easily distinguished by the foremost teeth in each jaw being all of them small, curved, pointed, and dense.

Numerous examples of this genus occur in the Mediterranean; and two species, the *P. erythrinus* and *P. centrodonatus*, have been found on our own coast. The former appears to be of very rare occurrence on the British coast; the latter, known by the name of the Sea-Bream and Gilt-Head, is by no means an uncommon fish on the southern shore of England, and is not unfrequently found on the coast of Ireland.

To the second section belong the genera *Lethrinus*, *Dentex*, and *Pentapus*. The first of these genera is at once distinguished from all other genera of the first section by there being no scales on the cheeks; the mouth is but little cleft; and the teeth are, some of them strong, pointed, and curved; others very small and dense, and the molars form only a single row.

In the genus *Dentex* the teeth are conical, and generally confined to a single row; some of the foremost of them are elongated, curved, and sharply pointed.

The species of this genus, which are very numerous, appear to be almost entirely confined to the temperate and tropical portions of the Old World. But one species is found on the British coast, the Four-Toothed Sparus of Mr. Yarrell's work, *D. vulgaris*, Cuv. and Val.

The genus *Pentapus* is founded upon certain Sparoid Fishes found in the Indian Seas, and off the coast of Australia, which approach the genus *Dentex*, but have two strong canine teeth in front of each jaw, between which sometimes are two or four much smaller teeth; the other teeth are minute, prickly, close together, and arranged in a single row in each jaw.

Close to the ventral fins on each side is a spine, and a third spine is situated between these fins. Similar spines are found in other species, but they are usually less developed than in the present genus. The name of *Pentapus* is applied to these fishes from these spines giving to them the appearance of having five ventrals.

The third section, in which all the teeth are minute and dense as the pile on velvet, contains but one genus, *Cantharus*. Of this genus an example is found on the British coast, and is known by the name of the Black Bream (*C. grius*, Cuv. and Val.). This fish, though more rare than the Sea-Bream, is not uncommon on various parts of our coast.

In the fourth section Cuvier arranges the genera *Box*, *Oblata*, *Scatharus*, and *Crenidens*. All these genera have the foremost range of teeth compressed, placed close together, and with a cutting edge which is more or less notched. In the genus *Box* there is but one series of teeth in each jaw. The *B. vulgaris* (*Sparus boops*, Linn.) is a common species in the Mediterranean, and lives upon vegetable substances.

The genus *Oblata* is founded upon a fish from the Mediterranean, the *Sparus melanurus*, Linn., in which, in addition to the compressed front teeth, which are emarginated at the apex, there is an inner series of minute teeth.

The genus *Scatharus* is also founded upon a Mediterranean fish; here there is but one series of compressed teeth, and these are pointed, or lancet-shaped.

Lastly, the genus *Crenidens* is distinguishable by the foremost row of compressed teeth being dilated at the apex and notched; behind

these are numerous small globular teeth. There is but one species, the *C. Forskalii*, Cuv. and Val., an inhabitant of the Red Sea.

SPARRMANNIA, a genus of Plants belonging to the natural order *Tiliaceæ*. The genus is known by its calyx of 4 sepals, 4 roundish petals, numerous stamens, intermixed with tomentose threads; echinated, 5-angled, 6-celled, 6-valved capsules, with 2-seeded cells. There is only one species, the *S. Africana*, which is a native of the Cape of Good Hope. It is a beautiful shrub, much cultivated, flowering in the beginning of the spring.

SPARROW. [PASSER.]

SPARROW-HAWK. [FALCONIDÆ.]

SPARTALITE. [ZINC.]

SPARTINA, a genus of Grasses belonging to the tribe *Chlorideæ*. It has upright 1-flowered spikes in racemes, the glumes unequal, the upper long and acuminate; the paleæ unequal, the outer boat-shaped, compressed, retuse; the styles elongated, united half-way up; the stigmas filiform, protruding at the summit of the floret. There are two British species, the *S. stricta* and *S. alterniflora*. The former grows in muddy salt-marshes, the latter has been found only on the mud-flats of the river Itchin at Southampton. (Babington, *Manual of British Botany*.)

SPARTUM, a name applied by the Romans to the plant much used by them for cordage. It is fully described by Pliny ('Nat. Hist.' xix. 2). Authors have differed much respecting the plant intended; some conceiving that some of the brooms are intended, as *Spartium junceum*, or Spanish Broom, which produces a fibrous thread of which cloth is made; and *S. monospermum*, which is found on the coasts of Spain as far as the moving sands reach; its twigs are used for tying bundles, and herbs are brought to market tied together with them. The leaves of both afford food for sheep and goats. Others are of opinion that some of the grasses are intended, which grow in the same places and are used for the same purposes, as, for instance, *Lygeum Spartum* and *Stipa tenacissima*, both of which are called Esparto by the Spaniards, and both are used for making ropes, baskets, utes, and for filling palliasses.

SPARUS. [DENTEX.]

SPATANGUS. [ECHINIDÆ.]

SPATHE (the Greek σπάθη). This term is applied to the sheathing involucrum of many plants. It is seen in the greatest perfection in the flowers of *Palmaceæ* and *Araceæ*, where, during the flowering of the plants, it embraces the entire inflorescence. This organ is considered by most botanists to be a modification of the bract.

SPATHODEA, a genus of Plants belonging to the natural order *Bignoniaceæ*. The calyx is spathaceous, cleft and toothed or entire on the other side; the corolla is funnel-shaped, with a 5-lobed rather unequal limb; the four stamens are divided into two long and two short, with the addition of a fifth sterile filament; the capsule silique-formed, falcate, falsely 4-celled, and corky; the seeds are furnished with membranous wings; the species are erect shrubs or trees, rarely climbing shrubs; the flowers somewhat paniced, orange-coloured, yellow, or purple.

S. Rheedii has downy impari-pinnate leaves, roundish downy leaflets, terminal erect racemes, and a much-curved slender corolla; the shoots are covered with a whitish down; the racemes the length of the leaves; the flowers white and pretty large; the limb spreading; the fruit about a foot long, pendulous, twisted in various forms.

S. Roxburghii has its leaves three in a whorl or scattered impari-pinnate; the leaflets from 4 to 5, in pairs, serrated and smooth; the panicles erect, terminal, dense, downy, and many-flowered; the fruit narrow and 4-celled; the calyx generally 2-parted, with the upper lip 2-cleft and downy. It is a native of the Circars. The branches are very spreading; the bark gray, with a few scabrous spots; the flowers large, rose-coloured, and delightfully fragrant; the limb of the corolla nearly equal, and elegantly waved at the edges. This species is remarkable on account of its serrated leaves. The wood is employed for many purposes by the natives.

S. longiflora is an arboreous plant, and has large spreading terminal panicles, a bilabiate corolla, long pendulous slender sub-cylindrical follicles, with sharp edges and variously curved; the flowers are large, yellow, and very fragrant; the follicles very long; the wood of this tree is high-coloured, hard, durable, and of much use amongst the inhabitants of the hills about the coasts of Coromandel and Malabar, where it is plentiful.

SPATULA. [DUCKS.]

SPATULARIA, a genus of Fishes of the Sturgeon tribe, remarkable for the form of their snouts, which are enormously prolonged and leaf-like in form. The Paddle-Fish of the Mississippi is the type.

SPAWN, the white fibrous matter which, shooting through earth, dung, decaying vegetable matter, &c., is the matrix from which mushrooms and other *Fungi* are produced. It is generally composed of small white thready fibres, which produce, at various distances, little white knobs, from which the stem and cap of the mushroom proceed. This matrix or spawn, called Mycelium, is in fact the real stem of the mushroom, and the stipes and pileus, with their appendages, are the inflorescence. This spawn is made use of for the purpose of procuring from it the growth of the Edible Mushroom (*Agaricus campestris*). [FUNGI.]

SPEARMINT. [MENTHA.]

SPECIES OF PLANTS. All the individual forms of plants, as well as animals, that occur on the globe, may be collected into groups resembling each other, and these groups are called species. A species has been defined to be "a combination of individuals alike in all their parts;" "a systematic combination of homogeneous individuals;" "a collection of individuals which will breed together and produce fertile offspring." De Candolle says, a species is "a collection of all the individuals which resemble each other more than they resemble anything else, which can by mutual fecundation produce fertile individuals; and which reproduce themselves, by generation, in such a manner that we may from analogy suppose them all sprung from one single individual." However clear such a definition may be, it would assist a botanist only in a very limited degree in determining whether a new plant should be looked upon as a new species. If there were perfect structural identity between two individuals of the same species, or if we could ascertain, on the physiological ground, that the individuals after fecundation reproduced similar individuals, it would then be a more easy task. But perfect structural identity does not exist, and the physiological test cannot be always applied, and hence the difficulty of determining what is really a species. From this some have gone so far as to deny the existence of species altogether, and assert that the supposed distinctions between plants are altogether arbitrary and imaginary. This notion is however altogether upset by the well-known fact of plants maintaining for centuries the same structural characters.

However much it may be regretted, on account of the vexatious multiplication of species, that some fixed rules cannot be laid down for their formation, it does not appear at present that anything more than general rules can be given, and that much must depend on the judgment and experience of the observer.

As a general rule species are not distinguished by differences in the internal organisation, such differences being left for the higher divisions into genera, orders, and classes; but upon those superficial and external differences which are independent of internal structure. Of these may be named duration, dimension, surface, form, division, numerical proportion, and colour. The value of each of these points varies according to circumstances, and in proportion to the knowledge of the observer will be the skill with which he selects them for distinguishing species. The duration of a plant is a point of great importance, as in no instance do we find, unless from change of climate, plants of the same species differing in being annual, biennial, &c. Dimension is rarely of any importance, and should only be taken into consideration in extreme cases. Differences of surfaces, depending on structural peculiarities, are of importance; smoothness, roughness from tubercles, and the existence of stinging hairs and prickles, are points of value. The presence or absence of lymphatic hairs on the surface of leaves is a point that may mostly be disregarded; they are of more importance on other parts. The form of parts is only of importance when it is the consequence of anatomical differences, that is to say, the arrangement of the veins, &c. The division of organs is not of much importance where it depends on the degree of the laceration of the parenchyma. The union or non-union of contiguous organs, as the parts of the calyx, corolla, &c., is of the greatest value, being mostly uniform in all the individuals of the same species. The numerical proportion of the parts of a plant is of value in proportion to the small number of parts or organs; the greater the number, the more subject it is to variation. Differences in colour are little to be relied on; the same may be said of odour and taste; as all these properties are liable to undergo change by a slight alteration of the circumstances of the plant.

Those departures from identity of structure, which are considered insufficient to constitute a species, are called Varieties, and the points of structure that should constitute a species or variety is frequently a matter of difference, and it is no unfrequent thing for one author to reduce the species of another to mere varieties. Thus, Borrer has made 71 species of *Salix*, but Koch has reduced them to 29, and numerous examples could be cited. A careful attention to the influence of climate, soil, elevation, &c., on species, would save much trouble and vexation on this point. De Candolle has elegantly summed up the influence of these agents on plants:—"Let us suppose," he says, "what really happens, that the seeds of plants are scattered at hazard over the surface of the earth; or, to speak more correctly, by causes that have no necessary connection with the existence of those plants; such seeds will find themselves in an infinite variety of situations: some which have fallen in soil that is too tenacious or too loose, too dry or too wet, too hot or too cold, do not grow, and are soon destroyed. But between these extremes some will succeed, although it may be under very different circumstances. Thus, for instance, if the place has not light enough, the plant will be half blighted, which will be indicated by its paleness and feebleness, or by being spotted, or by the diminution or even loss of its hairs; if the light is too bright, the plant will be stronger, smaller, more deeply coloured, harder, and more velvety than usual. Temperature also exercises some influence, though in a less degree; in a cold climate the same plants are smaller and weaker than ordinary, the colour of the flowers and fruit is paler, the wood worse ripened, their leaves more deciduous, their fruit often abortive, and the sap destined to nourish it throwing itself into the neighbouring parts, sometimes

changes their appearance. In a hot climate plants become larger, produce more wood, and their leaves have brighter colours and a higher flavour. In the same climate humidity causes the appearance of differences without end; plants that grow in water lose all their hairs, their leaves become divided into capillary segments so as to look like hairy rods, their stems and flower-stalks lengthen to reach the surface of the water, and these different effects are further variable as the water is still or agitated, clear or turbid, pure or mixed with heterogeneous substances; the varieties of *Ranunculus aquatilis* offer a remarkable example of this. If, on the other hand, a plant accustomed to water is found to live in a drier soil, it becomes covered with hairs, remains smaller than usual, and acquires greater hardness. In air rarified like that of mountains, plants are generally found smaller and more stunted than usual, while their flowers are larger than upon the plains. The influence of soil is not less manifest: if it is tenacious, the roots, which penetrate it with difficulty are small, hard, and clustered; if it is very sandy, the roots become large, fleshy, and fully formed; if it contains a great quantity of carbon, the colours of the flower are often altered, as those of the *Hydrangia* into blue, and of the Pink into violet; if it is charged with salt, or if the plant is within the reach of salt, even brought through the atmosphere, we usually find the leaves more fleshy and more glaucous, as in *Lotus corniculatus*. All these different circumstances, combined with each other in nature, are fertile causes of varieties, which are still further multiplied by cultivation."

SPECTACLE-SNAKE. [NATA.]

SPECULARIA (so called from *Speculum Veneris*, Venus's Looking-Glass, the old name of one of the species), a genus of Plants belonging to the natural order *Campanulaceæ*. It has a rotate corolla, a linear-oblong prismatic capsule opening by lateral pores between the calycine segments. In other respects this genus resembles that of *Campanula*, from which it has been separated by recent systematists. The species are small annual plants inhabiting the regions of the Mediterranean and the temperate parts of Europe. One species, the *S. perfoliata*, is a native of North and South America.

S. hybrida has a simple or branched stem; the leaves slightly crenate, wavy, oblong, sessile, the lower leaves spatulate; the calyx scabrous; the segments lanceolate, longer than the corolla, shorter than the ovary. This plant is a native of the corn-fields of Great Britain, and is found commonly throughout the region of the Mediterranean. There are several other species of this genus, all of which are worth cultivating on account of their showy flowers. The seeds should be sown in the open ground, where it is intended the plants should remain. By sowing the seeds in the autumn an early blossoming may be ensured in the following summer, and by successive sowings in the spring and summer they may be made to blossom for several months during the summer.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*.)

SPEEDWELL. [VERONICA.]

SPELTER. [ZINC.]

SPIERGULA, a genus of Plants belonging to the natural order *Caryophyllææ*. It is possessed of a 5-parted calyx, 5 undivided petals, 5 or 10 stamens, 5 styles, 8-celled 5-valved many-seeded capsule. This genus is found in fields and cultivated ground, especially on sandy soils, all over the world. It is divided into two sections, one of which possesses stipules; the other is without these organs. On this ground many writers have constituted new genera.

S. arvensis, Coru-Spurrey, or Yarr, has its leaves in whorls, with minute membranaceous stipules at their base; the stalk of the fruit reflexed; and the seeds hispid, with a narrow border. It is a native of Europe, in gardens and fields, and in North America on the banks of the Columbia, and is common in Great Britain. Though not cultivated in England, this plant is of some importance on the continent, and in the Netherlands and Germany is sown for fodder.

Three other species—the *S. nodosa*, Knotted Spurrey; *S. saginoides*, Pearl-Wort Spurrey; and *S. subulata*, Awl-Shaped Spurrey—are also natives of Great Britain, but are neither ornamental nor useful.

SPERMACEI, or *Cetaceum*, a fatty material obtained from the *Physeter macrocephalus*. This animal, called the Cachalot, or White Whale, is of immense size, frequently 60 or more feet in length, of which the head constitutes one-third. This part is the chief reservoir of the spermaceti, which however is found in several other parts of the body, mixed with the sperm oil. It is mostly lodged in two large cavities of the upper jaw, one above and the other below, divided from each other by the nostrils. These cavities are subdivided into numerous cells of unequal size, by ligamentous or tendinous partitions; these partitions are of the same nature as those which separate the fat in other animals, but, owing to the great size of the creature, of a larger and stronger kind. The purest spermaceti is contained in the largest and least ligamentous cells. The part in which it is lodged is quite distinct from the cranium containing the brain, which spermaceti was at one time supposed to be. During the life of the animal the spermaceti is in a fluid state, and on the head being opened has the appearance of an oily clear white liquid. On exposure to the air the spermaceti concretes and deposits from the oil. They are then separated, and put into different barrels.

SPERMACEI-WHALE. [CETACEA.]

SPERMATOCOSÉ, a genus of plants belonging to the natural order *Rubiaceæ*, so named from the seeds being terminated by two remarkable points. The genus is characterised by having the calyx 2-4-dentate; corolla 4-lobed; stigma bifid or entire; capsule 2-celled, crowned with the limb of the calyx, which is sometimes obliterated. Seeds oval, oblong, marked in the inner side with a longitudinal furrow. The species are very common and abundant in tropical parts of the world; and have usually quadrangular stems and branches, with small white or blue flowers. Some of the species, as *S. Poaya* and *S. ferruginæ*, are useful, like other plants of the same family, in having roots which form substitutes for ipecacuanba.

SPERMADICTION, a genus of Plants belonging to the natural order *Rubiaceæ*, named from σπέρμα, seed, and δίκτυον, a net, from the manner in which the seeds cover the placenta. The genus is characterised by having the calyx-tube ovate, 5-partite, persistent; corolla densely pubescent; tube long, straight, 5-lobed; stamens 5, included within the corolla-tube; stigma 5-cleft; capsule crowned by the calyx, contains 5 nuts. The species form shrubs, with white and light blue very fragrant flowers, with leaves lance-shaped, shortly petioled; stipules short. They are natives of Hindustan. *S. suaveolens*, the *S. Hamiltonia* of Roxburgh, ascends the Himalayas to elevations of 3000 feet, and has been cultivated in this country as a stove-plant.

SPERMESTES, Swainson, a sub-genus of *Fringillidæ*.

SPERMOEDIA, the name given by Fries to a certain altered form of the seeds of rye and other grasses, and to which the name Ergot and Spurred Grain has been commonly applied. The bodies to which this name is given are solid elongated masses, growing from the inside of the ovary of Grasses, rootless, of a firm mealy substance, with a concrete scaly or powdery crust. Fries says they have no proper fructification; but other authors state that the interior is composed of flocci and sporules firmly compacted into a solid homogeneous mass. The precise nature of these grains, both on account of their peculiar medicinal effects and their poisonous quality when taken as food, have excited much attention amongst botanical observers. Willdenow supposed the Ergot to be merely a diseased state of the grain, and stated that he could produce it at pleasure by excessive watering. General Field made some observations which led him to suppose that it originated from the puncture of insects. De Candolle and others more recently determined that the Ergot was a distinct parasitic plant, developing itself from the ovary of Grasses, and referred it to the genus *Sclerotium*. Fries, in his 'Systema Mycologicum,' considered the Ergot to be a diseased state of the grain, and placed it in the doubtful genus *Spermoedia*. More recently this production has been carefully investigated by Mr. Edward Quekett, who communicated the results of his observations to the Linnæan Society in November 1838. From his examinations, it appears that the great mass of the Ergot consists of the aluminous matter of the grain in a diseased state. The interior of these grains had been described as being filled by flocci and sporules compacted together; but on examination with the microscope, after the outside was scraped off, the interior was found to be composed of irregular cells filled with globules of a fatty oil. The cause of this changed state of the internal parts of the grain was found on the outside of the ergotised grain, where a number of very small oval or elliptical bodies were found, about 1-6000th of an inch in diameter, and containing within them a number of smaller granules. These were found to be the sporidia and sporules of a fungoid plant, which, attached to filaments, developed themselves early in the growth of the grain, and produced its diseased state. Mr. Quekett has since succeeded in obtaining ergotised rye by applying to healthy plants of rye water containing the sporules of this fungus diffused through it; thus affording additional proof that plants become diseased by imbibing the seeds or sporules of other plants from the soil in which they grow. For the plant as above described, Mr. Quekett proposes the name *Ergotaria abortans*. It belongs to the tribe *Mucedines* and sub-order *Concomyces* of the order *Fungaceæ* of Fries, thus occupying a different position to the *Sclerotium Clavus* of De Candolle, or the *Spermoedia Clavus* of Fries. [ERGOT.]

SPERMO'PHAGA (Swainson), a sub-genus of *Fringillidæ*.

SPERMO'PHILA (Swainson), a sub-genus of *Fringillidæ*.

SPERMOPHILUS. [MURIDÆ.]

SPERMOPHORE. [FRUIT.]

SPERMOSPIZA (G. R. Gray), a sub-genus of *Fringillidæ*.

SPHÆRALCÆA, a genus of Plants belonging to the natural order *Malvaceæ*. It is characterised by a 3-leaved deciduous involucre; 5-cleft calyx; 5 obliquely emarginate petals; numerous stamens united together, the stamen-tube being longer than the petals; many-celled ovary, with three seeds in each cell; styles consolidated and stigmas capitate; a globose umbilicated downy capsule, with cells debiscent at the back. The species are trees or shrubs with toothed or 3-5-lobed leaves. Flowers on peduncles, 1- or many-flowered, of a reddish or flesh colour. This genus was separated from *Malva*, which it greatly resembles, by Auguste St.-Hilaire. With the exception of one, a native of the Cape of Good Hope, the species are all found in South America.

S. Cisplatina, the Cisplatine Globe-Mallow, has a slender shrubby stem, ovate 3-lobed toothed or crenate leaves, tomentose beneath; axillary racemose flowers. It is a native of Brazil, in the western part of the Cisplatine province. It is used medicinally in Brazil, in the same manner as marsh-mallows are in Europe.

NAT. HIST. DIV. VOL. IV.

SPHÆRANTHUS, a genus of Plants belonging to the natural order *Compositæ*, so named from σφαῖρα, a globe, and ἄνθος, a flower, on account of the globular form of the heads of the flowers. The species are small herbs common in tropical parts of the Old World, with alternate decurrent leaves. Flowers tubular, external ones female, many-rowed, the central ones male with imperfect style; receptacle naked. Pappus wanting. *S. mollis* is common in most parts of the plains of India, and has a strong aromatic odour, and is used by the natives in medicine. *S. microcephalus* (*S. Indicus*, Linn.) has also an aromatic odour, and is employed as a diuretic in Java, according to Dr. Horsfield, and as an anthelmintic in India, according to Rheede, and in fevers, according to others.

SPHÆ'REDA, a fossil Plant from the Yorkshire coast.

SPHÆ'RIA, a genus of Plants belonging to the natural order *Fungaceæ*. This genus is known by possessing a rounded external receptacle, which opens at the top with a minute orifice. Within the receptacle, the sporidia, or seed-vessels, are found inclosed in tubes which are arranged in one or more rows. These tubes are called Asci. The size of the rounded receptacles of these *Fungi* varies from that of a millet-seed to that of a small marble. They are generally found upon decaying vegetable matter, and seem as if they were immersed in the substance on which they grow. Their most frequent position is on the bark of the stem and branches of decayed trees. They are however by no means confined to this situation, being frequently found on decaying leaves, on the stems of grasses, and on the surface of decaying wood. Some of them are found occupying the bark, leaves, &c. of plants that are still living, but in most instances this must be looked upon as indicative of a loss of vitality in the part of the plant thus attacked. One of the species, *S. militaris*, is remarkable for growing from the dead bodies of caterpillars and other decaying animal matters. Another species, the *S. entomorrhiza*, is also found in the same positions.

Although the plants of this genus are so simple in their structure, yet their receptacle, with its contents, presents so great variety in form, size, colour, &c., that upwards of 600 different species have been described. Of these, 201 species have been recorded as British, by the Rev. M. J. Berkeley, in the 2nd vol. of Hooker's 'British Flora.' These plants are very generally diffused throughout the world in the temperate zones. So abundant are they, that scarcely a decaying stick can be taken up in autumn without presenting some form of them.

Like the great mass of the vast order of *Fungi*, the species of *Sphæria* have not been used as food or medicine, or cultivated as ornament. Their great use in the economy of nature appears to be the appropriating those elements as materials of their growth, which, if left unconsumed, would become a source of deterioration to the atmosphere. As examples of this genus we shall select a few of the more common of the British species.

S. hypoxylon, Flat-Horned Sphæria. Receptacles of a black colour, of a corky consistence, single or branched, compressed, at first covered over with a mealy powder, then becoming naked, the stem villous. This is a very common species, and is found on sticks and stumps of trees. Unlike most of the species, it has a great tendency to sport, being sometimes exceedingly branched, sometimes palmate, and sometimes quite simple.

S. stigma, Black-Dotted Sphæria. Effused, often nearly surrounding the branch, flat, even, at length becoming black, the orifices nearly plain. In the course of its growth, it pushes off the cuticle of the bark of the stick on which it grows; it is at first brown, and then becomes black. It is perhaps the most common of all the species.

S. verruciformis, Wart-Like Sphæria. Receptacles ovate with a short neck; plant of a black colour. Found on branches of the hazel and beech.

S. quaternata, Quaternate Sphæria. Receptacles generally grouped four together, naked; orifices collected together. It is found on beech-trees alone. Many other forms are found on only one kind of plant.

S. sanguinea, Blood-Coloured Sphæria. The receptacles scattered, very small, ovate; papillary of a blood-red colour. It is very common on all kinds of decaying wood and sticks, and is easily recognised by its red colour; there are however many other forms with a red colour, but not so common as this.

(Fries, *Systema Mycologicum*; Hooker, *British Flora*; Groville, *Scottish Cryptogamic Flora*.)

SPHÆROCA'RYA, a genus of Plants belonging to the natural order *Hamnaceæ*, so named from σφαῖρα, a sphere, and κάρυον, a nut. The species forms moderate-sized trees in Nepal. The calyx is 5-parted. Petals 5, and alternate with the 5 stamens, which, like the petals, are inserted into the calyx, and with 5 fringed scales placed between the stamens, and opposite the calycina segments. Drupe pear-shaped, containing a smooth round nut. *S. edulis* is so called from its fruit being eaten and relished by the Nepalese, though not very palatable to a European taste. This tree is a native of the forests of Nepal, and has alternate, ovate-entire, exstipulate leaves, with axillary and terminal villous racemes of small greenish-coloured flowers, which are without odour.

SPHÆROCOCITES, a genus of Fucoid Fossil Plants, from the Oolitic series of the Yorkshire coast. (Presl.)

SPHÆROCOCCLUS, a genus of plants belonging to the natural

order *Algae*. It was formed by Stackhouse, and applied to the plants belonging to it on account of their globose fructification. A great number of species of this genus have been described, including amongst them some of the most useful of the sea-weed tribe. These species have been distributed by later botanists into the genera *Rhodomenia*, *Gigartina*, *Chondrus*, *Gelidium*, and *Phyllophora*, and the genus *Sphaerococcus* has only one species, the *S. coronopifolius*. The genus *Chondrus* affords the Carrageen-Moss, which is so much used as an article of diet. It is a species of *Gelidium*, with which the swallows build their nests in the Eastern Archipelago, and which are so highly valued as articles of food by the Chinese.

SPHÆRODUS, a Fossil genus of Fishes. [FISH.]

SPHÆROMA. [ISOPODA.]

SPHÆRONITES. [ECHINODERMATA.]

SPHÆROPS. [IGUANIDE.]

SPHÆROSIDERITE. [IRON.]

SPHERULITE, a Mineral occurring in small botryoidal and spheroidal masses. Surface sometimes rough, at other times smooth. No regular cleavage. Structure compact, fibrous. Fracture conchoidal. Hardness 7 to 7.5. Brittle. Colour gray, brown, red, yellow, of various shades. Opaque; translucent on the edges. Specific gravity 2.4 to 2.54. Before the blow-pipe almost infusible, the edges becoming covered with a sort of enamel. It is found embedded in pitchstone at Speitshausen in Saxony; in pearlstone at Glashutte, near Schemnitz, Hungary, and also in Iceland and Scotland. It yields by analysis:—

Silica	79.12
Alumina	12.00
Potash and Soda	3.58
Magnesia	1.10
Oxide of Iron	2.45
Water	1.75

—100

SPHAGNUM, a genus of Plants belonging to the natural order of Mosses. It is known by the following characters:—Receptacle pedunculated, its peduncle resembling a fruit-stalk; capsule sessile, entire, its lid deciduous, its mouth naked; calyptra irregularly torn. The plants of this genus are very widely diffused over the surface of the earth, perhaps more so than any other, hardly any limits being ascertained for their geographical distribution. They are aquatic plants, and constitute the great mass of our bogs in swampy and moory districts. All the species of this genus used to be included under the name of *S. palustre*; but later writers have multiplied the species to fourteen. Of these, Sir William Hooker, in his 'Muscologia Britannica,' admits only four, and one or two even of these he thinks may be varieties.

S. obtusifolium, Obtuse-Leaved Bog-Moss, has tumid branches, with obtuse ovate leaves. It is found on the surface of watery turfy bogs throughout Europe.

S. acutifolium, Narrow-Leaved Bog-Moss, has attenuated branches and ovate-lanceolate leaves; and is very abundant, especially in bogs in mountainous situations.

S. cuspidatum, the Long-Leaved Floating Bog-Moss, seems to be a variety of the last, having peculiar characters from growing constantly under water. Its leaves are looser and narrower than those of the narrow-leaved bog-moss. It seldom bears fruit; its stems are sometimes 4 feet long, and its leaves three-quarters of an inch broad.

SPHAGNIS. [CHLORION.]

SPHÆCIDÆ, Leach (*Sphægides*, Latreille), a family of Hymenopterous Insects of the section *Possore*, distinguished by the following characters:—Hinder tarsi at least equal in length to the head and thorax; antennæ generally slender, and formed of elongated joints, which are often arched and contorted, at least in the females; prothorax forming a kind of neck, very distinctly separated from the mesothorax, and contracted in front. The base of the abdomen constricted into a long petiole; mandibles internally toothed. The following are the principal genera contained in this family:—

Pepsis (Fab.), has the labrum distinct; the antennæ, at least those of the males, are nearly straight, composed of joints closely applied to each other; maxillary palpi scarcely longer than the labial, prominent, and with the joints unequal; all the cubital cells perfect; the first recurrent nervure inserted near the anterior extremity of the second of these cells. The males have the tibiae and the first joint of the posterior tarsi compressed.

All the known species of *Pepsis* are exotic, and they abound most in South America and in the West Indian islands; they are usually of large size, and have dark-coloured wings.

Ceropalæ.—The labrum and antennæ resemble those of *Pepsis*, but the maxillary palpi are much longer than the labial, pendent and unequal-jointed.

Pompilus (Fab.).—This genus is placed by Latreille in the *Sphægida*, but, according to Leach, it forms the type of a distinct family (*Pompilidae*), characterised by having a transverse prothorax, at least as broad again as long, with its posterior margin acute; the abdomen obovoid, without any contraction, in the shape of a long petiole, at its base. The antennæ are setaceous and long; the superior wings have one marginal cell, nearly semicircular, and three sub-marginal cells, the

first as long or longer than the two following; the second receiving about its centre the first recurrent nervure; the third, which is either triangular or subquadrate, receives the second; a fourth submarginal cell is sometimes traceable.

Several species of this genus are found in England; they usually make burrows in the sand for nidification, but some are said to make their nests in wood. The perfect insect provides its cell with spiders, these constituting the food of the larvæ.

Ammophila (Kirby).—Abdomen with the petiole long; superior wings with one oval marginal cell, and three submarginal cells; the first as long or longer than the two following, the second receiving both the recurrent nervures, the third very small and narrow towards the marginal cell; legs long, the anterior tarsi slightly ciliated.

These insects, observes Mr. Shuckard, on the authority of St.-Fargeau, construct their burrows in sand alone, and supply their larvæ with *Arachnida* and the larvæ of *Lepidoptera*, and select by preference those of the *Noctua*, sometimes as large as themselves. They sting them towards the middle of the body, which renders them torpid, but does not kill them, and prevents their motion. The *Ammophila* then extending itself in its whole length upon the larvæ, seizes it with its mandibles near the head, and supports the remainder of the body with its legs. But thus encumbered it can no longer fly; it therefore proceeds slowly, dragging it along. Should it perceive any obstacle in the path, such as a stone or tuft of plants, it quits its load at an instant, and springs lightly forward to reconnoitre and explore its way, but returns immediately to resume its burden.

A female has been observed by St.-Fargeau, thus loaded, to clear a wall eight or ten feet high, but not without much ingenious contrivance. The caterpillar fell several times to the ground, when the *Ammophila* placed it upon a projecting stone to rest itself and recruit its strength; but it renewed its task with extraordinary perseverance, and succeeded in accomplishing it.

In the genera *Sphex*, *Pronæus*, and *Chlorion*, the mandibles and labrum are comparatively short, and more or less curved at the point.

Pronæus.—The second cubital or submarginal cell receives the two recurrent nervures.

Sphex.—The superior wings have one long and narrow marginal cell, which is rounded at the apex, and three submarginal cells, the first as long as the two following; the second quadrate, receiving the first recurrent nervure towards its extremity; the third forming a truncated triangle with its posterior margins slightly rounded, and receiving the second recurrent nervure in its middle: a rudimentary fourth cell is sometimes observable. One species has been found in England, but appears to be extremely rare.

Chlorion has the first recurrent nervure inserted under the first cubital cell, and the second beneath the third cubital.

Dolichurus, Latr., has the maxillary palpi much longer than the labial, and nearly setaceous; the mandibles are deuted.

The remaining genera of this family have no teeth to the mandibles: they are, *Ampulex*, *Podium*, and *Pelopæus*. The first of these genera resembles *Chlorion* as regards the insertion of the recurrent nervures in the superior wings, and in the genera *Podium* and *Pelopæus* the second cubital cell receives two recurrent nervures.

SPHÆCOTHERES. [MERULINÆ.]

SPHÆGIDÆ. [SPHÆGINÆ.]

SPHENACANTHUS, a genus of Fossil Fishes. [FISH.]

SPHENE. [TITANIUM.]

SPHENISCUS. [PENGUINS.]

SPHENOCLEA, a genus of Plants belonging to the natural order *Campanulaceæ*, consisting of only a single species. The genus is characterised by having a superior 5-parted calyx with inflexed segments. Corolla 5-parted, with the segments inflexed and somewhat auricled at the base, and which conceal the 5 sessile stamens; ovary inferior; style very short and 2-lobed; capsule membranous, many-seeded, with a central fungous placenta, circumscissile; seeds minute, embryo without albumen, straight, with the radicle next the hilum. The only known species, called *S. Zeylanica*, is an annual, with alternate entire leaves, and without stipules; found in marsh situations in all parts of India. It is sometimes made the type of an order.

SPHENOCLEACEÆ, a natural order of Plants, consisting of only one species, belonging to the monopetalous sub-class of Exogens. It was formed by Martins, and consists of a single genus, which at that time was called *Sphenoclea*, but now known as *Pongatium*. This plant is very like a *Campanula* in its structure, but it is distinguished from all *Campanulaceæ* by the absence of albumen in its seeds, and also the want of collecting hairs on its styles. It has also round subsessile anthers, and a habit different from that of plants allied to it in structure. [SPHENOCLEA.]

SPHENOID BONE. [SKELETON.]

SPHENONCHUS, a genus of Fossil Fishes. [FISH.]

SPHENOPHYLLUM, a genus of Fossil Plants. [COAL-PLANTS.]

SPHENOPS. [SCINCINÆ.]

SPHENOPTERIS, a genus of Fossil Ferns. [COAL-PLANTS.]

SPHENURUS, Swainson, a sub-genus of *Columbida*.

SPHERCHEUS. [HYDROPHYLLINÆ.]

SPHEROSTILBITE, a Mineral, occurring in globular masses. Structure radiated. Fracture brilliant. Lustre pearly. Fibres flexible. Hardness above 3.0. Specific gravity 2.31. It is found in Iceland and

the Faroe Islands. An analysis, by Gehlen, of a specimen from Iceland gave—

Silica	55.61
Alumina	16.68
Lime	8.17
Soda	1.53
Water	19.80

—101.29.

SPHIGURUS. [HYSTRICIDÆ.]

SPHINCTER (from σφιγγω, 'I restrain') is a name applied generally to the muscles which close the external apertures of organs, as the sphincter of the mouth, of the eyes, &c., and more particularly to those among them, which, like the sphincter ani, have the peculiarity of being, during health, in a state of permanent contraction, independently of the will, and of relaxing only when it is required that the contents of the organs which they close should be evacuated. [NERVOUS SYSTEM.]

SPHINGIDÆ, a family of Lepidopterous Insects belonging to the section *Crepuscularia*; in fact, regarding the family in its most extended sense, it composes the section named.

The section *Crepuscularia* by most authors is placed between the Diurnal and Nocturnal *Lepidoptera* (sections *Diurna* and *Nocturna*), and corresponds with the genus *Sphinx* of Linnaeus.

The insects belonging to this division generally fly in the evening, or early in the morning, but there are many which fly in the daytime. The body is usually stout, and in the typical species remarkable for its pointed apical portion; in some the body is cylindrical. The antennæ are moderately long, angular, and generally increase in thickness from the base, and terminate in an elongated club, having the apex pointed and recurved. The wings when at rest are usually a little inclined, but sometimes horizontal, and in some species the inferior wings project beyond the upper margin of the superior. These inferior wings are provided at the base of their upper margin with a bristle-like spine, which, passing through a hook of the upper wing, serves to unite the two wings. The spines in question are visible upon viewing the under side of the insect; they are also found in the Nocturnal *Lepidoptera*, but here the antennæ are stoutest at the base, gradually decreasing in thickness. The larvæ are always provided with sixteen legs, six thoracic, eight abdominal, and two anal. In the more typical *Sphingidæ* the larvæ are moreover provided with a spurlike process on the upper surface of the last segment of the abdomen, the point of this somewhat curved and horny process being directed backwards.

According to the views of some authors, the *Crepuscularia* constitute a family, but most modern writers regard this division as one of higher value, and divide it into several families.

The following are the characters of four families adopted in Stephens's 'Illustrations of British Entomology':—

Sphingidæ.—Antennæ prismatic, sometimes serrated towards the middle, ciliated slightly in the males, terminated by a scaly seta, or naked filiform appendage; palpi short, 3-jointed, densely clothed with hair or scales, the terminal joint minute; abdomen conical, not tufted at the apex; larva exposed, cylindrical, or attenuated anteriorly, with a horn on the last segment, naked, sometimes granulated, the sides frequently with oblique or longitudinal stripes; pupa subterranean, or subfoliaceous.

The family embraces some of the largest European *Lepidoptera*: among others may be mentioned the Death's-Head Hawk-Moth (*Acherontia Atropos* of modern authors; *Sphinx Atropos* of Linnaeus), an insect not uncommon in some parts of England, and which measures from tip to tip of the expanded wings usually a trifle less than five inches. Its general colour is dark, the superior wings being mottled with brown, black, and yellow; the body is yellow, has a longitudinal black dorsal mark, and narrow black bands; the under wings are also yellow, and have two black bands; on the thorax are pale markings, which bear some resemblance to a skull. The larva is of a greenish-yellow colour, with the back speckled with black, and transverse lateral lines partly blue and partly white. It feeds upon the potato plant, jasmine, &c. When full-grown the larva measures about five inches in length; and when about to assume the pupa state, it buries itself in the ground. "Towards the end of September, or the beginning of October," says Mr. Stephens, "the imago is produced, and, like the rest of the group, flies morning and evening only. The conspicuous patch on the back of its thorax, which has considerable resemblance to a cranium, or death's-head, combined with the feeble cry of the insect, which closely resembles the noise caused by the creaking of a cork, more than the plaintive squeaking of a mouse, has caused the insect to be looked upon by superstitious persons as the 'baringer of death, disease, and famine,' and their sudden appearance in Bretagne, as we are informed by Latreille, during a season while the inhabitants were suffering from an epidemic disease, tended to confirm the notions of the superstitious in that district, and the disease was attributed by them entirely to the visitations of these hapless insects."

The Death's-Head Moth is at times very troublesome to the keepers of bee-hives, which it robs of the honey. [BEE.]

Zygenidæ.—Antennæ fusiform, sometimes bipectinated, without a fascicle of scales at the apex; head smooth; palpi short or elongated,

clothed with long scales or hair, the terminal joint elongated; abdomen cylindric, with a slight tuft at the apex; larva exposed, fusiform, slightly villose, not tailed; legs minute; pupa folliculated.

The insects of this family, observes Mr. Stephens, are of a gregarious nature, and, unlike the *Sphingidæ*, they fly chiefly by day. Their flight is very heavy and slow. Their caterpillars subsist upon the leaves of divers plants, and they form a silken web in which they change to pupæ.

The species of this group are generally very brilliant in their colouring, and many exotic species have the wings transparent in parts. Examples of two genera are found in this country, *Ino* and *Anthrocera* (or *Zygana*). Of the former of these genera but one English species is known, *Ino Statices*, an insect measuring from the points of the expanded wings rather more than an inch. Its superior wings are of a brilliant green-colour, and the inferior are brownish.

The genus *Anthrocera* contains several indigenous species: the superior wings are usually of a deep metallic green-colour, spotted with red, and the under wings are red margined with black. The species are known by the name Burnet-Moth. The Six-Spotted Burnet-Moth (*Anthrocera Filipendula*) measures nearly an inch and a half in width, the wings being expanded, and has six red spots on the superior wings. It is very common in various parts of England, making its appearance in meadows, &c. about the end of June. The caterpillar is yellow, spotted with black. It feeds upon the plainant, trefoil, dandelion, &c.

Sesiidæ.—Antennæ prismatic, ciliated in the males, slightly hooked, the apex terminating in an oblique scaly process; palpi short, clothed with scales, the terminal joint extremely minute; abdomen conical, with the apex tufted; larva naked, with a horny appendage on the hinder segment; pupa smooth, without spines, inclosed in a cocoon upon the ground.

To this family belongs the Humming-Bird Hawk-Moth (*Macroglossa stellatarum*), an insect not uncommon in various parts of England. Of this species Mr. Stephens says there are usually three broods in the year, appearing respectively at the end of April, June, and August; some of the last brood have been known to hibernates. The moth measures in width about an inch and three-quarters, or rather more, and is of an ashy-brown colour; the upper wings have two transverse waved black marks; the under wings are of an orange-colour, edged with black, and on the sides of the body are some white patches. This insect flies about in sunny weather; and is remarkable for the swiftness of its motions; in which respect it greatly resembles the humming-bird, as well as in its habits of feeding upon honey, which it extracts from the flowers by means of its enormously long proboscis, but without settling upon the plant.

Other species of the present family are found in England. They constitute the genus *Sesia*, and are distinguished from *Macroglossa* by the disc of their wings being transparent.

Egeriidæ.—Antennæ fusiform, a little curved, ciliated in the males, the apex terminating in a plume of scales; ocelli two, minute, placed behind the antennæ; palpi elongate, thickly clothed with scales and long hairs, the last joint elongate; abdomen cylindric, tufted at the apex; wings horizontal and generally transparent, with the exception of the apical portion, which is more or less covered with scales; larva tailless, assumes the pupa state in the stems of plants or dead wood of trees; pupa furnished with spines on the segments of the body.

The species of this family are usually of small size, and remarkable for their transparent wings and the possession of ocelli, or simple eyes, in addition to the ordinary compound eyes. They fly by day, and many of them bear superficial resemblances to insects of other orders, and hence have received such names as *Crabroniformis*, *Ichneumoniformis*, &c. Numerous species are found in England, and these constitute the two genera *Trochalium* and *Egeria*. In the former of these genera the maxillæ are very short, and the antennæ are short, whilst in *Egeria* the maxillæ are elongated, and the antennæ also long.

SPHINX. [CREPUSCULARIA; SPHINGIDÆ.]

SPIDER-ORCHIS. [OFMYS.]

SPIDER-WORT. [COMMELYNACEÆ.]

SPIDERS. [ARACHNIDÆ; ARANEIDÆ.]

SPIGELIA, a genus of Plants belonging to the natural order *Spigeliaceæ*. It is commemorative of Adrian Spigellius. The characters of this genus are:—Calyx 5-parted; corolla funnel-shaped, with a 5-cleft equal limb; anthers converging; capsule didynamous, 2-celled, 4-valved, many-seeded. This genus consists of annual and perennial herbs, and under-shrubs with opposite leaves and rose-coloured or purple flowers. They are natives of North and South America, and are found in various soils.

S. Marylandica, Maryland Worm-Grass, is an herbaceous perennial, with simple tetragonal scabrous stems; opposite, sessile, glabrous, ovato-lanceolate leaves; solitary spikes; funnel-shaped corolla, and inclosed stamens. It is a native of Virginia, Maryland, the Carolinas, and Georgia, in rich moist soils, by the edges of woods; also in the forests on the banks of the Arkansas. Although all the species possess active properties, the Maryland Worm-Seed is that which is principally used in medicine.

S. Anthelmia, Annual Worm-Grass, is an herbaceous annual, with branched nearly square stems; ovate or oblong-acute leaves, with short petioles; floral leaves four in a whorl; funnel-shaped corolla, and inclosed stamens. It is a native of Guyana, Trinidad, and Brazil. It possesses powerful narcotic properties, and is used in the same manner as the last. This species is often cultivated: it has small pale-red flowers.

SPIGELIACEÆ, a small natural order of Plants belonging to the monopetalous sub-class of Exogens. The order consists of herbaceous plants or under-shrubs, with opposite, entire, stipulate leaves, and flowers arranged in 1-sided spikes. The calyx is inferior, regularly 5-parted; corolla regular, with five lobes, having a valvate aestivation; stamens 5, inserted in the corolla, all in the same line; pollen-grains 3-cornered, with globular angles; ovary superior, 2-celled; fruit a capsule, 2-valved, many-seeded, valves turned inwards at the margin, and separating from the central placenta; embryo very small, lying in the midst of fleshy albumen, with the radicle next the hilum.

The order consists of two genera, *Canala* and *Spigelia*, the species of which are natives of America. [SPIGELIA.]

SPIKE. [INFLORESCENCE.]

SPIKENARD is a substance which has enjoyed celebrity from the earliest period of the world's history, and has engaged the attention of numerous commentators on the works of the ancients, as well as of some modern authors. It is interesting therefore not only as making us acquainted with one of the substances known to and esteemed by the Greeks and Romans, but it is important likewise as being mentioned in the Bible, since the Nard of Scripture is supposed to be the same substance as the Nardos of the ancients, called also *Nardostachys* (*ναρδοστάχυς*), and hence Spikenard, the word *Stachys* being rendered by the word Spike.

Dioscorides, in the first chapter of his first book, treats of the various aromatic and stimulant substances which were known to the ancients, and among these of the various kinds of Nard. Of the first kind, called simply Nardus (*νάδος*), there are two varieties, the one Syrian, the other Indian; the former so called not because it comes from Syria, but because the mountains in which it is produced have one part turned towards Syria and the other towards India. This may refer either to the Hindu-Kush, or to so many Indian products finding their way to Syria, by the way of the Red Sea and the Euphrates, from the earliest times. The other variety is called Gangitis, from the river Ganges, near which, while flowing round a mountain, it is produced, bearing many hairy spikes from one root. These are strong-smelling, but those growing in moist situations less so than those found on the mountains. One variety, he further says, is called Sauphariticon, from the name of a place. This first kind being called Nardus, and distinguished into the Syrian and Indian varieties, the second kind he calls Celtic Nard (*νάδος Κελτική*), and the third kind a Mountain Nard (*νάδος ὄρεινῃ*). On consulting Avicenna, we are referred from Narden to Sunbul, pronounced Sunbul, and in the Latin translation from Nardum to Spica, under which the Roman, the mountain, the Indian, and Syrian kinds are mentioned. This proves, as has been already stated by Sir William Jones, that Sunbul, &c., was always considered by Arabian authors as synonymous with the Nardos of the Greeks. In Persian works on Materia Medica, all translated from the Arabic, as, for instance, the 'Mukhzun-ul-Adwiah,' or 'Magazine of Medicines,' we have four different kinds of Sunbul:—1, Sunbul Hindes; 2, Sunbul Roomee, called also Sunbul Ukleete, and Narden Ukleete, evidently the above Celtic Nard, said also to be called Sunbul Italian, that is, the nard which grows in Italy; 3, Sunbul Jibullee, or Mountain Nard: hence it is evident that the kinds described by Dioscorides are alluded to, and in fact the accounts given are merely translations of his descriptions. The fourth kind of Sunbul appears to be a hyacinth or polyanthus. But the first is that with which alone we are at present concerned. The synonyms given to it are—Arabic, Sunbul-al-Teah, or Fragrant Nard; Greek, Narden; Latin, Nardoo; and Hindes, Balchur, and Jatamasce.

Having the Hindes and Sanscrit names of an Indian plant, the next step was to obtain it. This was first attempted by Sir William Jones, at a time when we had no access to the Himalayan Mountains, and a wrong plant was sent him. Dr. Royle informs us that on making inquiries on the subject, when at Saharaspore, in 30° N. lat., about 30 miles from the foot of the Himalayas, he learnt that Jatamansl, better known in India by the name Bal-Chur, was yearly brought down in considerable quantities from the mountains, such as Shalma Kedar-kanta, near the Ganges and Jumna rivers, to the plains. Having obtained some of the fresh brought down roots, he planted them both in the East India Company's Botanic Garden, and in the mountains, in a nursery attached to it. The plant produced was found to belong to the natural order *Valerianaceæ*, and has been named *Nardostachys Jatamansi* by De Candolle, and formerly *Patrinia Jatamansi* by Mr. Dou, from plants sent home by Dr. Wallich from Gossainthan, a mountain of Nepal. Mr. Don obtained the additional corroboration that spikenard bought in a chemist's shop by this name exactly corresponded with the roots of the Jatamansl. (Royle, 'Illustr. Himalayan Bot.,' p. 242.)

Hence there can be no doubt that the Nardos described by Dioscorides is the Jatamansl of the Hindoos, and probably the same substance

which has been mentioned by such writers as Hippocrates; and there is nothing improbable in its being the Nard of Scripture, and it has been shown to be a plant belonging to the natural order *Valerianaceæ*. It is curious that the Celtic and mountain nards are also Valerians, the former being yielded by *Valeriana Celtica* and *V. Salunca*, still exported from the mountains of Austria to Egypt, whence it has spread into both Africa and Asia, being valued for its fragrance, and hence employed in perfuming baths; and the other by *V. tuberosa*. Dr. Royle mentions it as a curious coincidence, if not allowed to be a sign of accurate knowledge, that the Persians should translate the *φν* of Dioscorides, which he also calls Wild Nard, *Foo* of the Arabians, by the term Bekh-i-Sunbul, Root of Soonbul. The plant correctly ascertained by Sibthorp has been named by him *Valeriana Dioscoridis*.

SPILANTHUS, a genus of Plants belonging to the natural order *Compositæ* and the sub-order *Corymbifere*. It has a many-flowered head, either heterogamous with the florets of the ray ligulate, or homogamous with all the florets tubular and 5-toothed; the involucre is in two rows, adpressed, shorter than the disc, the outer scales somewhat leafy, the inner rather membranous and folded up.

S. oleracea, has a branched diffused stem; opposite stalked broadly ovate leaves, obtuse at the base, truncate or somewhat cordate; the pedicels are 1-headed, longer than the leaf; the heads thick, ovate, and discoidal; the achænia ciliated at the angles, bi-aristate or awnless. The whole plant, but especially the involucre and receptacle, acts as a powerful stimulant of the salivary organs.

(Lindley, *Flora Medica*.)

SPINACH. [SPINACIA.]

SPINACIA, a genus of Plants belonging to the natural order *Chenopodiaceæ*. This genus is dioecious, the male and female flowers being on different plants; the male flowers are composed of a calyx, with 5 deeply cloven concave oblong obtuse segments; 5 stamens, with filaments longer than the calyx, with oblong double anthers. The female flowers have a monopetalous calyx, with four divisions, two of which are smaller and opposite; a superior ovary with 4 styles and simple stigmas. As the fruit ripens the calyx hardens and adheres to it. The ovary contains a single seed. There are only two species, which are herbaceous plants with alternate leaves, and axillary flowers of a green colour.

S. oleracea, the Common Spinach, is well known on account of its use in the kitchen. It has an herbaceous stem one or two feet high, branched, and hollow; arrow-shaped leaves; male flowers in long spikes, abounding with pollen; female flowers on another plant, axillary, herbaceous, and small. The fruit is a small round nut, which is sometimes very prickly.

SPINDLE-TREE. [CELASTRACEÆ; EUONYMUS.]

SPINE. [SKELETON.]

SPINE, in Botany, is applied to the sharp hard conical extremities of the branches of plants. The spine is seen in great perfection in the *Gleditschia*, *Sloe*, *White-Thorn*, and other plants. Spines differ from prickles in being in connection with the wood of the stem, and in being composed of bark and wood, as the stem itself. The prickle consists of merely hardened cellular tissue, and can be removed from the wood with the bark.

SPINE-BACKS, a name given to the *Notacanthidae*, a family of Acanthopterygious Fishes.

SPINELL, *Spinell Ruby*, *Balas Ruby*, *Ceylanite*, *Candite*, &c., a Mineral occurring in loose and imbedded octohedral crystals. Primary form the cube. Cleavage easy, parallel to the faces of the octohedron of the black opaque variety; difficult in the other varieties. Fracture conchoidal. Hardness greater than that of quartz, but less than that of corundum. Colour red, blue, violet, green, yellow, brown, and black. The first is the most common. Streak white. Lustre vitreous. Transparent, translucent, opaque. Specific gravity 3.5 to 3.7. Infusible by the blow-pipe; the red varieties are rendered black and become opaque by exposure to it, but on cooling, at first of a fine green by transmitted light, then nearly colourless, and at last become again red.

Spinel is found in Ceylon and Siam in isolated and rolled crystals in the beds of rivers. It is found embedded in carbonate of lime in North America and Sweden.

Several varieties have been analysed: red transparent spinell by Vauquelin; blue, by Berzelius; green and black, by Dr. Thomson:—

	Red.	Blue.	Green.	Black.
Silica . . .	—	5.43	5.62	5.59
Alumina . . .	82.47	72.25	73.30	61.78
Magnesia . . .	8.78	14.63	13.63	17.86
Protoxide of Iron . . .	—	4.26	7.42	10.56
Lime . . .	—	—	trace	2.81
Chromic Acid . . .	6.18	—	—	—
	97.43	96.62	99.97	98.60

SPINELLANE, a Mineral occurring crystallised. Its primary form is the cube; its usual form the rhombic dodecahedron. Cleavage parallel to the faces of the dodecahedron. Fracture conchoidal, uneven. Hardness 5.5 to 6. Colour brown, gray, grayish black. Lustre vitreous. Translucent; opaque. Specific gravity 2.28. It gelatinises in acids.

It is found on the borders of Lake Laach, near Andernach on the Rhine. Its analysis by Klaproth gives—

Silica	43.0
Alumina	29.5
Soda	19.0
Lime	1.5
Peroxide of Iron	1.0
Sulphuric Acid	2.0
Water	2.5

—98.5

SPINIGRADA. [ECHINODERMATA.]

SPIRÆA. [MILLEPEDIÆ.]

SPIRÆA, a genus of Plants belonging to the natural order *Rosaceæ*, tribe *Spiracææ*. The name occurs in ancient authors, and is supposed to be derived from *σπείρα*, a cord, in allusion to the fitness of the plants for twisting into garlands. The genus is diffused through the temperate parts of the northern hemisphere, and is characterised by having a 5-cleft permanent calyx; stamens 10 to 50, inserted in a torus with the 5 petals, which are inserted into the calyx; carpels sessile, solitary or several, rarely connected into a capsule; seeds 2-15, pendulous, very rarely ascending. The species, upwards of 50 in number, form small unarmed shrubs or perennial herbs; leaves usually simple, sometimes pinnately cut; flowers white or reddish. They are found in Europe, North America, Siberia, China, and the Altaï and Himalayan Mountains.

S. Ulmaria, Meadow-Sweet, is found in our meadows; and *S. filipendula* on our downs, &c. Pigs are said to be fond of the tubers of the roots. Several of the species are astringent, and might be used in tanning. *S. trifoliata* is sometimes called Ipecacuanha de Virginia, being employed as an emetic.

SPIRAL STRUCTURES. In the development of the tissues of plants and animals two tendencies are observed; the one simply that of extension in a vertical direction, the other is that of curvature, mostly resulting in the production of a spire. The tendency to develop parts in a spiral direction, though much more prominent in the vegetable than in the animal kingdom, is by no means confined to it. In the ninth volume of the 'Annales des Sciences Naturelles,' Mandl has shown that all the tegumentary appendages of animals, as the scales, feathers, hair, &c., have a spiral arrangement, and that many of the internal organs are subject to the same law. The tendency to develop structures in a spiral form appears to be dependent on some of the higher laws regulating organic life; and in this view the subject has been investigated by recent botanists. Göthe, the German poet, in his 'Essay on the Spiral Tendency of Vegetation,' published in 1831, gives the following view. He supposes that there is a dependence of those properties which plants possess of resisting external agents, and of enduring for a length of time, upon those parts that are developed vertically, while the nutritive and reproductive functions are connected with spirally-developed structures. In support of this generalisation he adduces a number of facts. If a branch of an ash-tree is injured, so that the lower parts become over-nourished, it possesses a tendency to become spiral. When the leaves of the Italian poplar are injured by insects, the petioles become twisted. Spiral vessels exist in greatest numbers in the growing parts of plants, as the alburnum. They also exist in greater numbers in the higher plants, the lowest possessing none. A spiral arrangement of parts is also much less observable in the lower than in the higher groups of plants. The organs of nutrition and reproduction, the leaves and parts of the flower, have normally a spiral arrangement. Von Martius, Mohl, and others, have also written on the general theory of spiral structure.

Cellular tissue was at one time supposed to consist of plain simple cells, but the researches of later botanists have proved that the cells of this tissue are often furnished with fibres, which are twisted in a spiral manner. This spiral fibrous tissue is abundant in the roots of orchidaceous plants, in the seed-coats of many plants, and in the linings of the valves of almost all anthers. Spiral fibres, independent of any cells, and apparently surrounded by vegetable mucus, have been found in the testa of the seeds of *Collomia linearis*. In the seed-coats of the seeds of species of *Blepharis* and *Acanthodium* spiral fibres inclosed in membranous tubes are found in a very great abundance. The organs called elaters, which are contained with the sporules in the conceptacles of *Jungermannia*, consist of spiral fibres surrounded by a tube. In the reproductive cells of both animals and plants a spiral arrangement of the protoplasm is often observed, and as a rule the spermatozoa and spermatozooids of plants and animals are developed in this form.

In the vascular tissue of plants is found a tissue, which on account of its spiral structure has been called Spiral Vessels. These vessels appear to be little more than fibrous cellular tissue elongated, the parietes of the cell forming an elongated tube, which is tapering at each extremity, and contains within it one, two, three, or more spiral fibres. This tissue is exceedingly abundant in exogenous and eadogenous plants, but is not found in the lower families of *Cryptogamia*. It exists however in *Ferus*, *Lycopodiaceæ*, and *Equisetaceæ*. It is only sparingly found in *Conifereæ*. These spiral fibres possess the power of moving when touched.

The spiral tendency is developed in the structure of the stem and leaves of plants. The part of the latter which exhibits this structure

is the petiole, and in this organ all forms of the spire may be seen, from a single twist to the complicated spires observed in the organs called cirrhi. In most plants these cirrhi assist them in climbing, their structure adapting them to this purpose. The spires of the cirrhi twist in some from right to left, in others from left to right; and in the cirrhi of the genera *Passiflora* and *Bryonia* the direction changes several times in the course of the spire from right to left and from left to right.

In the structure of many of the *Conferveæ* a spiral arrangement of the tissues is observed, especially of those which approach the animal kingdom in their movements, as the *Oscillatoria*. The setæ which support the conceptacle of *Jungermannia*, and which contain the spiral elaters before mentioned, possess in many instances a spiral structure. This is also occasionally developed in the same organ in mosses, a remarkable instance of which occurs in *Funaria hygrometrica*. In this moss the setæ are quite straight when young, but assume the spiral structure as they increase in age. In this setæ the spire turns in two directions: from the base about two-thirds up the stem it goes from right to left; it then becomes quite straight, and turns in the opposite direction from left to right. A curious property is possessed by these setæ when the capsules are ripe. If the upper part of the spire is moistened, the capsule commences turning from right to left; but if the lower part only is moistened, it turns from left to right.

The entire stems of plants are frequently spiral, as is seen in the plants which are called Climbers. These plants, by reason of the spiral arrangement of their tissues, twine around the nearest objects, whether organic or inorganic. In most of them the winding of the spire is to the left side, but in a few the turning is to the right. Amongst the former are the genera *Cuscuta*, *Phaseolus*, *Dolichos*, *Passiflora*, *Banisteria*, &c.; amongst the latter are the genera *Humulus*, *Dioscorea*, *Lonicera*, *Polygonum*, &c. This winding in a particular direction is not only confined to the species of a genus, but to the genera of an order; and Mohl, who has paid great attention to this subject, states that he knows of but one exception to this rule, which is the genus *Abrus*, in the order of *Leguminosæ*, which twines to the left, whilst all the others twine to the right. The direction of the spires of the cirrhi is not so constant. Between the twining of the cirrhi and the stems of plants Mohl has pointed out an essential difference. The cirrhi are first developed longitudinally, and the spiral tendency proceeds from the point to the base; but in stems the first three or four internodes grow straight, and the next internode is developed very rapidly; and from this lower internode the spiral tendency is developed upwards. Sometimes a spiral direction is seen in the direction of trees that ordinarily grow straight; and Göthe records several instances of twisted trunks in the chestnut, the white-thorn, beech, and others. A remarkable instance of spiral structure connected with function is seen in the peduncle of the female flowers of *Valisneria*, which is a water-plant. The female flowers spring to the surface of the water in the summer, at the time the male flowers have perfected their pollen, and scattered it upon the surface of the water. As soon as the pollen is conveyed to the female flower its spiral stem becomes contracted, and its fruit is perfected at the bottom of the water.

The most remarkable and important exhibition, in a practical point of view, of the spiral tendency in plants, is the arrangement of the leaves upon the axis of the plant. If we take a branch of the willow, oak, pear, apple, or many others, and examine the leaves, we shall find they are arranged in such a manner, that if we were to draw a line from leaf to leaf up the stem, we should produce upon it a spiral which would in the case of any of these trees be of a different character from any of the others. In theoretical botany the spiral arrangement of the leaves which makes them alternate upon the stem is looked upon as their normal form, and those leaves which are opposite or verticillate are supposed to be produced by the suppression of an internodium. The spiral arrangement of the leaves on the stem has been made a matter of mathematical investigation by Braun and Schimper, and it is found that this arrangement is possessed of certain fixed mathematical properties. Of course the same observations are applicable to all those parts of the plant, as the bracts, sepals, petals, scales of the fruit, &c., which are considered modifications of the leaf. The fruit of the common pine may be taken as an illustration of these properties. If the cone of a pine or a spruce-tree be broken through the middle, three scales will be observed, "which, at first sight, appear to be upon the same plane; but a more attentive examination shows that they really originate at different heights, and moreover that they are not placed at equal distances from each other; so that we cannot consider them as a whorl, but only a portion of a very close spiral. But considering the external surface of the cone viewed as a whole, we find that the scales are disposed in oblique lines, which may be studied—1, as to their composition, or the number of scales requisite to form one complete turn of the spire; 2, as to their inclination, or the angle, more or less open, which they form with their axis; 3, as to their total number, and their arrangement round the common axis, which constitutes their co-ordination. Finally, we may endeavour to ascertain whether the spires turn from right to left, or vice versa." (Lindley.)

In the arrangement of the leaves several series of spires are discoverable, and between these there constantly exists a certain arith-

metrical relation which may be expressed by figures, and which results from the combination of the elements of which they are composed. All the spires depend upon the position of a fundamental series, from which the others are deviations. The nature of this series is expressed by a fraction, of which the numerator expresses the number of turns which make up one spire, whilst the denominator expresses the number of leaves, scales, &c., upon the spire. So that suppose we mark the seat of one leaf at the bottom 0, and go on following the leaves, we shall come at one directly over the first, and this completes the spire; if this leaf occurs after ten turns of the spiral, and there should be eighteen leaves upon the spire, the expression for this series would be $\frac{10}{18}$. By applying this rule very different figures may be obtained for various plants. The following are results obtained by Braun:—

$\frac{1}{1}$ is the expression for the leaves of *Woad*, *Plantago lanceolata*, and the bracts of *Digitalis lanata*. $\frac{2}{3}$ in *Sempervivum arborescens*, and the bracts of *Plantago media*. $\frac{1}{2}$ is a common form; it exists in the bay-tree, the holly, and *Aconite*. $\frac{3}{5}$ is the most common, representing the *Quincunx*. It is seen in *Mezerium*, *Lapsana communis*, the potato, &c. $\frac{1}{3}$ is seen in the spikes of all grasses, in *Asraum*, the lime tree, the vetch, and pea.

No application of this doctrine has at present been made, and these researches are only in their infancy. It seems in some genera to be a mode of distinguishing species. Thus the expressions for the following species of *Pinus* are—*P. pinaster*, $\frac{2}{3}$; *P. sylvestris*, $\frac{3}{5}$; *P. Cembra*, $\frac{1}{2}$; *P. larix*, $\frac{1}{1}$; *P. microcarpa*, $\frac{1}{1}$.

(Göthe, *Ueber die Spiral-Tendenz der Vegetation*; Meyen, *Pflanzen-Physiologie*, band iii.; Lindley, *Introduction to Botany*; Henslow, *Botany*, in *Cabinet Cyc.*; Virey, *Philosophie de l'Histoire Naturelle*.)

SPIRAL VESSELS. [TISSUES, VEGETABLE.]

SPIRALIS. [HYALIDE.]

SPIRATELLA. [HYALIDE.]

SPIRICELLA. [SMAPHYLIDIAN.]

SPIRIFER (Sowerby), a group of Fossil *Brachiopoda*.

SPIRIT-DUCK. [DUCK.]

SPIROTBIS. [TUBICOLIDÆ.]

SPIRULA. [SPIRULIDE.]

SPIRULIDÆ, Professor Owen's name for a family of Polythalamous Decapodous Dibranchiate *Cephalopoda*.

The family is thus characterised:—Shell partly internal; cylindrical, multilocular, discoid; the whorls separated; septa transverse, concave next the outlet, and with regular intervals. Siphon marginal and internal, uninterrupted. Animal having an oblong body with minute terminal fins, the mantle supported by a cervical and two ventral ridges and grooves. Anus with six rows of very minute cups; tentacles elongated. Funnel valved.

The character of the family is that of the genus *Spirula*, of which it is at present composed.

Professor Owen makes three species of the *Nautilus Spirula* of Linnaeus. These are *Spirula Peronii*, *S. Australis*, and *S. reticulata*. The shell of one or other of these species is not unfrequently found on the British coast, and instances are recorded of its having been found on the coasts of Ireland, Cornwall, and Devon. The animal has been very seldom taken whole, and the portions that have been found led to much discussion, till one was obtained perfect by Mr. Percy Earle on the coast of New Zealand. The shells are found in great abundance on the coasts of New Zealand. They abound also on the Atlantic coasts.

SPIRULA (J. E. Gray), a genus of *Conchifera* founded on *Mactra fragilis* and similar species.

SPIZÆTUS (Vieillot), a genus of Birds. [FALCONIDÆ.]

SPIZELLA (Bonaparte), a genus of *Fringillina*.

SPLACHNUM, the name of a genus of Cryptogamio Plants belonging to the natural order of Mosses. The word is adopted from Dioscorides, who used both *Σπλάχνον* and *Βρίον* to designate the families of Lichens and Mosses. It is known by its terminal fruit-stalk; single peristome with eight double teeth; capsule with an evident apophysis, and mitriform glabrous furrowless calyptra. They are generally annual plants, and remarkable amongst their tribe for their size and beauty as well as singularity. Seven of the species are British. The most common in England is the *S. ampullaceum*, Purple Gland-Moss, which is found growing chiefly on rotten cow-dung. The receptacles are obtuse, inversely conical, of a greenish-purple colour, and three times as thick as the capsule.

S. sphaericum, Green Globular Gland-Moss, has a green globular receptacle, with ovato-lanceolate, pointed, entire leaves, and a capillary fruit-stalk. It is a native of alpine situations in the north of Europe and Scotland, and is generally found on cow-dung. It occurs in green tufts, and has elegant slender wavy tawny fruit-stalks from one and a half to three or four inches high.

S. rubrum, Red Umbrella Gland-Moss, has an orbicular convex red receptacle, with partially toothed leaves. The fruit-stalks are six inches in length; the receptacle is very conspicuous, being half an inch wide, and having the form of an inverted cup, which is of a rich crimson colour and finely reticulated, making this moss one of the most remarkable and beautiful in the family. It is a native of Norway, Finland, Russia, and Siberia.

SPLEEN (*Σπλήν*, *Lien*, *Splen*). There are few parts of the human

body on which more has been written than on the Spleen, and none where the result has been more unsatisfactory. The purpose which it serves in the animal economy is still only imperfectly known, and the record of the theories which have been entertained of its uses is a most uninteresting page in human physiology.

The Spleen is an organ which is not found in any tribe of animals below the class of fishes. Some animals have two, and this number has not unfrequently been found in man; for, as Haller says ('Elem. Physiol.' t. vi. p. 388), everything connected with this organ is uncertain and variable. Its form is generally somewhat oval, being smooth and convex on the exterior, where it is in apposition with the diaphragm, and irregularly concave on the opposite side, which is unequally divided into two parts by a transverse slit for the transmission of its vessels. (Quain, 'Elem. of Anat.') It is for the most part placed in the left hypochondriac region, between the diaphragm and the stomach, and beneath the cartilages of the ribs. (Quain.) It varies so much in size, that it is almost impossible to say what are its normal proportions. (Bichat, 'Anat. Descr.') It is much enlarged by disease, as will be hereafter noticed; but in health, taking a general average, its greatest diameter may be said to measure about four inches, its breadth three inches, and its thickness from two to two and a half inches; its usual average weight is from eight to ten ounces. It is of a slight spongy consistence (*ἀραιὸς καὶ σπογγώδης*, Hippocr. 'De Morb. Mulier.' lib. i. tom. ii. p. 683, ed. Kühn), and is at all times easily torn; and in many cases it is found, soon after death, so soft as to be readily broken by a slight pressure, when it appears a grumous, dark, confused mass. Its colour is deeply red, with a tinge of blue, particularly round its margin. It has a peritoneal investment prolonged to it from the stomach, by which, as well as by vessels, it is connected with that organ; but it has also a smooth and fibrous tunic proper to itself, which is so firmly adherent to the serous investment above-mentioned, that they cannot be separated except at its concave surface. (Quain.) No organ receives a greater number of bloodvessels in proportion to its size than the spleen; a fact noticed by all anatomists, and the more so because it secretes no fluid of any sort, at least none that has hitherto been discovered. (Bichat.) Almost all the blood that it receives is derived from the Spleenic Artery (Haller, p. 400, 401); this is the largest branch of the celiac axis, and near the Spleen divides into several branches, some of which enter the fissure in that organ, and are distributed to its substance. These are called the Rami Splenici; they are five or six in number, and vary in length and size. (Quain.) They are the proper terminal branches of the artery, and by infinite ramifications form within the substance of the Spleen a capillary system, which probably anastomoses in a direct manner with the capillaries of the veins (Bichat), as is proved by the facility with which injections pass from one to the other. The Splenic Vein is a vessel of very considerable size compared with the bulk of the organ; and it returns the blood not only from the Spleen, but also from the pancreas, duodenum, the greater part of the stomach and omentum, the left colon, and part of the rectum. It commences by five or six branches, which issue separately from the fissure of the Spleen, but soon join to form a single vessel. Its direction is then traversed from left to right, embedded in the substance of the pancreas, in company with the Splenic Artery, beneath which it is placed. On reaching the front of the spine it joins the Superior Mesenteric Vein nearly at a right angle, from the conflux of which proceeds the vena portæ. (Quain.) The nerves of the Spleen accompany the Splenic Artery, and are derived from the solar plexus, forming an interlacement called the Spleenic Plexus, previous to their entrance into it. (Ibid.) They are small compared with the size of the organ; and accordingly the Spleen has very little sensation, a fact which was noticed as early as the time of Aræteus. ('De Caus. et Sign. Diuturn. Morb.' lib. i. cap. 14, p. 111, ed. Kühn; Haller.) Its lymphatic vessels are very numerous; but as no appreciable product is elaborated by this apparatus, it has no excretory duct. (Quain.) The fibrous or proper coat of the Spleen sends into its interior a multitude of cellular bands and fibres, which form by their intersections cells of various forms and sizes, and support the soft, pulpy, red tissue of the organ. In the red substance there are in many animals contained whitish round corpuscles, visible to the naked eye, which were first discovered by Malpighi, and of which the existence in the human Spleen has been at one time admitted and at another denied. The corpuscles of the human Spleen are described by Dupuytren and Aschles as grayish bodies, devoid of internal cavity, and measuring one-fifth of a line to one French line in diameter, and so often as to take a liquid form when raised on the knife. Meckel describes them as roundish whitish bodies, one-sixth of a line to one line in diameter, most probably hollow, and at all events very soft and very vascular. In the human Spleen the Malpighian corpuscles are distinguished with great difficulty. They vary from one-third to one-sixth of a line, and much smaller corpuscles are seen, which are probably commencing stages of the larger ones. Each of the corpuscles is formed of a fibrous envelope, which it appears to derive from the coat of the artery to which it is attached, and is often surrounded by minute capillaries. When crushed the corpuscles are found to consist of very minute indented cells and free nuclei. Dr. Sanders describes also a layer of nucleated spherical cells, which are placed beneath the corpuscle. Each corpuscle, according to Dr. Sanders, is traversed by

arterial twigs of considerable size, which may be seen by hoiling the Spleen in acidulated water, and cutting it into thin sections.

The function and structure of the Spleen have been recently studied with great care by Mr. Gray, and his Essay on this subject obtained for him the Astley Cooper prize. He sums up his researches under the following heads:—

1. The Spleen exists without exception in all Vertebrate Animals.
2. It presents however by far its greatest development of structure, and consequently its function is most perfectly developed, in the *Mammalia*, this being partly dependent upon the greater general completeness and requirements of their organisation.
3. Part of the offices of this organ are plainly those of a diverticulum for blood. This is especially seen in the Diving Animals, where its large size is undoubtedly associated with considerable obstruction to the circulation which takes place under these circumstances. Its large size also in those animals in which assimilation of food rapidly occurs, and in which, consequently, new material is suddenly added to the circulation as compared with its extremely diminutive size under the opposite conditions, also affords evidence of its diverticular function.
4. The total absence in Reptiles and Fishes of one of the main elements of this gland in *Mammalia* and Birds, is in perfect accordance with their low grade of organisation, and the remarkable faculty they possess of sustaining hunger for almost an unlimited period; whilst in the former they form a ready, although a scanty, sinking fund for albuminous materials that can be rapidly given up to the blood during their temporary and occasional abstinence, and which cannot be borne by them with impunity for any long period.
5. Its function then is not for specific hut for general purposes, serving to regulate under many varied and opposite conditions the quantity and also the quality of the blood.

SPLEENWORT. [ASPENIUM.]

SPODUMENE, Triphane, a Mineral occurring in imbedded crystalline masses. Primary form a rhombic prism. Cleavage parallel to the primary faces and to the diagonal planes; that parallel to the smaller diagonal is most brilliant, and that parallel to the greater most difficult. Fracture uneven, granular. Hardness, scratches glass and gives fire with steel. Colour whitish- and greenish-gray. Streak white. Lustre pearly on the cleavage planes. Specific gravity 3.17 to 3.193. Before the blow-pipe it swells and fuses into a glass almost colourless and transparent; with borax it swells, but does not easily dissolve.

It is found at Uto in Sweden, in the Tyrol, Ireland, and North America. The analyses of this mineral by Arfwedson from Sweden, by Stromeyer, and Le Hunt from Ireland, gives the annexed results:—

	Arfwedson.	Stromeyer.	Le Hunt.
Silica	66.40	63.288	63.812
Alumina	25.30	23.776	28.503
Lithia	8.85	5.626	5.604

SPONDIACEÆ, a natural order of Plants belonging to the Syncarpous group of Polypetalous Exogens. It has unisexual flowers; a 5-cleft regular calyx; 5 petals, inserted under the disc; 10 perigynous stamens arising from the same part as the petals; superior sessile ovary, 2-5-celled, with 5 very short styles and obtuse stigmas; one ovule in each cell. Fruit drupaceous. Seeds without albumen. The plants of this order are trees without spines, having alternate unequally pinnate leaves without pellucid dots. The flowers are arranged in panicles or racemes. This order was formerly included in *Terebinthaceæ*, but has been separated by Kunth and Lindley, on account of their syncarpous fruit and the absence of a resinous juice. The real affinity of *Spondiaceæ* appears to be with *Aurantiaceæ*, from which they differ in little beyond their perigynous stamens and the absence of dots on their leaves. They are natives of the West Indies, the Society Islands, and the Isle of Bourbon. The fruit of some of the species of *Spondiaceæ* is eatable, and is known in the West Indies by the name of Hog-Plums.

SPONDYLIDÆ. [PECTINIDÆ.]

SPONDYLUS. [PECTINIDÆ.]

SPONGARIUM, a genus of Silurian Fossils.

SPONGIA, the generic name under which Linnæus and many subsequent systematists have ranked the very numerous forms of organisation analogous to the sponges of commerce. Generally, and we think justly, zoologists have claimed these organisations for the animal kingdom, and ranked them among the *Zoophyta*; but there are eminent writers who dissent from this view on different grounds, and prefer to rank the marine and freshwater sponges with plants. For in regard to their constituent structure, they are composed, as so many of the *Polypifera* are, of a firm bony or stony skeleton, immersed in a soft gelatinous living mass; in respect of the aspect of these two substances, the resemblance which they offer to *Alecyonia* appears very strong, while their external forms, uncommonly varied,

Spondias Mombin. [SPONDIACEÆ.]

a, branch with leaves and fruit; b, flower, showing the hypogynous disc, with the stamens and petals under it; c, portion of branch, showing inflorescence; d, section of fruit, showing its five cells.

sometimes resemble *Alecyonia*, often approach to *Palmipora*, frequently to *Pavonia*, *Agaricia*, and other forms of Lamelliferous *Zoophyta*. The currents of water which pass through the canals of their substance are analogous to many operations among *Polypifera* and *Mollusca*, and depend on similar ciliary organs, which have been detected in situ in *Grantia ciliata*. As however they contain no *Polypi*, it is difficult to rank them under the *Polypifera*. Dr. Johnson omits, in his excellent work on British *Zoophyta*, the sponges, and the following summary of his reasons deserves attention:—"If they are not the productions of *Polypes*, the zoologist who retains them in his province must contend that they are individually animals, an opinion to which I cannot assent, seeing that they have no animal structure or individual organs, and exhibit no one function usually supposed to be characteristic of the animal kingdom. Like vegetables, they are permanently fixed; like vegetables, they are non-irritable; their movements, like those of vegetables, are extrinsic and involuntary; their nutriment is elaborated in no appropriated digestive sac; and, like cryptogamous vegetables or algae, they usually grow and ramify in forms determined by local circumstances, and if they present some peculiarities in the mode of the imbibition of their food, and in their secretions, yet even in these they evince a nearer affinity to plants than to any animal whatever." On this we may remark, that very many animals are as permanently fixed as sponges; that irritability is not to be looked for in every part of a sponge, any more than in a *Rhizostoma*, whose divided digestive cavities are very unlike ordinary stomachs; and that the forms of sponges include remarkable analogies with the supports of *Polypi*.

It is to our countrymen Ellis and Grant that the history of sponges is most indebted. The former established the existence and nature of the currents of water which pass through the substance; and the latter, besides confirming the results of Ellis, added a vast quantity of new and valuable observations. Mr. Bowerbank has contributed precise information regarding both the fossil and recent sponges. (Ellis, 'On Corallines'; Grant, 'On Sponges,' in 'Edinburgh Philosophical Journal'; Bowerbank, 'Geological Proceedings,' 1840; and 'Microscopical Journal,' 1841.)

Sponges may be thus characterised:—They consist of an albuminous skeleton and gelatinous matter, forming a mass not irritable, with numerous boles, connected internally with anastomosing canals. The skeleton is either simple, consisting of bony fibres, as the species so commonly used for domestic purposes; or compound, being strengthened by calcareous or siliceous spicula. Some of the skeletons of sponges are entirely horny; others are entirely siliceous; some are entirely calcareous; but the greater number are compound, and consist of horny matter with additions of spicula in various proportions. The gelatinous matter, abounding in horny matter and transparent globules, connects the different parts of the skeleton and membranes, lines the various canals, and forms the margins of the openings. The pores are minute openings (on the surface) with a gelatinous margin, strengthened or defended by the skeleton or spicula, into which the water enters in currents, generated probably by a ciliary apparatus, which however has not yet been detected by the microscope, except in *Grantia ciliata*. The water, after traversing the interior canals, is ejected by means of orifices which are larger than

the pores, and in many species are elevated above the surface in the form of tubular prolongations of the canals. The ova are numerous, at first appearing like groups of minute irregularly shaped opaque granules, derived from the gelatinous matter, which unite into ovate bodies, falling at maturity into the canals, and are expelled by the orifices. These ova float in the water, and exhibit spontaneous motion by the rapid action of the cilia, which cover the anterior portion of the body, and at length attach themselves, and then expand into the forms of maturity. The currents from the orifices are best examined by placing the recent animal in a shallow dish of water, and throwing a little powdered chalk on the surface, the motion of which will indicate the direction of the streams. For the purpose of examining the skeleton, it is requisite to macerate the sponge in hot water, which removes the gelatinous matter, and leaves the skeleton in a state fit to be examined under a microscope. When the spicula are siliceous, the animal matter may be removed by nitric acid, or by combustion, as was practised by Müller ('Zool. Dan.' t. 85), when the vitreous needles will appear unaltered.

The gelatinous substance of sponges is scarcely capable of conservation. It is usually of a rosy consistence, sliding off from the skeleton, or else pressed off by the divers for sponge. It is of various colours, but commonly fawn-coloured or orange-coloured; in this respect resembling the gelatinous parts of *Polyparia*.

Horny Sponges with anastomosing fibres, fit for domestic use, belong mostly to warm zones of the sea; sponges with calcareous spicula are rather numerous on the British coasts; and siliceous spicula are common in the sponges of most latitudes. [SPONGIADÆ.] Remains of both horny and spicular sponges occur in a fossil state.

SPONGIADÆ. Regarding sponges as Apolypiferous Zoophytes, composed of flexible or rigid skeletons enveloped in a gelatinous mass, productive of inward currents through small surface pores, and outward currents through continuous canals, we may proceed to analyse the large group of organic forms possessing these characters, by the nature and arrangement of the skeleton, for the gelatinous part (though perhaps conservable, if due care be used) is not probably capable of being examined so as to furnish distinctive and recognisable characters.

Dr. Grant pointed out the principles of this analysis, by his observations on the nature and arrangement of the horny fibres, the calcareous and siliceous spicula, and the formation and distribution of the pores and orifices of sponges. Dr. Fleming ('British Animals') gives the following genera, under the family of *Spongiada*:—*Tethya*, *Halichondria* (including *Spongilla* of Lamarck), *Spongia*, *Grantia*. (*Siphonia*, *Choonites*, and *Ventriculites* of Parkinson and Mautell are included in *Halichondria*.)

Blainville ('Actinologie') arranges under the head of *Amorphozoa*—*Alcyonellum*, *Spongia*, *Calcispongia* (*Grantia*, Fleming), *Halispurgia*, *Spongilla* (*Ephydatia*, Lamouroux), *Geodia*, *Caloptechium* (fossil), *Siphonia*, *Myrmecium* (fossil), *Scyphia*, *Eudea* (fossil), *Halirrhoa* (fossil), *Hippalimus* (fossil), *Cnemidium* (fossil), *Lymnorea* (fossil), *Chenendopora* (fossil), *Tragos* (fossil), *Manon* (fossil), *Ierea* (fossil), *Tethium*.

Very few of these genera, adopted from Schweigger, Goldfuss, and others, can be considered as at all sufficiently determined, because the constituent structures of the fossil masses, on which alone they can be justly founded, have, in most cases, been altogether left unexamined. When the modern achromatic microscope shall have been directed upon them, with such perseverance as Mr. Bowerbank ('Proceedings of Geol. Soc.' 1840) has employed on the spicular structures of the sponges imbedded in or constituting the nodules of flint in chalk, so that the forms of the anastomosing fibres or stiffening spicula, the sections and distribution of the canals, &c., can be certainly defined, a great benefit will arise to this branch of zoology, and an equal advantage for geology.

I. Groups of which the Constituent Structure is known.

Spongia.—Mass soft, elastic, more or less irregular in shape, very porous, traversed by many tortuous canals which terminate at the surface in distinct orifices. Substance of the skeleton cartilaginous, fibres anastomosing in all directions, without any earthy spicula.

Ex. *S. communis*. (Blainville, 'Actinologie,' pl. 93, fig. 3.)

Calcispongia, Blainville (*Grantia*, Fleming, Grant).—Mass rigid, or slightly elastic; of irregular form, porous, traversed by irregular canals, which terminate on the surface in distinct orifices. Substance of the skeleton cartilaginous, fibres strengthened by calcareous spicula. The spicula are seldom simple, often triradiate in figure.

Ex. *C. compressa*. (Montague, 'Wern. Trans.' vol. ii.)

Altogether, Fleming and Blainville admit five species of this genus as determined. They occur on the British and other northern shores.

Halispurgia, Blainville (*Halichondria*, Fleming).—Mass more or less rigid or friable, irregular, porous, traversed by tortuous irregular canals, which terminate at the surface in distinct orifices. Substance cartilaginous, fibres strengthened by siliceous (generally fusiform or cylindrical) spicula.

Ex. *H. papillaria*, Grant. ('New Edinb. Journal,' vol. ii.)

Blainville admits fourteen species. Fleming, who includes in it the fresh-water *Spongilla* (*Ephydatia*, Lamouroux), counts eighteen

species. In what manner the immense number of species of sponges mentioned by Montague and Lamarck are to be distributed among these three groups, which ought to be considered families rather than genera, does not appear.

The remarkable siliceous sponge [SPONGIA] examined by Mr. Stutchbury of Bristol, would appear justly entitled to constitute a new genus.

Spongilla, Lamarck and Blainville (*Ephydatia*, Lamouroux).—Mass more or less rigid or friable, irregular, porous, but not furnished with regular orifices to internal canals.

Ex. *S. fluviatilis*, Linn.; *S. lacustris*, Linn. For the animal nature of these fresh-water sponges the argument is less complete than for the marine tribes. By experiments as to the effect of light on them, Mr. John Hogg ('Linn. Trans.') has endeavoured to show that they are influenced by this agent in the same manner as plants are, and that their green colour depends upon exposure to it.

II. Groups depending on Characters of Surface or general Figure.

Geodia, Lamarck.—Mass fleshy, tuberous, irregular, hollow within, externally incrusting by a porous envelope, which bears a series of orifices in a small tubercular space.

Ex. *G. gibberosa*, Schweigger. (Blainville, 'Actinologie'.)

Caloptechium, Goldfuss.—Mass fixed, pedicled, the upper part expanded, agariciform, concave, and radiato-porose above, flat and radiato-sulcate below. Substance fibrous.

Ex. *C. agaricioideum*, Goldfuss. ('Petrefactenkunde,' pl. 9.) From the chalk of Westphalia.

Siphonia, Parkinson.—Mass polymorphous, free or fixed, ramose or simple, concave or fistulous above, porous at the surface, and penetrated by anastomosing canals, which terminate in subradiating orifices within the cup.

Ex., living, *S. typum*. (Blainville, 'Actinologie,' pl. 95.) Sicily.

Ex., fossil, *S. pyriformis*, Goldfuss. ('Petrefactenkunde,' tab. 6, fig. 7, a, b, c, d, e.)

Siphonia abound in the Greensand Formation.

Myrmecium, Goldfuss.—Mass subglobular, sessile, of a close fibrous texture, forming ramified canals which radiate from the base to the circumference; summit with a central pit.

Ex. *M. hemisphericum*, Goldfuss. ('Petref.' tab. 6.)

Scyphia, Oken.—Mass cylindrical, simple, or branched, fistulous, ending in a large rounded pit, and composed entirely of a reticulated (firm) tissue.

Ex., living, *S. fistularis*, Esper. (Tab. 20, fig. 2.)

Ex., fossil, *S. mammillaris*, Goldf. ('Petref.' tab. 2, fig. 1.)

Eudea, Lamouroux.—Mass filiform, attenuated, subpedicellated at one end, the other enlarged, rounded, with a large terminal pit; surface reticulated by irregular lacunae, minutely porous.

Ex. *E. clavata*, Lamouroux. ('Gen. des Polyp.' tab. 74, fig. 1-4.)

Halirrhoa, Lamouroux.—Mass turbinated, nearly regular, circular, or lobate; surface porous; a large central pit on the upper face.

Ex. *H. costata*, Lamouroux. ('Gen. des Polyp.' pl. 73.) From the Oolite of Caen.

Hippalimus, Lamouroux.—Mass fungiform, pedicellated below, conically expanded with a central pit above; surface porose, and irregularly excavated.

Ex. *H. fungoides*, Lamouroux. ('Gen. des Polyp.' pl. 79.) From the Oolite of Caen.

Cnemidium, Goldfuss.—Mass turbinated, sessile, composed of close fibres and horizontal canals, diverging from the centre to the circumference; a central pit on the upper surface, cariose in the exterior, and radiated at the margins.

Ex. *C. lamellosum*, Goldf. ('Petref.' tab. 6.)

Lymnorea, Lamouroux.—Masses mammellated, finely porous and reticulated, agglomerated within a common calyciform wrinkled adherent base.

Ex. *L. mammosa*, Lamouroux. ('Gen. des Polyp.' tab. 79, fig. 2.) From the Oolite of Caen.

Chenendopora, Lamouroux.—Mass conical, infundibuliform, external surface sulcated across; internal face porose.

Ex. *C. fungiformis*, Lamouroux. ('Gen. des Polyp.' pl. 75.) From the Oolite of Caen.

Tragos, Schweigger.—Mass composed of dense close coalescing fibres; surface covered by distinct scattered orifices.

Ex. *T. difforme*, Goldfuss. ('Petref.' tab. 5, fig. 3.)

Manon, Schweigger.—Mass composed of reticulated fibres, pierced on the upper face by distinct encrusted circumscribed orifices.

Ex. *M. tubuliferum*, Goldf. ('Actinologie,' pl. 95.) From the Chalk of Maastricht.

Ierea, Lamouroux.—Mass ovoid, subpediculated, finely and irregularly porous, pierced on the upper part by many orifices, the terminations of internal tubes.

Ex. *I. pyriformis*, Lamouroux. ('Gen. des Polyp.' tab. 73.) From the Oolite of Caen.

Tethium, Lamarck.—Mass subglobose, tuberose, composed of a cariose firm substance, strengthened by abundance of simple (siliceous) spicula fasciculated and diverging from the centre to the circumference.

Ex. *T. lycurium*, Marsigli. ('Actinologie,' pl. 91, fig. 3.)

(From Dr. Grant.)

1, *Spongia oculata* (British), showing the orifices and currents outwards; 2, anastomosing horny substance of *Spongia communis*; 3, siliceous spiculum of *Spongia papillaris*; 4, of *Spongia cinerea*; 5, of *Spongia panicea*; 6, calcareous spiculum of *Spongia compressa*; 7, transverse section of a canal of *Spongia papillaris*, to show the structure and the ova passing along the canal; 8, ovum of *Spongia panicea* seen laterally—the ciliae are anterior; 9, the same seen on the end, with a circle produced by the ciliary action; 10, young *Spongia papillaris*, grown from an ovum which had ceased to move about.

SPONGIOLE, or **SPONGELET**, is a term applied by De Candolle to the extremities of the ultimate fibrils into which the roots of all plants are divided. [Root.]

SPOONBILL. [PLATALEA.]

SPORANGIUM (from *σπορᾶ*, a sowing, and *ἄγγος*, a vessel), a term first employed by Hedwig to designate the capsule of Mosses, and since applied very generally in cryptogamic botany to that part of the reproductive apparatus which contains the spores. It is used in almost all the cryptogamic tribes synonymously with the terms *Theca*, *Capsule*, *Conceptacle*, *Folliculum*, *Involucreum*, *Sporocarpium*. The multiplication of names applied to parts performing the same functions in the various tribes of *Cryptogamia* has often led to much inconvenience; and it is much to be desired that writers on this department of botany would agree to the adoption of a few well-defined terms, that would apply to the whole of this class of plants.

In the Ferns the sporangia are seated in the back of the frond, forming little heaps called *Sori*. [SORUS.] They are small brittle compressed bags, consisting of cellular membrane, and are partially surrounded by a thickened ring called the *gyrus*. By means of this ring the sporangia burst, and emit the spores which they contain.

In *Ophioglossaceæ*, a small tribe of ferns, there are no sporangia, the spores being contained in two lines parallel with the midrib of the fertile frond, and are emitted when the frond unfolds itself.

In *Lycopodiaceæ* the sporangia are seated in the axils of a bract upon the fruit-stalk, and either burst by distinct valves or are indehiscent. In this order there are two kinds, the one containing minute powdery granules, the other containing only three or four roundish fleshy bodies. The contents in both cases are considered spores.

In *Marsiliaceæ* the sporangia form a Sporocarpium. [SPOROCARPIUM.]

In *Salviniaceæ* they are of two kinds: in the one kind the sporangia are composed of a thin reticulated membrane, and contain one or six and nine granules in their interior; in the other kind the granules are attached by pedicles to a central column, and are much smaller than the first. These latter have been supposed to be male organs, and the former female organs.

In the Mosses the sporangia are open and unshaped, and are mostly elevated on a slender stalk called the *Seta*. The rim of this organ is furnished with an elastic ring called the *Annulus*, and it has an interior organisation called *Peristomium*. This internal part of the sporangium has been called by Endlicher the *Sporangidium*. In the small section *Andræaceæ* the sporangia are closed, and split into four valves. Linnaeus supposed the sporangia were the male organs of the Mosses.

In the *Jungermanniaceæ* the sporangium has no central column, as in the Mosses, nor does it open by an operculum. It is a valvular brown case elevated upon a cellular frequently twisted seta. It is filled with spiral fibres, called *Elaters*, among which the sporules lie intermixed. The spiral fibres by their hygrometric properties open the sporangium, which is composed of four valves, and in this way the spores escape.

In *Marchantiaceæ* the sporangium is placed, in some, beneath a fungus-like receptacle, which is covered by a calyptra; and in others it is buried in the substance of the frond or seated upon it.

NAT. HIST. DIV. VOL. IV.

Sporangium is not applied to the reproductive organs of Lichens, but the analogues of this organ in these plants are what are called the *Shields*, or *Apothecia*, which are filled with little tubes called *Asci*, in which the sporules are contained. There is also another form of the reproductive organs in Lichens, called *Soredia*, which are little heaps of powdery grains scattered over the surface of the plant, which are also the analogues of the sporangia.

In the *Algae*, the sporules are scattered in most instances throughout the substance of the plant, so that they have no proper seed-case or sporangium; but whenever the sporules are collected together into one spot, and covered over by a distinct case, this is called a sporangium.

Among the *Fungi* the spores are frequently disseminated throughout the cellular tissue of the plant, so that they have no particular organ to contain them. Some of the *Fungi* however consist of a hollow case containing spores, as the *Lycoperdons* and *Sphærias*, and the case consisting of the whole plant is called by many writers the sporangium.

SPORENDO'NEMA, a genus of Plants belonging to the natural order *Fungi*, and the tribe *Mucedines*. It is exceedingly simple in its organisation, consisting merely of sporidia disposed in rows within the tubular pellucid flocci. There are two species of this form of mould; the one, *S. Casei* (Red Cheese-Mould), is found on cheese, presenting little red tufts, which, under the microscope, exhibit the flocci somewhat branched and woven together. The other species, *S. muscæ*, is called Fly-Mould, and is found on the bodies of flies in the autumn of the year. It consists of flocci glued together, forming little white-lobed tufts, which make their appearance between the plates of the abdomen of the insect. This is one of the few instances of plants being parasitic on animals. This however has been denied, and some writers assert that the fly-mould is nothing more than a diseased secretion from the body of the fly. But Fries, Berkeley, and other cryptogamists, have recognised this mould as a plant.

SPORES. [SPORULES.]

SPOROCARPIUM (from *σπορᾶ*, a seed, and *καρπός*, fruit), a term proposed by Link, and very generally adopted by German cryptogamic botanists, to express a combination of sporangia when placed near together, and more especially when any number of sporangia are inclosed in a common membrane.

Sporocarpium in this sense has been applied by Endlicher to the organ containing the reproductive organs in the order *Marsileaceæ*. To this part the name *Involucre* has been given by many writers. The sporocarpium of *Marsilea* when cut into exhibits several cells, which contain little granular bodies. In the course of time these granular bodies are projected from the sporocarpium, which splits into two valves, being arranged around a mucilaginous cord, which when it first appears is curved round, as seen at *c* in the accompanying drawing of *Marsilea Fabri*. This mucilaginous cord eventually becomes

Marsilea Fabri.

a a, Sporocarpia or Involucro seated in the axils of the leaves; *b*, sporocarpium bursting; *c*, a mucilaginous curved cord, to which the sporangia are attached; *d*, the sporangia; *e*, the same removed from the cord, exhibiting the valves; *f*, reverse side, showing the anthers; *g*, the mucilaginous cord straightened, and the sporangia seated on it.

straight (*g*), bearing upon it the granular bodies arranged in a spiral whose expression is $\frac{1}{2}$. The granular bodies, or sporangia, consist of two parts: first, the upper surface, which presents a number of small globular bodies, *c*, called ovules, and are surrounded by a little projecting hood surmounted by a papilla; and, second, the under surface, which presents a number of little membranous sacs, which are filled with grains resembling pollen, and hence have been called anthers.

SPOROCHNUS. [ALGÆ.]

SPORULES, or SPORES, the minute organs in Cryptogamic or Flowerless Plants from which new plants are produced, answering to the seeds in the Phanerogamic or Flowering Plants. Although these organs perform the same office in the economy of the plant as seeds, yet they differ essentially in the relation they bear to the new plant. Although in some instances they stand in the same relation to the young plant as seeds, yet they not uncommonly are found to be the homologues of buds. They generally differ from seeds in their origin, structure, and germination.

The situation of the sporules is exceedingly various. In the *Fungi* and *Algæ* they are frequently diffused throughout the substance of the plant without any proper covering or receptacle. In the higher forms, as the Mosses, Ferns, Jungermannians, &c., they are contained in a special organ called the Sporangium. [REPRODUCTION IN PLANTS AND ANIMALS; SPORANGIUM.]

SPRAT. [CLUPEIDÆ.]

SPRENGELIA. [EPACRIDACEÆ.]

SPRING-BUCK. [ANTILOPEÆ.]

SPRINGS. [WATER.]

SPRINGS, MINERAL. [WATER.]

SPRUCE-FIR. [ABIES.]

SPUR-WING. [RALLIDÆ.]

SPURGE-LAUREL. [DAPHNE.]

SQUALIDÆ, a family of Fishes of the section *Chondropterygii*. In this family, which includes the various species of Sharks, the branchiæ are attached by their outer margin to the skin, and the water taken in for respiration makes its escape through narrow outlets corresponding in number to that of the interspaces between the branchiæ: the number of these openings is usually five. So far the present fishes agree with the Ray or Skate family [RAIIDÆ]; but the peculiar rhomboidal form of the body renders it easy to distinguish the Rays, which moreover have a peculiar cartilage arising from the nasal part of the skull, and extending towards and even meeting the anterior part of the crest of the pectoral. This character is pointed out by Müller and Henle, who state that it is found in all the Ray tribe, and also in *Rhinobatus* and *Pristis*, whereas there is no trace of it in any Shark.

In the Sharks the body is elongated, and tapering gradually from the head to the tail, or but little dilated in the middle. The muzzle is rounded or pointed, depressed, and projects over the mouth; the nostrils are situated on the under side of the muzzle, in the form of oblique openings, which vary somewhat in figure, according to the species. The fins generally consist of two dorsals, two large pectorals, two ventrals, an anal fin, and a caudal, the form of which is peculiar.

The portion of the tail of the Shark which supports the tail-fin is almost always bent upwards at an obtuse angle with the body; the fin itself may be divided into three parts—a superior, an apical, and an inferior portion; that which runs along the upper surface is usually narrow; that on the under surface is broader, but decreases in width to its point of junction with the apical portion, which is more or less dilated at the extremity and obliquely truncated. Such is the most common character of the tail and tail-fin in the present fishes, and one which is not found in any recent fishes not belonging to the Chondropterygian group.

The Male Sharks are smaller, and differ externally from the Females in possessing two elongated appendages, one of which is attached to the hinder edge of each of the ventral fins, the uses of which are not known. Some species of sharks bring forth their young alive, whilst others are inclosed in ohlong simitransparent horny cases, at each extremity of which are two long tendrils. These cases are frequently found on the sea-shore, and are called Sea-Purses, Mermaids' Purses, &c. They are deposited, observes Mr. Yarrell, by the parent shark near the shore in the winter months. The convoluted tendrils, hanging to sea-weed or other fixed bodies, prevent the cases being washed away into deep water. Two elongated fissures, one at each end, allow the admission of sea-water; and the young fish ultimately escapes by an opening at the end, near which the head is situated. For a short time the young shark continues to be nourished by the viteline fluid contained in the capsule attached to its body by the connecting pedicle, till having acquired the power of taking food by the mouth, the remains of the ovum are taken up within the abdomen, as in birds and some other animals.

"A curious peculiarity has been observed in the young hoth of the Sharks and Skates during a very early stage of their existence. From each of the branchial apertures branchial filaments project externally; each filament contains a single minute reflected vessel, in which the blood is thus submitted to the action of the surrounding medium. The appendages are only temporary, and the blood of the fish is afterwards aerated by the true gills. This very interesting discovery, which, I believe, is of recent date, forcibly reminding us of the tem-

poral external branchiæ in the young Batrachian Reptiles in the tadpole state, has been observed by Mr. Richard Owen in the Blue Shark (*Carcharias glaucus*); by Mr. John Davy, in the Torpedo; and by Dr. Allen Thompson, of Edinburgh, in the Thornback. Cuvier had previously noticed it, and, in the 'Règne Animal,' has referred to a figure, published by Schneider, of a very young shark in this condition, for which, regarding it as the normal state of the fish, that industrious pupil of Bloch had proposed the name of *Squalus ciliaris*." (Yarrell.)

The teeth of the Sharks are arranged in several series, one within the other, of which the outermost row is that in use; the other rows are decumbent, and serve to replace the foremost when injured. Their form varies much in the different species, and even those of the upper and lower jaw are often very dissimilar. Though very variable however, they most commonly exhibit modifications of a triangular form, are sharply pointed, and have the lateral edges sharp and frequently serrated. It is upon the modifications observable in the form of the teeth, the form of the snout, mouth, and lips, and of the caudal fin; the existence or absence of the eyelid (membrana nictitans), spiracles, and of the small depression on the root of the tail; the situation of the branchial openings, and of the dorsal fins, &c., that the various divisions of the present family are formed.

The *Squalidæ* and *Ratidæ* have long occupied the attention of Professor Müller and Dr. Henle, who have conjointly published an excellent work on these groups, 'Systematische Beschreibung der Plagiostomen.' The characters of the various genera into which they divide the Sharks are here given. At the head of the Sharks these authors place the *Scyllia*, a group in which the species have the teeth small and pointed, and with one, two, or more lateral denticles; an anal and two dorsal fins; the first dorsal placed behind or opposite, but never before the abdominal fins; the spiracles are distinct in all, and tolerably large in most of them; the eyelid (membrana nictitans) is wanting. To this section belong, as it would appear, all the oviparous sharks.

Scyllium, Cuv.—This genus is restricted to such species as have the anal fin placed nearer to the head than the second dorsal fin. Eleven species are known, of which three are found on the British coast: the Small Spotted Dog-Fish (*S. canicula*), the Large Spotted Dog-Fish (*S. catulus*), and the Black-Mouthed Dog-Fish (*S. melanostomum*). (Yarrell.)

Pristiurus, Bonap., differs from *Scyllium* in having a long snout, and also in possessing a series of larger scales, arranged like the teeth of a saw on the upper edge of the tail. It contains but one species.

Chiloscyllium.—In this genus the anal fin is placed farther back than the second dorsal, and the last branchial opening approximating to the fourth. The under lip is broad and membranaceous, and separated from the skin of the throat by a kind of furrow; the upper nasal valve bears a cirrus. Four species are known.

Hemiscyllium, Müller and Henle.—Here the situation of the fins is the same as in *Chiloscyllium*; the nose and mouth as in *Scyllium*. One species.

Crossorhinus, Müller and Henle.—Remarkable for a great number of small membranaceous lobules situated between the nostrils and the first branchial opening. The mouth is nearly at the extremity of the muzzle; the two dorsal fins are placed towards the posterior end of the animal, the first of them being situated above, and a little behind the abdominal fins. This genus is founded on the *Squalus lobatus* of Bloch, the only known species.

Ginglymostoma, Müller and Henle.—It has small spiracles; the two last branchial openings approximating to each other; the first dorsal fin above the abdominal fins, and the second dorsal opposite the anal. In adult specimens the inferior part of the fold bordering the corners of the mouth is distinctly separated from the skin of the lower jaw by a vertical furrow. The number of lateral denticles to the teeth is four on each side. One species.

Stegostoma, Müller and Henle.—In this genus the first dorsal fin begins a little before the abdominal ones. The branchial openings are as in *Chiloscyllium*. A large and thick wreath or rim conceals the upper jaw, and the opening of the mouth, which is placed transversely: the nasal valves are reduced to lateral edges of this wreath. The teeth are in the form of trifid leaves. Type and only species of the genus, *Squalus fasciatus*, Bloch, Schu.

The second division of Sharks contains species having, like the *Scyllia*, an anal and two dorsal fins, and five branchial openings; but the first dorsal fin is always placed between the pectoral and abdominal fins.

A large group is distinguished by the possession of a membrana nictitans, by the situation of the second dorsal fin, which is opposite the anal one, and by the situation of the branchial openings, the last or last two of which are always placed above the base of the pectoral fins. They are divided as follows:—

A. Without Spiracles.

a. Teeth flat, sharp, the edges serrated or smooth.

1. *Carcharias*, Cuv.—Teeth flat, sharp, and serrated on each side, either in the upper jaw only, or in both jaws. Spiracles are never met with in the adult specimens, though the rudiments of these organs may be observed in the fetus of a few species. Twenty species of this genus are known, three of which are British: *C. glaucus*,

the Blue Shark, *C. vulgaris*, the White Shark, and *C. vulpes*, the Fox-Shark, Thresher, Sea-Fox, or Sea-Ape.

2. *Scoliodon*, Müller and Henle, differs only in having the teeth of both jaws alike: the points of these teeth are directed towards the corners of the mouth; their edge is smooth, and they have a truncated protuberance, which is either smooth or indented on the exterior side of the base. Five species.

3. *Zygana*, Cuv.—The species of this genus are remarkable for having the sides of the head greatly produced in a horizontal direction, from which circumstance they have received the names of Hammer-Headed Sharks. The teeth are as in *Scoliodon*, but in adult specimens they are distinctly serrated. Three species are known. *Z. malleus*, the Hammer-Headed Shark, is taken on the coasts of Britain.

These three genera have the valve of the intestine longitudinal and rolled, an incision near the extremity of the elongated upper lobe of the caudal fin, and a small dimple at the root of the fin.

b. Teeth pointed, and with lateral Denticles, as in *Scyllium*.

1. *Triacodon*, Müller and Henle.—Teeth with a denticle on each side, which on the exterior side of most of those of the lower jaw is double. Caudal fin, as in *Carcharias*, with a dimple at the root. One species.

2. *Leptocharias*, Andrew Smith.—Teeth numerous, one or two lateral denticulations on each side. The dimple near the caudal fin wanting, and the inferior lobe of the fin scarcely indicated. The nasal valve elongated into a cirrhus. One species.

B. Possessing Spiracles.

a. Teeth flat, sharp, serrated or not serrated.

1. *Galeocerdo*, Müller and Henle.—Teeth strongly serrated on the exterior edge, finely on the interior. Spiracles small. A dimple on the root of the tail: the upper lobe of the caudal fin elongated, with two incisions. Valve of the intestines short, as in *Carcharias*. Two species.

2. *Loxodon*, Müller and Henle.—Teeth without serrature, as in *Scoliodon*. Spiracles very small. Valve of intestine, dimple of the tail, and caudal fin, as in the preceding genus; but the upper lobe of that fin with only one incision. One species.

3. *Galeus*, Cuv.—Teeth in both jaws serrated on the exterior edge, inclined outwardly. Tail as in *Carcharias*, but wanting the dimple. Valve of intestine spiral. One species is known, *G. vulgaris*, the Common Tope, and this frequents the British seas.

b. Teeth pointed as in *Scyllium*.

Triakis, Müller and Henle.—Teeth as in *Triacodon*. Dimple of the tail wanting: the inferior lobe of the caudal fin not distinct. One species.

c. Teeth pavement-like, or presenting a general continuity of surface, as in the Skates.

Mustelas, Cuv.—Spiracles large. Inferior lobe of the caudal fin very short. Membrana nictitans rudimental. Valve of intestine spiral. One species is known, *M. levis*, the Smooth-Hound, and is recorded as British.

The remaining genera have no trace of the membrana nictitans, and belong to the second section *Lamnoides*, which have the branchial openings large, all situated before the pectoral fins. Spiracles small. Caudal fin in the form of a crescent, with a lateral keel and a distinct dimple, and the small anal and second dorsal fins opposite each other.

1. *Lamna*, Cuv.—Head pointed, conic; spiracles extremely small; teeth long, pointed, with two lateral denticles, indistinct or wanting in young individuals. The third tooth of the upper jaw, sometimes also the fourth or fifth, smaller than the rest. There are two species, one, *L. cornubica*, the Porbeagle, or Beauman's Shark, occurs on the British coasts.

2. *Oxyrrhina*, Agassiz.—Teeth long and thick, like nails, without lateral denticles, the anterior ones inversed; the third tooth of the upper jaw small and short. Two species.

3. *Carcharodon*, Andr. Smith.—Teeth as in *Carcharias*, serrated on both edges; the third tooth of the upper jaw smaller. One species.

4. *Selachus*, Cuv.—Teeth very small, narrow, conic, and numerous; snout short. One species, the *S. maximus* of Le Pelerin, the Basking Shark of Yarrell's 'British Fishes.' It is found in British seas.

5. *Rincodon*, Andr. Smith.—Teeth exceedingly small, pointed; mouth at the apex of the snout.

The following three genera differ as much from each other as from the preceding group, and, in the opinion of Messrs. Müller and Henle, should in a system be regarded as the types of families.

Triglochis, Müller and Henle.—Branchial openings large, spiracles small, as in *Lamna*. The first dorsal fin stands before the abdominal fins: the second dorsal between the abdominal and anal fins, and they are all tolerably large; teeth long, pointed, with one lateral denticle, or two on each side. This is probably the genus *Odontaspis* of Agassiz.

Alopias.—Head, dorsal and anal fins, and spiracles, as in *Lamna*; but the branchial openings small, and the last above the pectoral fins; the upper lobe of the caudal fin extremely elongated; a dimple on the tail, but no lateral keel; teeth sharp, triangular, without serrature or protuberance; intestinal canal spiral. One species.

Centracor.—Branchial openings as in *Alopias*; second dorsal fin

between the anal and abdominal ones, like *Triglochis*; spiracles small; teeth arranged in pavement; the anterior rows small and pointed; a bony spine before each dorsal fin. One species.

The third division of Sharks comprises those species which, like the preceding divisions, have an anal fin, but they have only one dorsal. It contains two genera, which are distinguishable by the number of branchial openings. They are the *Hexanchus* and *Heptanchus* of Rafinesque. In the former genus there are six branchial openings, and in the latter seven.

In the fourth division there is no anal fin; the membrana nictitans is wanting, but the spiracles are present. It is divided into two groups, according to the presence or absence of certain bony spines. The first is called *Acanthorhinus* by De Blainville, and contains species which are provided with a bony spine in front of each dorsal fin. It is divided into four genera.

1. *Acanthias*, Bonap.—Teeth alike in both jaws, with a transverse edge, the point directed outwardly. Four species, one occurs on the British coasts, *A. vulgaris*, the Picked Dog-Fish, Bone-Doz, or Hoe.

2. *Spinax*, Bonap.—Teeth in the lower jaw as in the preceding genus; teeth of the upper jaw with an elongated point in the middle and two shorter points on each side.

3. *Centrina*, Cuv.—Teeth of the lower jaw nearly straight, leaf-like, with a serrated edge, and a flat triangular point; those of the upper jaw also straight, but more narrow, conic, pointed, and forming a cluster in the central portion of the maxilla. One species.

4. *Centrophorus*, Müller and Henle.—The lower teeth with a transverse edge indistinctly serrated, the point of each being directed towards the corner of the mouth: the point of the upper teeth is directed downwards; they are equilateral, and without any serrature. One species.

The group without spines to the dorsal fins (*Scymnus*, Cuv.) comprises three genera:—

1. *Scymnus*, Müller and Henle.—Teeth in the upper jaw straight and narrow; in the lower jaw crooked, pyramidal, and equilateral. The first dorsal fin before, and the second behind, the abdominal fins. Two species, one of which, the Greenland Shark (*Scymnus borealis*), is occasionally found on the British coasts.

2. *Lamargus*, Müller and Henle.—Fins situated as in the preceding genus. Lower teeth with a transverse edge, as in *Acanthias*; upper teeth narrow, conic, straight, or curved outwardly. Three species.

3. *Echinorhinus*, Blainv. (*Gonoidus*, Agassiz).—First dorsal fin opposite the abdominal fins. Teeth in both jaws broad and low, the edge nearly horizontal. The lateral edges with one or two transverse denticles. One species is British—*E. spinosus*, the Spinous Shark.

The fifth and last division contains but one genus (*Squatina*), of which there are two species. They have no anal fin; the mouth is protractile, and at the apex of the muzzle. The eyes are placed on the dorsal surface of the head, and not at the sides as in other sharks. The muzzle is obtuse, the body is broad and depressed, and the pectoral fins are very large. Both the dorsal fins are situated behind the ventrals. To this genus belongs the Angel-Fish of British authors, the *Squatina angelus* of Dumeril, Cuvier, &c. It is very frequent on the southern coasts of Britain.

(Yarrell, *British Fishes*.)

SQUALORARIA, a genus of Fossil Fishes. [FISH.]

SQUAMA, in Botany, a Scale, is a term applied to parts which, strictly speaking, are not bracts or leaves, and are arranged upon a plant in the same manner as the scales of fishes and other animals. Almost all the organs that are thus designated are parts of the plant which stand in the position of leaves, but are not developed sufficiently when seated on the stem to become bracts or true leaves, or, when forming parts of the flower or fruit, to become sepals, petals, stamens, &c.

SQUATAROLA. [CHARADRIADÆ.]

SQUATINA. [SQUALIDÆ.]

SQUID. [CEPHALOPODA.]

SQUILL, SQUILLA. [SCILLA.]

SQUILLA. [STOMAPODA.]

SQUILLERICHTHUS. [ERICHTHUS.]

SQUIRRELS. [SCIURIDÆ.]

STA'AVIA, a genus of Plants belonging to the natural order *Brniaceæ*, which was so named by Thunberg after Staaf, one of the botanical correspondents of Linnaeus. The genus consists of several small shrubs, which are indigenous at the Cape of Good Hope, and are remarkable for their flowers being arranged in heads resembling those of some of the *Compositæ*. Calyx with the lower part of its tube attached to the ovary; petals 5, stamens 5, inserted into the calyx; capsule crowned by the calyx, diocious, cocci bivalved at the apex, and 1-seeded. A few specimens are cultivated in our greenhouses, and may be propagated from cuttings in sand covered with a bell-glass.

STACHYS (from *stachys*, a spike), the name of a genus of Plants belonging to the natural order *Lamiaceæ*, or *Labiata*. It has a 5-toothed, 10-ribbed, nearly equal, acuminate, subcampanulate calyx; a corolla with the tube as long as the calyx, or longer; upper lip erect, or spreading, a little arched; lower lip usually longer, spreading, and 3-lobed; the middle segment large, entire, or emarginate; 4 stamens; bifid style with stigmas at each apex; fruit an acheneum. The species

are very numerous, above 100 being enumerated. They are herbs or under-shrubs, with their flowers arranged in whorls. The majority of them are European plants.

S. betonica, Common Betony. Stems erect, rather pilose; lower leaves on long petioles, and crenated; upper leaves sessile, toothed; uppermost ones linear, quite entire; whorls many-flowered; bracts ovate; corolla twice as long as the calyx. This species is the *Betonica officinalis* of Linnaeus. It is now a species of the genus *Stachys*, but it was formerly a species of the genus *Betonica*; but the characters which constituted the difference between the latter and the former having been considered too trifling to constitute separate genera, the genus *Betonica* has been abolished by later botanists. The Common Betony is a native of Europe and some parts of Asia, inhabiting woods, heaths, and pastures. It is very plentiful in Great Britain. It was formerly much used in medicine, and is now a popular remedy for some complaints. When taken fresh it is said to possess intoxicating properties. The leaves have a rough bitter taste, and are slightly aromatic. The roots are nauseous and very bitter, and when taken act as purgatives and emetics.

S. lanata, Woolly Woundwort. Whole plant clothed with dense silky wool; leaves oblong, narrowed at both ends; floral leaves small, the upper ones of which are shorter than the whorls; whorls many-flowered; bracts linear-lanceolate, the same length as the calyx; calyx incurved, toothed; corolla woolly. This plant is a native of Europe, in the neighbourhood of the Mediterranean. Dr. Sibthorp found it in Laconia, where it is called *Σταχδς* by the modern Greeks. This plant is remarkable for its woolly covering, as well as the *S. Germanica* (German Woundwort), on which account they have been introduced into our gardens. Many other species are covered with hairs so as to give them a powdery-looking woolly character, as the *S. alpina*, *S. italica*, &c.

S. coccinea, Scarlet Hedge-Nettle. Stem erect, clothed with soft villi; herbaceous ovate-lanceolate petiolate leaves; flowers 6 in a whorl; corolla pubescent, three times as long as the tube. This is the most beautiful species of the genus, having large dark scarlet flowers an inch in length. It is a native of Chili and Peru. It must be cultivated as a greenhouse plant, and is readily increased by cuttings or parting its roots.

S. palustris, Marsh Woundwort, or Clown's All-Heal. Stems erect, pubescent, herbaceous; leaves subsessile, oblong, crenated, wrinkled, hispid; whorls with 6 or more flowers; calyx with lanceolate acute teeth; corolla twice as long as the calyx. It has pale purple flowers, with a variegated lower lip of the corolla. This plant is a native of Europe, Asia, and North America. It is abundant in watery places, by road-sides, in meadows, and corn-fields in Great Britain. It is called Clown's All-Heal by Gerard. The young shoots and the roots also, when cooked, form an excellent esculent. On the farm it is a weed that should be well looked after, as it exhausts the soil and increases very rapidly.

S. sylvatica, the Hedge Woundwort, is another common British species, differing from the last in having stalked leaves which are cordato-ovate shaped. It inhabits woods, hedges, and shady places. This herb is very pungent, and has an unpleasant fetid smell.

S. Corsica, Corsican Woundwort. Proeminent, pilose; leaves with petioles; flowers in 2-4-flowered whorls; corolla twice as long as the calyx, lower lip large. This is a pretty little plant worthy of cultivation. It has downy, rosy-white, or pink flowers, which are large for the size of the plant. It is a native of corn-fields in Corsica and Sardinia.

S. laxandulifolia, Lavender-Leaved Woundwort. Leaves of the stem oblong, lanceolate with petioles, floral leaves sessile; whorls 2-6-flowered; teeth of calyx longer than corolla. It is a native of the Caucasus, in dry stony places. It is shrubby in its habit, and is well adapted for rock-work.

STACHYTARPIA (from *σταχς*, a spike, and *ταρπης*, dense), the name of a genus of Plants belonging to the natural order *Verbenaceae*. It is known by its tubular 4-toothed calyx; hypocrateriform unequal 5-cleft corolla with a curved tube; 4 stamens, 2 of which are fertile. The species are natives of South America and the West India Islands. Many of them have been described as Vervains, but they are distinct from that genus. They are herbaceous or shrubby, and many of them are handsome plants.

S. Jamaicensis, Jamaica Bastard-Vervain, is an under shrub, with scattered hairy branches; leaves nearly two inches long, oblong-ovate, coarsely and sharply serrated, quite entire at the base, with the midrib beset with hairs; the spike is dense, bearing flowers of a lilac colour, and having ovate bracts which are shorter than the calyx. This plant is a native of the West India Islands, and has there a reputation something like that which distinguished our common Vervain.

STACKHOSIA. [STACKHOSIACEAE.]

STACKHOSIACEAE, *Stackhosiaceae*, a small order of Plants belonging to the Syncarpous group of Polypetalous Exogens. They are herbaceous plants, with simple, entire, alternate, sometimes minute leaves, with lateral very minute stipules. The flowers are arranged in spikes, each flower having 3 bracts. The calyx is 1-leaved, 5-cleft, equal, tube inflated; petals 5, arising from the top of the tube of the calyx, the claws forming a tube which is longer than the calyx;

stamens 5, arising from the throat of the calyx; ovary superior 3-5-lobed; fruit dry, with albuminous seeds and erect embryo. This order was constituted by Brown, and its nearest relations are with *Celastraceae* and *Euphorbiaceae*. From the first it differs in the possession of stipules, the cohesion of the petals, and the deep-lobed ovary; from the last, in the structure of the fruit, and in the position of the seeds. All the species are natives of Australia. The only genus of the order at present is *Stackhousia*, which was named in honour of John Stackhouse.

Stackhousia monogyna.

1, Spike with flowers; 2, cutting, with leaves; 3, calyx, corolla, and bract; 4, petals, showing their union to form a tube; 5, stamens arising from calyx; 6, ovary and styles.

STAG. [CERVIDÆ.]

STAG-BEETLES. [LUCANIDÆ.]

STA'GMARIA, a genus of Plants belonging to the natural order *Terebinthaceae*. It was named by Mr. W. Jack, assistant-surgeon in the East India Company's service, and author of 'Malayan Miscellanies,' from the Greek word *στάγμα*, 'a dropping fluid.' The tree *S. verniciflua*, which is the *Arbor vernicis* of Rumphius, and the Kayo Rangas of the Malays, is full of acrid resinous juice, and is a native of the Eastern Islands, but not very abundant in Sumatra, though occasionally found in the neighbourhood of rivers.

The calyx is tubular, with the limb irregularly ruptured, deciduous. Petals 5, longer than the calyx, obtuse, spreading, subreflexed. Stamens 5, alternating with, but inserted above, the petals into the stipe-like torus. Filaments filiform, equal to the petals in length. Anthers oblong. Ovary stipitate, 3-lobed, lobes 1-seeded, 1-2 of which are usually abortive. Styles 1-3, terminating the lobes of the ovary. Stigmas obtuse. Berry kidney-shaped, furrowed, 1-seeded, with a warty rind. Embryo exalbuminous, erect; cotyledons united; radicle incurved. The genus is nearly allied to *Rhus*, but besides the difference indicated in the above character, it has simple leaves, which are without stipules.

The wood of the tree is of a fine dark colour towards the centre. The bark exudes a resin which is extremely acrid, causing excoriation and blisters when applied to the skin; in this, as well as in becoming black when exposed to the air, it resembles the *Melanorrhæa*, Casheew-Nut Tree, Poison-Oak, and many others of the *Terebinthaceae*. According to Rumphius, this tree yields the celebrated Japan lacquer, or varnish, and he considers it the same with that of Siam and Touquin. Loureiro however represents the latter to be the produce of an *Augelia*. Mr. Jack says the varnish of Siam and Cochin-China is probably the best, but that of Celebes and of Java, which is the produce of this tree, is also employed for the same purposes, and cannot be much inferior, as it bears an equally high price. Rumphius says the exhalations of this tree are considered noxious, and the people of Macassar, and of other parts of Celebes in particular, entertain such dread of it, that they dare not remain long under it, much less repose under its shade. As however it furnishes the celebrated varnish, the Chinese and Tonkinese boldly repair to the tree, but employ caution in collecting the resin. This they do by inserting into the trunk two pieces of bamboo, sharpened at their points, in such a manner as to penetrate the bark in a somewhat oblique direction. These remain all night, and are extracted before sunrise the next morning, the trees yielding no juice during the day. This fluid resin bears a high price, being sold in Tonkin and Camboja for 30, 50,

or 60 dollars, the pecul of about 133 lbs., but in many of the provinces of China for 200 or 300 dollars.

The varnish is prepared for use by boiling it with an equal weight of the oil of Tang-yu, which is a Chinese tree allied to the *Mimusops Elengi*, from whose fruit an oil is prepared. The proportions are varied according to the purposes for which the varnish is required. Sometimes dry pigments are added for the sake of red or other colours. The Japanese are the most skilful in preparing and ornamenting all kinds of work with this varnish, and their black lacquered works are conveyed to all parts of the world.

(Jack, *Malayan Miscellany*, No. 3, reprinted by Sir W. Hooker.)

STALACTITE and STALAGMITE. Stalactitic Carbonate of Lime occurs chiefly in long masses suspended from the roofs of caverns in limestone rocks. Stalactites appear to be continually forming; water containing carbonate of lime held in solution by carbonic acid, trickling through crevices in the roofs of the caverns, gradually during its exposure to the air loses its carbonic acid, and consequently deposits its carbonate of lime; the water passing over the portion first deposited gradually adds to it, and eventually gives the carbonate of lime its great length and stalactitic character. The flatter deposits, called stalagmites, are formed on the floor of the cavern by the water there depositing that portion of its carbonate of lime which is not separated during the formation of the stalactite. Stalactitic Carbonate of Lime is met with in the veins of lead-ore in Durham and Northumberland. Caverns are sometimes nearly filled with these deposits, which in some cases are of very large dimensions. The most remarkable instances of their occurrence in Britain are in the cavern at Castleton in Derbyshire, and Macallaster Cave in the Isle of Skye. The grotto of Antiparos in the Archipelago, the Woodman's Cave in the Harz in Germany, and that of Auxelle in France, are striking instances of their formation in other countries.

Besides the occurrence of this variety of carbonate of lime in the stalactitic form, it is sometimes met with reniform and tabular, and in other imitative shapes. The fracture is sometimes perfectly lamellar, occasionally fibrous, the fibres diverging from a centre, with a pearly or silky lustre, and sometimes resinous or waxy. The colour varies from white to grayish, brown, red, and yellowish-white. Opaque, but frequently translucent.

The Oriental Alabaster, much employed by the ancients in statuary and the formation of vases, appears to be of stalactitic origin.

STALAGMITES (from *σταλαγμός*, a dropping), the name of a genus of Plants belonging to the natural order *Clusiaceæ*, or *Guttiferae*. It has polygamous or bisexual flowers; 4-5 sepals, which are persistent and bractless; 5 petals alternating with the sepals; 4-5 united stamens, the bundles flat, elongated, and divided at the apex into several short antheriferous portions opposite to the petals, and alternating with 5 large truncated glands; the anthers are 2-celled, hursting longitudinally; the ovary is 3-5-celled, with 1 ovule in each cell; stigma 3-5-lobed; the fruit a berry. The species are trees natives of the East Indies and Ceylon, and belong to the family which produces the gamboge of commerce. Dr. Wight states that one of the species, the *S. orifolia*, which is a native of Ceylon, yields a true gamboge, which is employed in commerce. It is known by its oval shining leaves, its lateral fascicled flowers, male and hermaphrodite mixed. Its anthers are arranged in 6 or 8 bundles, and it possesses a 3-celled 1-3-seeded ovary.

STAMENS, in Botany, the organs which constitute the last whorl but one of the series which form the flower in plants, the pistil with its parts forming the last or innermost whorl. These organs were called by the older botanists Apices, and by English writers Chives. They constitute the male organs of the flower, and are formed principally of cellular tissue. They are composed in most cases of three parts: 1, the Filament, a long slender organ, on the summit of which is placed—2, the Anther, which is a little case, mostly double, containing—3, the Pollen, which is composed of little grains constituting the fructifying influence of the plant.

The Stamen, in theoretical Botany, is considered, as well as the other parts of the flower, a modification of the leaf. Although its form, structure, and functions differ so much from the leaf, it is not difficult to point out the series of modifications by which the one is converted into the other. In many plants the leaves cannot be distinguished near the flowers from the bracts, and these again cannot be distinguished from the sepals forming the calyx; whilst the calyx often insensibly passes into the corolla, and parts of flowers are often seen possessing both the characters of sepals and petals. In the case of the White Water-Lily, a good example is offered of the passage of petals into stamens, thus completing the series of changes from leaves to stamens. In this plant a gradual contraction of the inner petals is seen to take place at their upper parts, the cellular tissue becomes coloured, and partakes of the character of pollen-grains, and these changes become more and more decided till the whorl of stamens is fully established in the centre of the plant. Many other plants might be cited as affording examples of the same changes, as *Calycanthus*, *Illicium*, &c. These changes occur naturally in the above plants, but a more decided exemplification of the conversion of these organs will be found in what are called monstrous or double flowers, which are the result of cultivation. If, for instance, a garden rose is taken, it will be found that the natural position of the stamens in this flower

is occupied by petals, and in many the character of half-stamen and half petal may be clearly seen. In other double flowers the same backward change may be observed of petals into sepals, and so on.

In the change that has thus taken place of the leaf into the stamen, the filament of the latter represents the midrib of the former, whilst the anther and its pollen are modifications of the lamina and cellular tissue of the leaf. It is well known that the cellular tissue of the upper and under surface of the leaf differs very considerably, and it is to these parts that the anterior and posterior cells of the anther are analogous. On this point Schleiden has proposed the questions as to whether there is any corresponding difference in the character of the pollen in the anterior and posterior cells; whether they possess the power of fructifying; and whether in diöcious plants it might not be ascertained that the one produced pollen grains that would engender male embryos, and the other grains that would produce female embryos.

In their normal position in the flower the first row of stamens always alternate with the petals; and as these organs are alternate with the sepals, the stamens are opposite the latter. If there is a second row of stamens, they will be alternate with the first, and thus of course opposite the petals. It however frequently happens, as in the primrose, that there is only one row of stamens, and yet opposite the petals. In such cases the anomaly is accounted for by supposing that the first row has not been developed, and consequently the second stand in their original position, that is, alternate with the aborted row. When there are only five petals and ten stamens, as in *Silene*, the latter are supposed to form a double row.

The stamens are said to arise from various parts of the flower, and according to the part of the flower from which they arise terms have been applied to express this origin, which are of great importance in systematic botany. When the stamens arise from (or, as it is often expressed, are inserted into) the calyx or corolla, they are said to be Perigynous; when they arise from under the pistil or ovary, Hypogynous; when from the pistil itself, Epigynous. The classes and sub-classes of the natural system of Jussieu are subdivided according to the existence of these distinctions in the families of plants. The above terms however must not be supposed to express the fact that the stamens do really originate in the parts from which they are said to arise or are inserted into. The fact is, the stamens always arise from a point in the axis of the flower between the petals and ovary; and when attached to these or other parts, it must only be looked upon as an adhesion of one organ to another. Thus when it is said that the stamens are inserted into the calyx of the flower of the apple, it is meant that they adhere to the calyx up to a certain point, from whence they appear to rise. The same must be said of their connection with other parts.

The Filament of the stamen is the representative of the petiole or midrib of the leaf, and in structure and function resembles that organ, and is not any more essential to the existence of the stamen than the petiole is to the leaf. It is composed of very delicate cellular and woody tissue, with which are intermixed a few bundles of spiral vessels. It is mostly filiform and cylindrical in shape, and in most instances without colour. In some plants, as the *Canna*, and in the whole of *Zingiberaceæ*, the filaments are hardly distinguishable from petals except in the possession of anthers at their apex.

The filaments are often combined into a single mass, the anthers being separate; when this is the case, they are said to form a brotherhood, and the term *Adelphia* is applied to them. When there is only one such combination, the stamens are said to be Monadelphous, as in *Geranium*; when there are two such unions, or even if only one stamen is separated from the rest, they are called Diadelphous, as in *Fumaria*, *Vicia*, *Lathyrus*, &c.; when there are more than two, as in *Hypericum* and *Melaleuca*, they are Polyadelphous. The filaments are sometimes of different lengths; when two are tall and two are short, as is seen in the whole of the natural family *Lamiaceæ*, they are called Didynamous; if four are long and two are short, as is seen in the family of *Cruciferae*, they are Tetradynamous.

The number of stamens in flowers is expressed by a Greek numeral being prefixed to the word androus: thus flower with one stamen are Monandrous; with two stamens, Diandrous; with three stamens, Triandrous, and so on.

It was on the number of stamens, and their arrangement and relations, that Linnæus founded the classes of his celebrated sexual or artificial system of the arrangement of plants. [SYSTEM, SEXUAL.]

For the function of the stamens, see REPRODUCTION IN PLANTS AND ANIMALS.

STAPELIA, the name of an extensive and curious genus of African Plants, given to it by Linnæus in honour of John Bodæus a Stapel. This genus belongs to the natural order *Asclepiadaceæ*, and possesses the following characters:—Corolla rotate, 5-cleft, fleshy, in the inside of which is a double nectary, consisting of two rows of leaves; the inner leaves, of which there are five, are subulate; the outer leaves are broader and undivided; the anthers are simple at top; the pollen masses are fixed by their base, having one of their edges cartilaginous and pellucid; follicles two, smooth; seeds numerous, comose. Most of the species of this genus are natives of the Cape of Good Hope. They are succulent plants without leaves, frequently covered over with dark tubercles, giving them a very grotesque

appearance. From uncertain points of their succulent stems large flowers expand themselves, exhibiting a variety of colours, and marked in the most grotesque manner. In most instances the flowers give off very unpleasant odours, which have been compared to carrion, rotten cheese, putrid water, and other unpleasant-smelling substances. These odours however have not prevented their being very generally cultivated on account of their singular and beautiful flowers. The genus is at present imperfectly understood, and many species that were originally referred to *Stapelia* are now placed under a variety of other genera, as *Podanthes*, *Tridentea*, *Orbea*, *Piранthus*, *Huernia*, &c. The great diversity in the form, colour, size, and structure of the flowers of these plants, have afforded the means of distinguishing a large number of species, but the whole have a family likeness which is possessed by few genera. We shall therefore only give two or three examples.

S. hirsuta, Hairy Stapelia, or Carrion-Flower. Corolla with the segments villously ciliated with white hairs, and the base villous from red hairs, the segments ovate, acute, and transversely corrugated; segments of outer whorl of nectary acute, lanceolate, of the inner spreading. The stem is angular and erect, the flowers appearing at its base. The corolla is very large, of a dark chocolate-crimson colour, streaked with yellow; the marginal fringe resembles a gray fur; the nectaries are red. The whole flower is the size of a French rose. The smell of this plant is so like that of carrion, that flesh-flies deposit their ova in the flower, and when the maggots are produced they are starved for the want of food. Sir John Hill wrote an essay to prove that the fly which attacked these plants was a peculiar species, whose larvæ lived on the flower, which seems to have been an error of observation, but for which Fabricius, the entomologist, spoke of him as "*damnandæ memoriæ Johannes Hill.*" This plant is a native of the Cape, and is one of the earliest species brought to Europe by the Dutch.

S. puleinata, Cushion-Flowered Stapelia, has a procumbent stem, with quadrangular erect branches, at the base of which the flowers appear; the segments of the corolla are roundish, wrinkled transversely, ciliated; bottom of corolla elevated, covered with hairs. This is the most elegant of the species, and, notwithstanding its unpleasant odour, the Dutch natives of the Cape call it the Arabian Rose. The corolla is very large, and its segments are of a deep violet-colour, variegated with whitish transverse wrinkles, and red at the bottom.

S. Gordoni, Gordon's Stapelia. Stem with square branches and tubercles ending in a spine; corolla orbicular, slightly 5-cleft, segments broad, roundish, acuminate. It has erect long foliicles which are solitary, and thus form an exception to the rest of the genus. The flowers are very large, almost three inches in diameter, of a brownish yellow-colour with a whitish centre; the segments of the nectary are black in the middle, and white on the edges.

STAPES. [EAR.]

STAPHYLEA (from *σταφυλή*, a bunch of grapes), the name of a genus of Plants, the type of the natural order *Staphyleaceæ*. It has a coloured 5-parted calyx, with an urceolate disc at the base; five upright petals; five stamens standing round the disc; an ovary with from two to three styles, with a small stigma; a membranaceous swelled capsule with two or three cells, and one or two seeds in each. This genus has six species, of which one is a native of Europe, one of North America, one of Japan, two of Jamaica, one of Peru, and one of the Himalayas.

S. pinnata, Common Bladder-Nut, is known by its pinnated leaves, petioles without glands, two styles, and bladdered capsules. It is a native of woods and thickets in the middle and south of Europe. It is admitted into the 'British Flora,' on the ground of its occurring occasionally in hedges and thickets in Yorkshire. It is frequently planted in shrubberies as an ornamental shrub, for which it is well adapted. It has a firm white wood, which adapts it well for various kinds of turning. The seeds are eatable, and act as a mild aperient: this arises probably from the oil they contain. The flower-buds, when gathered young, are pickled, and eaten as capers.

S. trifolia, Three-Leaved Bladder-Nut, is characterised by its ternate leaves, and its petals longer than the calyx. It is the species of North America, where it is found on dry hills in rocky situations from New York to North Carolina. It is also frequently cultivated as an ornamental shrub, and its wood and seeds may be used for the same purpose as the last.

S. Elmodi is an Indian species; it was found by Dr. Royle in the Himalayas, at an elevation of 7000 feet. (Royle, 'Hil. Him. Bot.', p. 166.)

STAPHYLEACEÆ, Bladder-Nuts, a small natural order of Plants belonging to the Syncarpous group of Polypetalous Exogens. They are shrubs with opposite pinnate leaves, having both common and partial petioles, and the flowers arranged in terminal stalked racemes. The calyx has five sepals, which are imbricated in æstivation; petals five; stamens five, alternate with the petals, perigynous; ovary 2- or 3-celled, seated on a disc; fruit membranous or fleshy, frequently deformed by the abortion of some of its parts; exalbuminous roundish ascending seeds, with a bony testa, large hilum, and thick cotyledons. There are only three genera and ten species belonging to this order, which are inhabitants of the warmer and temperate parts of the earth. Only one species, the *Staphylea pinnata*, is found in Europe. This order was separated by Lindley from the order *Celastraceæ*, with

which it is most nearly allied, but from which it is distinguished by its opposite pinnated stipulate leaves. One of the genera, *Turpinia*, has unisexual flowers. The species do not possess active properties. The seeds of all contain a mild oil, which may be expressed. [STAPHYLEA.]

Turpinia paniculata.

a, branch showing the opposite leaves (also the unisexual monœcious flowers of this genus); b, trilocular fruit; c, female flower; d, transverse section of fruit; e, section of seed.

STAR OF BETHLEHEM. [ORNITHOGALUM.]

STAR-APPLE. [CHRYSOHYLLUM.]

STAR-FISHES. [ASTERIADÆ; ASTERIAS; ECHINODERMATA.]

STAR-NOSE. [CONDYLURA.]

STARCH is a substance which is found very generally present in the vegetable kingdom. It occurs in the forms of irregularly-shaped granules inclosed in the cells of plants. It is easily detected in the cells of plants under the microscope, by the addition of a small quantity of solution of iodine, which immediately gives to the starch-granules a blue colour. [SECRECTIONS OF PLANTS.]

Starch can be readily separated from the tissues of plants, on a large scale, by bruising them, and stirring them in water; when left at rest the cellulose of the tissue falls to the bottom of the vessel, and the starch floats in the water. If the water containing the starch is now poured off, and allowed to stand a few hours, the starch will fall to the bottom of the vessel, and is easily collected. In this way it is obtained for commercial and dietetical purposes. Starch is thus found to be diffusible through water, but not soluble in it. It differs then from cellulose, on the one hand, by its diffusibility through water; and on the other, from dextrine, sugar, and gum, by its insolubility. In composition it resembles these substances, and during the growth of the plant it is evidently converted into one or the other [DEXTRINE] according to the necessities of the plant. It contains carbon, hydrogen, and oxygen ($C_{12}H_{20}O_{11}$), and belongs to that series of substances to which the term Dextrine has been applied. In certain groups of plants, intermediate substances between those mentioned have been obtained. Thus, in the Lichens, a substance exists which resembles starch in many of its properties, but does not assume its definite granular form. This is called Lichenin. [LICHENIN.] Another substance also closely approaching starch in its general characters is Inulin. This substance is not coloured blue by iodine, and has other distinctive properties. [INULA.] It is found in the various species of *Inula*, and has also been detected in other plants.

From these facts we may gather that Starch is the result of the chemical activity of the plant-cell at particular stages of its growth. It is one of those secretions to which the name assimilable is applied, and is evidently capable of undergoing great changes during the life of the plant. It is almost constantly present during the earlier stages of cell-growth, so much so as to lead to the supposition that its presence is universal during certain stages of the life of the plant-cell. In some plants and parts of plants however it rapidly disappears, being either converted into sugar or cellulose, or some of the numerous unassimilable secretions of plants. That the latter takes place very frequently is rendered probable by the discovery that caoutchouc and gutta percha can be artificially manufactured from starch, whilst it has long been well known that starch may be converted into sugar and gum.

Starch differs from sugar in its not being fermentable. It is however readily convertible into sugar by agents which induce fermentation. It has even been supposed that the protein of the plant-cell acts chemically in converting starch into sugar during germination, and the term Diastase has been applied to the proteinaceous matters found in connection with the starch of germinating seeds.

Starch occurs usually in the cells of plants in the form of granules. In the earlier stages of their growth these are attached to the sides of the cell, or to portions of the endoplasmic protein wherever they may be placed. In most cases these granules are simple or single; but when they are developed near each other a union is formed of one or more, and the result is a compound granule. Schleiden also describes Amorphous Starch, and states that in some plants the sides of the cells are lined with a layer of starch having no definitely-formed granules. In the majority of starch-granules a little spot may be seen which is called the hilum, and has been by some regarded as a nucleus or central point of the formation of the granule. It does not however seem to bear this relation in all cases.

Much difference of opinion exists as to the true nature of the starch-granule. Some observers have supposed that it consists of a series of flattened plates or dishes laid one upon the other, the result of successive depositions of starch matter. This view will be seen to be erroneous if the starch-granule is submitted to heat, or sulphuric acid, when it will be found to unfold and exhibit itself in the form of a vesicle or bag. From this it appears that this bag is compressed in the ordinary state of the starch, and its sides being folded in, gives it the appearance of dishes.

At one time it was supposed that starch was characteristic of the vegetable kingdom. Veichow has however demonstrated its existence in connection with cellulose in a large number of animals. Bush first pointed it out in the human brain. It has been found also in the human blood; and with cellulose and sugar it can no longer be regarded as truly characteristic of the vegetable kingdom.

(Schleiden, *Principles of Scientific Botany*; *Quarterly Journal of Microscopical Science*, vols. i., ii., and iii.)

STARLING. [STURNIDÆ.]

STAR-TICE (from the Greek *στατική*, intended to be used in the active sense, 'to stop,' so named from its supposed property of restraining hæmorrhages), a genus of Plants belonging to the natural order *Plumbaginaceæ*. It has spiked flowers with a 5-parted corolla, the calyx scarious above, the capsules not bursting.

S. Caroliniana has narrow obovate leaves on long petioles, smooth, veinless, obtuse, mucronated, level, and flat on the margin; the scape is round, smooth, slightly scaly, and terminated by a panicle of numerous branches, which bear the flowers on the upper side only; the flowers are alternate, erect, mostly in pairs, but appear singly in consequence of one expanding before the other; the calyx is funnel-shaped, scarious, and pink at the edge, 5-angled, the angles ciliate, and ending in long sharp teeth; the petals are obtuse, longer than the calyx, and of a bluish purple colour. This species is a native of North America, where it is called Marsh Rosemary. The root is a very powerful astringent, and is used as an application in aphthæ and similar affections of the mouth and fauces; it has been employed with success in *Cynanche Maligna*.

S. Limonium, Sea-Lavender, is a British species, and has much divided corymbose branches curved outwards; the ultimate subdivisions short, unilateral, ascending, and densely flowered; the calyx-segments entire, acute, with intermediate teeth; the outer bracts pointed and small. The roots possess astringent qualities.

S. rariflora is found near the sea in England and the coast of Gallo-way; it has oblong-lanceolate stalked leaves, the branches divided, the panicle ascending or incurved, the ultimate subdivisions elongated with unilateral rather distant flowers; the calyx-segments acute, denticulate, with intermediate teeth; the bracts obtuse, the outer ones large, the margins tinged with pink.

S. spathulata has spatulate leaves narrowed into a broadly winged stalk; the calyx-segments blunt, entire, and without intermediate teeth.

S. reticulata has spatulate leaves narrowed into a flat stalk, mucronate behind the point; 3-ribbed below; the scape paniced almost from the base with numerous slender zig-zag much-divided branches, of which the lower are barren; the calyx-segments acute, denticulate. It is found in muddy salt marshes in Norfolk.

(Babington, *Manual of British Botany*; Lindley, *Vegetable Kingdom*.)

STATYRA. [LAGRIDIÆ.]

STAUNTONIA, a genus of Plants belonging to the natural order *Menispermaceæ* and tribe *Lardizabaleæ*, named after Sir George Staunton. This genus is remarkable as being one of those which is common to China and the Himalayan Mountains, and has hence afforded useful inferences respecting the districts where the tea-plant might be successfully cultivated. The genus is characterised by having monococious flowers; the male having a 6-leaved calyx, with the leaflets in two rows; petals 6 or wanting; stamens 6, opposite to the petals, distinct or monadelphous; anthers adnate, opening outwards; rudiment of ovary. The female flower has the calyx of the male; no petals; 6 sterile dwarfish stamens; ovaries 3, distinct, oblong, with many ovules; stigmas sessile, simple-flowered. Berries often fewer than 3, divaricate, fleshy, opening longitudinally on their inner side. Seeds numerous, oblong-ovate, or reniform; embryo

minute in base of a fleshy albumen; radicle inferior. The species are divided into two sub-genera—*Stauntonia* being without petals and having monadelphous stamens: *Holboellia* having 6 gland-like petals and the stamens free. The species form large climbing shrubs, with alternate petiolate peltately digitate leaves. Leaflets leathery in texture, 3-nerved, very entire, with all the petioles swelled and jointed at both extremities; racemes fascicled, axillary, a few flowered at the base of the branches. Flowers white, externally purple, fragrant. Berries large and purple. The Himalayan species are found in Nepal and in 30° N. lat., at elevations of 5000 and 6000 feet. Their fruit, having a sweetish pulp, is eaten by the natives of these mountains, and they might no doubt be acclimated in the gardens of this country, as they experience a considerable degree of cold at the elevations where they are found.

STAUROLITE, *Staurolite*, *Grenatite*, a Mineral consisting of a silicate of alumina and iron. It occurs crystallised, the primary form being a right rhombic prism. Cleavage parallel to the lateral planes, and both diagonals. Fracture conchoidal, uneven. It scratches quartz with difficulty. Colour reddish-brown; streak white. Transparent; translucent. Lustre vitreous and somewhat resinous. Specific gravity 3.724. The crystals often intersect each other. It does not fuse by the blow-pipe; with borax it is slowly converted into a dark green transparent glass. It is found in France, Spain and Portugal, Switzerland, and North America. The analysis of a specimen from St. Gothard, by Klaproth, gives—

Silica	37.50
Alumina	41.00
Oxide of Iron	18.25
Oxide of Manganese	0.50
Lime	3.00
—100.25	

STAUROTIDE. [STAUROLITE.]

STAVESACRE. [DELPHINIUM.]

STEAMER-DUCK. [MICROPTERUS.]

STEARIN. [ADIPOSE TISSUE; FAT.]

STEATITE, *Soapstone*, *Speckstein*, *Talc-Steatite*, a Mineral consisting principally of hydrated silicate of magnesia. It is met with massive in amorphous masses, which sometimes contain crystals of this substance of the form of quartz and calcareous spar, and which are probably pseudomorphous. Structure compact. Fracture uneven, splintery. Soft, and has a greasy feel. Colour yellowish, greenish, and grayish-white. Streaksining. Dull. Translucent on the edges. Specific gravity 2.604 to 2.632. Before the blow-pipe it is infusible either alone or with additions. It occurs plentifully in Baireuth, Saxony; in Cornwall, in Scotland, and many other parts of the world. According to Klaproth it consists of:—

	Baireuth.	Cornwall.
Silica	59.50	45.00
Magnesia	30.50	24.75
Alumina	—	9.25
Oxide of Iron	2.50	1.00
Water	5.50	18.00
—98.00		—98.00

STEATORNIS. [GUACHARO-BIRD.]

STEENHAMMERA, a genus of Plants belonging to the natural order *Boraginaceæ*. The calyx is divided into 5 deep segments. The corolla bell-shaped, with a short cylindrical tube with 5 minute protuberances in its throat. The stamens protrude beyond the throat, the filaments elongated.

S. maritima, the only British species, differs but little from *Lithospermum* except in habit. It has a procumbent branched stem, ovate-acute leaves, with rough hard dots, glabrous, fleshy, and glaucous, having a taste resembling oysters. The nuts are smooth. The flowers in racemes, and of a purplish-blue colour.

STEIN-BOC. [ANTILOPEÆ.]

STEINMANNITE. [ANTIMONY.]

STELLA'RIA (from 'stella,' a star), a genus of Plants belonging to the natural order *Carpophyllaceæ*, and the section *Alsineæ*. The calyx has 5 sepals; the corolla is composed of 5 petals, which are either bifid or bipartite; the stamens are 10 in number; the ovary simple, with indefinite ovules; styles 3, and the fruit a capsule with 6 valves. There are 67 species of this genus enumerated. Most of them are weeds, which are distributed over all parts of the world. Eight of them are found in Great Britain. In common with the whole order to which they belong, they possess no active properties. Few of them are thought worthy of cultivation, and when planted in gardens they require but little care.

S. Holostea, the Greater Stitchwort, is a British species, and is the handsomest plant of the genus. It has a nearly erect stem; lanceolate acuminate finely serrated leaves; inversely heart-shaped bifid petals, twice as long as the calyx. It is often planted in gardens as a border flower, for which, on account of its early delicate white flowers, it is well adapted.

S. media is the Common Chickweed, which is so common and abundant on road-sides and waste places all over Europe. It is characterised by its procumbent stems possessing an alternate line of hairs between each pair of leaves. It has small white flowers, which

are open almost all the year. It is frequently eaten as a pot-herb, and small birds are very fond of its seeds.

S. cerastoides, and *S. scapigera*, the Alpine and Many-Stalked Stitch-works, are both of them British plants, and are sometimes cultivated in pots.

STELLATAE, the name of a natural order of Plants formed by Ray. The verticillate arrangement of the leaves of the plants of this order gives them a starlike appearance, whence the name. The order is called by Lindley *Galiaceæ*. [GALLIACEÆ.]

STELLERIDIANS. [ASTERIADÆ; ASTERIAS; ECHINODERMATA.]

STELLERUS. [CETACEA.]

STELLIO. [DRACONINA.]

STELLITE. [PREHNITE.]

STEM. [EXOGENS.]

STEMMATOPUS. [PHOCIDÆ.]

STENELYTRA, the third family of Heteromorous *Coleoptera* in the arrangement of Latreille. *Helops*, *Cistela*, *Deressa*, and *Edemera* are examples. They are usually oblong convex insects, with long legs and antennæ, which are thickened at their extremities. They live under the bark of old trees, or on leaves and flowers. [HETEROMERA.]

STENEOSAURUS, a genus of Fossil Saurians.

STENO. [CETACEA.]

STENOCERUS. [IGUANIDÆ.]

STENOCINOPS. [MAIDÆ.]

STENODACTYLUS. [GECKOTIDÆ.]

STENODERMA. [CHEIROPTERA.]

STENOPS. [LEMURIDÆ.]

STENOPUS. [PALEMONIDÆ.]

STENORHYNCHUS. [MACROPODIDÆ; PHOCIDÆ.]

STENOSOMA. [ISOPODA.]

STEPHANOMIA. [ACALEPHÆ.]

STERCORARIUS. [LARIDÆ.]

STERCULIA, a genus of Plants which gives its name to the natural order *Sterculiaceæ*, which-sometimes forms a section of the order *Byttneriaceæ*. The name is derived from 'sterculus,' as that from 'stercus,' some of the species being remarkable for the strong and disagreeable odour of their leaves or flowers. The genus is characterised by having polygamous or monœcious flowers; calyx 5-lobed, somewhat coriaceous; petals wanting; stamens monadelphous, disposed in a short sessile or stipitate urceolus; anthers adnate, ten, fifteen, twenty, in one or two rows; solitary or ternately aggregate; ovary stipitate or sessile; carpels follicular, five, or fewer from abortion, distinct, 1-celled, one- or many-seeded, opening on the inner side; seeds disposed in two rows along the suture of the carpels; sometimes, when the carpels have opened and become spread out, the seeds appear to be arranged along the sides of a leaf-like membrane; seeds with fleshy albumen, and flat, leafy, equal cotyledons. The species consist of various-sized trees, with soft timber, which are found in the tropical parts of the world, with simple or compound leaves and axillary panicles or racemes of flowers. Many of them are of considerable use in the countries where they are indigenous.

Like the order to which the belong, several species are mucilaginous; and others yield fibre, which, from its tenacity, is made into ropes. Some yield a gummy exudation resembling tragacanth, and which is sometimes substituted for it: thus the gum called Tragacanth, which is sometimes imported from Sierra Leone, is said by Dr. Lindley to be yielded by a species which he called *S. Tragacantha*, the *S. pubescens* of others. So Dr. Roxburgh states Kuteera Gum, which is often substituted for tragacanth, to be produced by *S. urens*, a tree of the mountains of the Coromandel coast. Dr. Royle however states that the kuteera gum of many parts of India is yielded by *Cochlospermum Gossypium*.

S. guttata yields a bark, from which the natives of Malabar prepare flax-like fibres, of which the natives of Wynaad make a sort of clothing.

S. acuminata is a native of the tropical parts of the western coast of Africa, where its seeds are everywhere known by the name of Cola or Kola, and are mentioned by most travellers. They are much esteemed by the natives, who take a portion of one of them before each of their meals, as they believe that these seeds increase the flavour of anything they may subsequently eat or drink. They are about the size of a pigeon's egg, are bitter in taste, and may be supposed to have some stomachic properties.

The seeds of *S. macrocarpa* and of *S. heterophylla* are also called Cola on the African coast. In Asia, in the same way, the seeds of *S. Balanghas*, are described by Rumphius as being roasted and eaten by the natives of Amboyna, while the capsules are burned for the preparation of the colouring matter called Cassoumba. The seeds of *S. urens* and of *S. fatida* are likewise eaten in India after having been roasted, as are those of *S. chicha* in Brazil. Those of *S. alata* are also said to be used as a cheap substitute for opium in the district of Silhet; but this statement, implying the presence of narcotic principles, requires careful examination before it can be received as a fact, as we generally find an accordance rather than so great a difference in the properties of species of the same genus.

STERCULIACEÆ, *Sterculiads*, a natural order of Plants belonging to the syncarpous group of Polypetalous Exogens. The plants belonging to this order are trees or shrubs, with alternate, stipulate, simple, often toothed leaves, with a variable inflorescence, and a stel-

late pubescence. The calyx is either naked or surrounded with an involucre, consisting of five sepals, with a valvular or nearly valvular æstivation; five petals, hypogynous, often saccate at the base; stamens definite or indefinite, and monadelphous; anthers 2-celled; the pistil consists of five carpels, often surrounding a columnar gynophore; fruit a capsule with three or five cells; seeds often winged, sometimes woolly; albumen oily or fleshy, and embryo straight; cotyledons either flat and plaited, or rolled round the plumule.

The order thus defined includes several groups of plants, which have by many writers been made to form distinct orders. *Sterculiaceæ* are most nearly allied to *Malvaceæ*, from which they differ in the possession of 2-celled anthers. From *Dipteraceæ* and *Tiliaceæ*, to which they are allied by the valvate æstivation of the calyx, they differ in the possession of monadelphous stamens. The subdivisions of this order are marked by very evident peculiarities of structure:—

Helicteræ have an irregular calyx and corolla.

Sterculia, no petals, and definite stamens placed at the end of a long column.

Bombacca, a calyx with a ruptile dehiscence, usually woolly seeds, and the cells of the anthers anfractuose.

Dombeyæ, a part of the stamens sterile, and flat well-formed petals.

Byttneriæ, a part of the stamens sterile, and small petals bagged at the base.

Lasiopetalæ, a petaloid calyx and rudimentary petal.

Hermannicæ, spirally twisted petals with only five stamens, and those opposite the petals.

Sterculiaceæ are natives of India, Australia, the Cape of Good Hope, and South America, with the West Indies. Most of its subdivisions have however a very definite geographical range.

Sterculiæ are found in India and equinoctial Africa. The genus *Sterculia* contains many species that are used as food or medicine. [STERCULIA.]

Sterculia chicha.

a, branch with leaves and apetalous flowers; b, monadelphous stamens surrounding pistil; c, ovary, style, and stigma; d, section of fruit, showing its five cells.

Byttneriæ are principally natives of South America and the West Indies; about one-seventh of the species are found in the East Indies, and the same proportion in Australia. To this group belongs the plant that produces the cocoa [THEOBROMA] of commerce. These plants, like the whole of the order and its allies, abound with mucilage, and are often used in medicine as demulcents. The fruit of *Guazuma ulmifolia* possesses a mucilaginous pulp, and is eaten in Mexico by

man, but principally employed for feeding cattle. The bark of this plant is bitter, and is said to be serviceable in the horrible disease called Elephantiasis.

Hermannice.—Two-thirds are found at the Cape of Good Hope; the remainder are natives of the East and West Indies, South America, and the islands of the Pacific. The species of *Waltheria* abound in mucilage, and are used in medicine as demulcents.

Dombeya are all African, East Indian, or South American. Their properties are similar to the preceding. One of the species, *Wallichia spectabilis*, forms a handsome tree, approaching the Linden, and points out a relation between this order and *Tiliaceæ*.

Lasiopetalæ are found entirely in Australia, and possess no remarkable properties. For further information on the properties of plants of this order see BOMBACEÆ, ADANSONIA, STERCULIA, and THEOBROMA.

STERNA. [STERNIDÆ.]

STERNBERGIA. [COAL-PLANTS.]

STERNBERGITE, a Mineral, occurring crystallised. Its primary form is a right rhombic prism. Colour pinchbeck-brown, with occasionally a violet tarnish in some of the faces. Streak black. Flexible in thin laminae. Lustre metallic. Opaque. Hardness 1.0 to 1.5. Specific gravity 4.2 to 4.25. It is found at Joachimsthal in Bohemia. Its analysis by Zippe gives—

Sulphur	30.0
Silver	33.2
Iron	36.0
	—99.2

STERNIDÆ, the name of a family of Web-Footed Long-Winged Birds which are commonly known as Sea-Swallows and Terns.

Linnaeus, in his last edition of the 'Systema Naturæ,' places the genus *Sterna* between *Larus* and *Rhynchops*.

Cuvier arranges the Hirondelles de Mer between the Goelands (*Larus*) and *Rhynchops*. He observes that these Hirondelles de Mer derive their names from their excessively long and pointed wings, their forked tail, and their short legs, which give them a port and flight analogous to those of the swallows. Their bill, he adds, is pointed, compressed, straight, without curvature or projection; their nostrils, situated towards the base, are oblong and pierced through; the membranes which unite their toes are very much notched, they therefore swim but little. They fly in all directions, and with rapidity over the sea, uttering loud cries, and cleverly picking up from its surface the molluscs and small fishes which form their food. They also advance inland to lakes and rivers.

Head and Foot of Tern.

The same author states that the Noddies may be distinguished from the other Sea-Swallows. Their tail is not forked.

Mr. Swainson makes the genus *Sterna* consist of the following sub-genera:—*Sterna*, Linn.; *Thalassites*, Sw.; *Phaeton*, Linn.; *Rhynchops*, Linn.; *Gavia*, Briss.

Prince Bonaparte places *Sterninae*, the second sub-family of his *Laridae*, between the sub-families *Rhynchopsinae* and *Larinae*. The *Sterninae* consist of the following genera:—

Sterna, Linn.; *Hydrochelidon*, Boie; *Megalopterus*, Boie (*Sterna stolidus* of authors); *Thalasseus*, Boie; *Gelochelidon*, Brehm; and *Stylochelidon*, Brehm. ('Birds of Europe and North America.')

Mr. G. R. Gray ('Genera of Birds') arranges the *Sterninae* as the third and last sub-family of *Laridae*, immediately after *Rhynchopsinae*, with the following genera:—

Phaetusa, Wagl.; *Gelochelidon*, Brehm.; *Thalasseus*, Boie; *Stylochelidon*, Brehm.; *Gygis*, Wagl.; *Sterna*, Linn.; *Sternula*, Boie; *Hydrochelidon*, Boie; *Anous*, Leach (*Sterna stolidus* of authors); *Onychoprion*, Wagl.; and *Pelecanopus*, Wagl. The *Pelecanidæ* immediately follow. [LARIDÆ.]

The following species of *Sternidæ* have occurred, some occasionally only, in Europe:—

The Caspian Tern, *Sterna Caspia* (genus *Stylochelidon*, Brehm); the Sandwich Tern, *S. Cantia* (genus *Thalasseus*, Boie); the Gull-Billed Tern, *S. Anglica* (genus *Gelochelidon*, Brehm); the Common Tern, *S. Hirundo* (genus *Sterna* of authors); the Roseate Tern, *S. Dougallii* (genus *Sterna*); the Arctic Tern, *S. Arctica* (genus *Sterna*); the Little Tern, *S. minuta* (genus *Sternula*, Boie); the Noddy, *S. stolidus* (genus *NAT. HIST. DIV. VOL. IV.*

Anous, Leach; *Megalopterus*, Boie); the Black Tern, *S. nigra* (genus *Hydrochelidon*, Boie; *Viralva*, Leach); the White-Winged Tern (*S. leucoparva* (genus *Hydrochelidon* (?), Boie); and the Moustache Tern, *S. leucoparva* (genus *Hydrochelidon* (?), Boie; *Viralva* (?), Leach). Of these, the largest is the Caspian Tern.

S. Hirundo, the Common Tern, is the Pierre Garin of the French; Fionco and Rondine di Mare of the Italians; Meerschwalbe and Rothfussiger Meerschwalbe of the Germans; Zee-Zwaluw of the Netherlands; Kria of the Icelanders; Tende, Tendelobe, Saud-Tolle, and Sand-Tærne, of the Norwegians; Tærne of the Danes; Sea-Swallow of the English; and Y Fôr-wennol Fwyaf and Yscrean of the Welsh.

The forehead, top of the head, and long feathers of the occiput, are deep black; posterior part of the neck, back, and wings, bluish-ash; lower parts pure white, with the exception of the breast only, which is slightly clouded with ash-colour; quills whitish-ash, terminated by ashy-brown; tail white, but the two lateral feathers blackish-brown on their external barbs; bill crimson-red, often blackish towards the point; iris reddish-brown; feet red. Length 13 to 14 inches. Such is M. Temminck's description of the adult male and female.

Common Tern (*Sterna Hirundo*).

Two adults: one in winter, the other in summer plumage. (Gould.)

"The Common Tern," says Mr. Gould, in his great work on 'The Birds of Europe,' "although not universally dispersed over our coasts, is nevertheless a very abundant species, being found in great numbers over the southern shores, but more sparingly over the northern, which are almost exclusively inhabited by its near ally, the Arctic Tern. It is now satisfactorily ascertained that the Common Tern does not extend its range to the American continent, and that its place is there supplied by another species, to which Prince Bonaparte has given the specific appellation of *Wilsoni*, in honour of the celebrated ornithologist by whom it was first described." The Prince however gives both *S. Wilsoni* and *S. Hirundo* as American species in his 'Birds of Europe and North America,' and M. Temminck states that individuals killed in North America differ in nothing from those of Europe. In the fourth part of his 'Manuel' (1840), though he adds to the synonyms and references, quoting among the rest Mr. Gould's work, he leaves his own observation above noticed uncontradicted. "How far," says Mr. Gould, in continuation, "the Common Tern is distributed over the Old Continent we have not satisfactorily ascertained; but we believe its range is extended from the Arctic Circle to the Mediterranean, and even to the coasts of Africa and India, to which southern and eastern countries it is supposed to retire during our winters. The Common Tern does not confine itself entirely to the sea, but frequently resorts to inland streams, &c.; and when thus ascending our creeks and rivers these little fairies of the ocean fearlessly fish around our boats, nothing can be more pleasing than to observe their poise and dip. When with their scrutinising eyes they have observed a fish sufficiently near the surface, they precipitate themselves upon it with unerring certainty, and a rapidity that is truly astonishing: this mode of capture strongly reminds us of the fissirostral tribe among the land birds, and they may indeed be truly termed the Swallows of the Ocean, their long and pointed wings and small but muscular bodies being admirably adapted for rapid and sustained flight, and affording the means by which they are enabled to traverse the surface of the deep with never-tiring wings."

We have seen them performing their graceful evolutions so far inland as near Oxford, where they were continually dipping in the Isis for bleak, as it appeared to us, which were abundant there.

Mr. Selby states that this Tern breeds upon the sand or shingle beyond high-water mark, making no artificial nest, but scraping a slight concavity for the reception of two or three eggs, which vary

much in colour, the ground in some being of a deep oil-green, in others of a cream-white, or pale wood-brown, but all blotched with blackish-brown and ash-gray. "In warm and clear weather," says Mr. Selby, in continuation, "this bird incubates but little during the day, in such situations the influence of the sun upon the eggs being sufficient; but it sits upon them in the night, and also through the day under a less favourable state of weather. The young, when excluded, are covered with a mottled gray and white down, and are assiduously attended by the parents, and well supplied with food until able to fly and accompany them to sea. During the time of incubation the old birds display great anxiety, and are very clamorous when any one approaches their station, in flying round and frequently descending so near as to strike the hat of the intruder."

The Tern was formerly considered choice food. Thus, in the 'Household-Book of the Earl of Northumberland,' we find 'Terns' among the delicacies for principal feasts or his lordship's own 'mees'; and they are charged at 4d. a dozen.

S. stolidus, the Noddy. In this form of Tern the wings reach beyond the rounded tail. Forehead white, passing into gray-ash towards the top of the head, and into a deeper gray at the occiput, in front of the eyes a deep black patch; throat and cheeks gray-brown; all the upper and lower plumage chocolate or sooty-brown. Bill and feet black. (Summer or nuptial dress.) Length about a foot.

It is principally found in America, where its head-quarters appear to be the Gulf of Mexico, the coasts of Florida, and the Bahama Islands. Dr. Latham was told that they breed in great numbers on certain small rocky islands near St. Helena. Mr. Audubon observed numbers collected from the American coasts above mentioned in 1832, on one of the Tortugas, called, from the flocks that visit it, Noddy Key.

Mr. Gould remarks that the Noddy, unlike the generality of terns, builds in bushes on low trees, making a large nest of twigs and dry grass, while hovering over or near which the old birds utter a low querulous murmur: the eggs, three in number, are reddish-yellow, with dull red and purple patches and spots, and the young are said to be very good eating. It does not take its prey like the other Terns, but as it skims along the water; and, when full grown, seeks its food at much greater distances from the land than the rest of the group.

Two were shot off Wexford in Ireland in 1830. Tommasek states that it has been seen in France, but he had never seen it on the coasts of Holland.

The Noddy (*Sterna stolidus*).

Mr. Nuttall gives a lively description of its habits:—"Familiar to mariners who navigate in the equatorial regions, the noddy, like the voyager, frequents the open seas to the distance of some hundreds of leagues from the land, and with many other birds of similar appetites and propensities, they are seen in great flights, assiduously following the shoals of their finny prey. They pursue them by flying near the surface of the water, and may now be seen continually dropping on the small fish, which approach the surface to shun the persecution of the greater kinds, by which they are also harassed. A rippling and silvery whiteness in the water marks the course of the timid and tumultuous shoals; and the whole air resounds with the clangor of these gluttonous and greedy birds, who, exulting or contending for success, fill the air with their varied but discordant cries. Where the strongest rippling appears, there the thickest swarm of noddies and sea-fowl are uniformly assembled. They frequently fly on board of ships at sea, and are so stupid or indolent on such occasions, as to suffer themselves to be taken by the hand from the yards on which they settle: they sometimes however, when seized, bite and scratch with great resolution, leading one to imagine that they are disabled often from flight by excessive fatigue or hunger. Some have imagined that the appearance of the noddy at sea indicates the proximity of land; but in the manner of the common tern, they adventure out to sea, and, like the mariner himself, the shelter of whose friendly vessel they seek, they often voyage at random for several days at a time, committing themselves to the mercy of the boundless ocean; and having at certain seasons no predilection for places, where the

climate suits, the roving flocks or stragglers find equally a home on every coast, shoal, or island." ('Manual of Ornithology.')

The vessel however is not always friendly. Bligh found the bird a seasonable supply to himself and his famished crew in his celebrated boat-voyage after the munity of the *Bounty*; and Byron has used the incident in the scene after the shipwreck in 'Don Juan.' [BOOBY.]

STERNOTHERUS. [CHELONIA.]

STERNUM. [SKELETON.]

STICHOSTEGA. [FORAMINIFERA.]

STICKLEBACK. [GASTEROSTEUS.]

STICTA. [LICHENS.]

STIGMA. [PISTIL.]

STIGMARIA. [COAL-PLANTS.]

STILAGINACEÆ, a small natural order of Plants belonging to the rectembryose group of Apetalous Exogens. They are trees or shrubs, with alternate simple stipulate leaves, the stipules being deciduous. The flowers are unisexual, mostly seated on amentiform spikes or racemes. Calyx 3-5-parted; stamens two or more, arising from an enlarged receptacle with capillary filaments and 2-lobed anthers dehiscing transversely; ovary superior, stigma sessile; fruit a drupe with one seed, which is pendulous; the embryo is green, lying in the midst of fleshy albumen.

The species of this order are all of them natives of the East. In its relations this order is obscure. It has some resemblance to *Urticaceæ*, from which it is distinguished by its enlarged disc, its peculiar anthers, and unelastic filaments. In these characters it resembles *Henslowiaceæ*, but they differ from this order in having but one carpel and a single seed. Many of the fruits of this order have a pleasant subacid flavour, and are eaten by the natives of the East Indies.

STILAGO, a genus of Plants sometimes united with, at other times separated from, the genus *Antidesma*, belonging to the natural family *Antidesmeæ*, which by some botanists is called *Stilaginaceæ*. The species are few in number, forming shrubs and moderate-sized trees, which are found in Madagascar and Mauritius, as well as in some of the Indian islands, and in India, where the species extend even to northern parts. The genus is characterised by having dioecious flowers, the male having a 3- or 5-parted perianth. Stamens 2, 3, or 5, inserted in an annular disc with the rudiment of an ovary. The female flower has the perianth of the male, and the disc surrounding the base of the ovate single-celled ovary. Ovules 2, pendulous from the apex of the cell. Stigma sessile, 3- to 5-rayed. Drupe 1-seeded, crowned by the stigma, with the nut rugose both inside and out. Albumen fleshy, scrobiculate. Cotyledons foliaceous. Embryo inverse. The flowers are arranged in axillary catkin-like spikes. The leaves of *Antidesma alexiteria* are employed in the Mauritius as an antidote against snake-bites. Cordage is made with its bark, as well as with that of *A. Zeylanica* in Ceylon. The small fruits of both species are eaten and preserved: the fruits of *A. pubescens* (*Stilago*), *Bunias*, and *Diandra*, are eaten by the natives of India.

STILBACEÆ, a small natural order of Plants belonging to the ucammentose group of Moucopenalous Exogens. They are small shrubs, with the habit of a *Phylla*, or a *Fir*, having whorled close narrow entire leathery rigid leaves, articulated at the base and without stipules. The flowers are arranged in dense spikes at the points of the branches; they are sessile, each having three bracts at its base. They differ but little from *Selaginaceæ*, except in their 2-celled anthers, their erect ovules, and in the want of an hypogynous disc. Kunth, who formed this order, points out also its relation to *Globulariaceæ*, and places it intermediate between that order and *Selaginaceæ*. The order consists of only two genera, *Stilbe* and *Campylostachys*, both of which are natives of the Cape of Good Hope.

STILBITE. [ZEOLITES.]

STILLINGIA, a genus of Plants belonging to the natural order *Euphorbiaceæ*, so named in compliment to Dr. Stillingfleet, known as an English botanist. The genus now includes the species of *Sapium*, and is distinguished by one of its species being the famous Tallow-Tree of China. The generic character of *Stillingia* is:—Flowers monocious; males aggregate; calyx cup-shaped, crenulate, or bifid; stamens two, inserted; filaments united at the base; anthers opening outwards; female flowers solitary; calyx tridentate or trifid; ovary sessile, 3-celled, each cell with a single ovule; style short, thick; stigmas three, simple, spreading; capsule globose, trilocular; cocci single-seeded. The species consist of milky trees or shrubs, found in the tropical parts of Asia and America, and likewise in the islands of Bourbon and Mauritius. The leaves are alternate, petiolate; petioles biglandular at the apex. Male flowers usually crowded in terminal spikes, supported at the base by a biglandular bract. The female flower is commonly below the spike, sometimes subsolitary on another branch.

S. sebifera, the Tallow-Tree of China, at one time attracted considerable attention, and was introduced into various European colonies in the East and West Indies. It may be met with in our hothouses. Dr. Roxburgh describes the plant as common in his time about Calcutta, but that it did not yield any useful product, and was therefore only an ornamental tree, being in flower and fruit most parts of the year. It is found in China on the borders of rivulets, and is also cultivated. It grows to the height of a pear-tree, having a trunk and branches like the cherry, and foliage like the black poplar, but which turns red in

autumn. It was met with in Chnsan by the late expedition, and seeds sent home by Dr. Cantor, which have been sown in the Horticultural Society's Garden at Chiswick. The fruit of this tree furnishes the Chinese with candles, and oil for their lamps. The seed-vessels and seeds are bruised, and then boiled in water. The fatty particles rising to the surface are skimmed off, and on cooling condense into tallow. To give it greater consistence some wax is added, together with linseed-oil, in the proportion of three parts to ten of the tallow. The candles made with it are beautifully white. Sometimes they are coloured red by the addition of vermilion. These candles are sometimes said to be coated with wax procured from another Chinese tree (probably *Ligustrum lucidum*), which forms an external crust and prevents them running. This tallow is also employed in medicine instead of lard.

STILPNOMELANE, a Mineral, occurring in crystalline, lamellar, and fibrous masses. Cleavage in one direction. Colour greenish or black. Streak greenish to liver brown. Lustre vitreous. Hardness 3 to 4.0. Specific gravity 3.27 to 3.4. It is found at Ohergrund and Zinkmantel, in Silesia. Its analysis by Rammelsberg gives—

Silica	46.500
Protoxide of Iron	33.892
Alumina	7.100
Lime	0.197
Magnesia	1.888
Water	7.000

—96.577

STILT-PLOVER. [CHARADRIADÆ.]

STINGS, in Botany. [HAIRS.]

STINT. [TRINGÆ.]

STIPA, a genus of Grasses belonging to the tribe *Stipaceæ*. It has stalked florets, the paleæ coriaceous, the inner entire. *S. pennata*, the only British species, has a very long twisted feathery awn, with a glabrous base. It is a very beautiful plant, and is common in our gardens. Found on rocks in Long Seadale near Kendal. [GRAMINACEÆ.]

STIPES, in Botany, a term applied to almost all parts of a plant performing the functions of a stalk, with the exception of the petiole and flower-stalk.

STIPULES, in Botany, are those organs which are found at the base on each side of the axils of the leaves of plants. They are not of constant occurrence, not being found in all plants, but where they occur they frequently characterise a whole family, as in *Leguminosæ*, *Rosaceæ*, *Malvaceæ*, &c. These organs are frequently very like leaves, and present themselves in the various forms in which leaves are found. But they are always to be distinguished from leaves by their position at the base of the leaf-stalk. In many cases they are green, like the leaf; they sometimes have petioles, and are sometimes sessile and cut into teeth, lobes, &c. In the *Mimosæ* the stipules frequently degenerate into hardened spines. In the family of *Polygonaceæ* they are membranous, and being united together they form a sheath around the stem, which is called an 'ochrea.' The stipules in *Cucurbitaceæ* assume the character of tendrils, and in *Trapa natans* they appear under the form of elongated filamentous hodies.

The stipules appear to be modifications of the leaves, but may always be distinguished from these organs by their being placed at the base of the leaf-stalk. Another distinction would also be found in their not possessing huds in their axils.

STITCHWORT. [STELLARIA.]

STIZOLOBIUM, a genus of Plants which was so named by Persoon, from *στίλβω*, to prick, and *λόβος*, a lobe or pod, from the pods of the several species being covered with hispid hairs. The species have now been removed chiefly to *Pachyrhizus* [DOLICHOS] and to *Mucuna*; of the latter of these *Stizolobium* now forms a sub-genus. The principal species are mentioned under COWITCH and MUCUNA. Cowitch is no doubt a corruption of the Hindustanee name Kiwach, which is the *Mucuna pruri* of Hooker, indigenous in various parts of India, but usually confounded with *M. pruriens*, a native of the West India Islands. The Indian *M. pruri* is distinguished by its smaller leaves, its more obtuse leaflets, the middle one being more truly rhomboidal, its flowers more constantly in threes, and by its legumes being much broader, compressed, and free from any raised line on the back of the valve, whilst in the American *M. pruriens* the pods are narrower, terete, and keeled on the valves. Another valuable but little known species is *M. utilis*, the Pois Noire of the islands of Mauritius and Bourbon, and thought to be a native of Arabia. It is universally employed in the above islands for enriching the soil for the cultivation of sugar. The thick covering of herbage with which the soil becomes covered, must be useful in preventing the soil from becoming parched, while the whole crop, being afterwards ploughed in, is found to be eminently useful in enriching the soil. The seed has been introduced into India and is spreading over the country.

STOAT. [MUSTELIDÆ.]

STOCK. [MATHIOLA.]

STOCK-DOVE. [COLUMBIDÆ.]

STOMACH. One of the most constant characters by which animals are distinguished is the possession of an internal digestive cavity, in which their food is received and subjected to a peculiar chemical

change before it is appropriated to the nutrition of the different parts of the body. In some animals the chemical change is effected in every part of the cavity; in others it goes on in one portion of it exclusively, and this portion is named the Stomach.

The Human Stomach is a membranous sac of an irregularly conical form, which lies almost transversely across the upper and left portion of the abdominal cavity. [ABDOMEN.] Its larger extremity is directed to the left, its smaller to the right. To the left it is in contact with the spleen; to the right with the liver: above it is covered by the diaphragm, and, at about one-third of the distance from its left to its right extremity, it communicates, by an orifice called the Cardia, with the œsophagus: at its right end it opens by another orifice, named Pylorus, into the intestinal canal. Of these orifices the pyloric lies rather lower than the cardiac: they are separated from each other by the upper and shorter border, or small arch, of the stomach, the greater part of the cavity being formed as if by the dilatation of the left side of the œsophagus into a great cul-de-sac and great arch, which form the left and inferior boundary of the stomach.

The coats or walls of the stomach are composed of three distinct membranes, connected by a firm but very extensible cellular tissue. The external or peritoneal coat is a layer of fine compact cellular tissue, woven into a thin membrane, and covered by a fine cuticle or epithelium, from which, like all the other organs within the abdominal cavity, it obtains a perfectly smooth and polished surface. The peritoneum invests every part of the stomach except the upper and lower borders, where there are spaces in which the trunks of the blood-vessels run, and from each of which the peritoneum is continued in a double layer to form the greater and less omenta. [OMENTUM.] Its only purpose seems to be to permit the stomach to move easily upon the adjacent organs.

Between the peritoneal and the internal or mucous membrane, there is a stratum of loose cellular tissue, in which are inlaid the fibres of the middle or muscular coat. This is composed of three different sets of fibres, resembling in their structure those of most involuntary muscles. [MUSCLE.] The fibres in the first and most superficial layer run longitudinally; they are continued from those of the outer coat of the œsophagus, which, at the cardia, expand or radiate, and pass in fasciculi at some distance apart, from left to right, along both the anterior and posterior surfaces of the stomach. The second layer is composed of circular fibres which form numerous fasciculi, each of which encompasses a considerable portion of the circumference of the stomach. The third and internal layer consists of two principal fasciculi of muscular fibres, which proceed from the cardia and expand over the great cul-de-sac and middle portion of the organ.

The interior or mucous coat of the stomach is that in which the essential apparatus for the production of the digestive material is placed. To the naked eye it appears a soft spongy membrane, about one-tenth of an inch thick, with a polished slippery surface. After death it varies considerably in its colour, but during life has a light pinkish tinge, and, accordingly as the stomach is distended or contracted, is either perfectly smooth or is thrown into various deep and irregular but chiefly longitudinal wrinkles. At the pylorus it forms a deep fold, between the two layers of which are strong fasciculi of circular muscular fibres: these constitute the Pyloric Valve, by which the aperture between the stomach and the intestines is guarded. At the cardiac orifice the boundary between the mucous membrane of the stomach and that of the œsophagus is marked by a jagged line, at which the thick and opaque epithelium of the latter terminates, and the much finer epithelium lining the stomach commences.

The more intimate structure of the mucous membrane can be seen only with the aid of the microscope. If its surface be examined with a lens whose magnifying power multiplies about forty diameters, it appears to be covered by minute polygonal fossæ, from 1-100th to 1-350th of an inch in width, surrounded by narrow sharp-edged borders, to which little leaf-like processes are sometimes attached. At the bases of each of these fossæ there are, at least during digestion, from six to ten minute apertures leading into tubes which pass vertically into the substance of the mucous membrane. A thin section of the membrane, made perpendicularly to its surface, shows that nearly its whole substance is composed of these tubes, which are minute cylindrical glands, opening on the surface in the fossæ just described, but closed below, and set compactly side by side in groups. They vary in length from one-fourth of a line to nearly a line, the longest being situated near the pylorus. Near their bases they measure about 1-300th of an inch in diameter, and near their orifices about 1-500th of an inch. Their lower closed extremities sometimes seem (but only seem) a little convoluted or baccated. They lie in every part of the mucous membrane, but are largest and most densely set, so that they are actually in contact, near the pylorus; a few of them are branched, two or more tubules opening by a single orifice. The small blood-vessels pass vertically in the cellular tissue between the groups of tubules from the submucous tissue to the surface of the stomach, on which they form an angular network, marking out the borders of the shallow fossæ.

The walls of these little tubular glands are composed, near the surface of the stomach, of a fine structureless membrane, and at the deeper part of minute nucleated cells adhering by their edges. Their office seems to be the production of cells containing the fluid for

digestion. In different parts of the stomach, and at different times, they vary in the nature of the substance which they contain; and it seems probable that these variations depend on whether the tubes are, or are not, engaged in producing digestive fluid. Those which are so occupied are completely filled with cells in different stages of development; those which are inactive are empty, and have their walls lined internally by epithelium, similar to that which invests the interior of the stomach. In the production of the cells containing the digestive fluid, small granules are first generated in the deeper part of each tubular gland: these, coalescing by twos or threes form nuclei, on which the cells are developed according to the ordinary mode of formation of primary cells. The cells are of an oval form, about 1-2000th of an inch in length; and, as fast as they are produced, they are pushed towards the orifices of the tubes, from which, while digestion is going on, they are discharged in such numbers as to form, with a small quantity of fluid separated at the same time, the thick layer of mucus by which the whole interior of the stomach is lined, and by which the portions of food are invested. In the intervals between successive acts of digestion, it seems probable that the orifices of the tubules are closed by small portions of epithelium similar to that by which they are lined, and which are elevated and broken through for the discharge of the cells as soon as the active process commences.

During digestion there are also often found, just beneath the surface of the mucous membrane, around either the cardiac or pyloric orifice, and along the lesser arch of the stomach, a number of small closed sacculi, filled with an opaque white fluid containing cells, which, when their contents are matured, burst and discharge them into the interior of the stomach. But the exact office of these bodies (which have been generally described as the gastric follicles, or lenticular glands of the stomach) is not known; they are certainly not always present, but probably are produced rapidly while digestion is going on, and, having discharged their contents, are again rapidly absorbed. [INTESTINES; DIGESTION; FOOD.]

STOMAPODA. M. Milne-Edwards comprises in the order *Stomapoda* all the Podophthalmous Crustacea which are deprived of thoracic branchiæ lodged in internal cavities.

This division is entirely composed of Swimming Crustaceans, whose body is elongated, and whose general form often approaches closely to that of the Macrourous Decapods; but in those animals the concentration of the rings of the head and thorax is carried less far. In the greater part of the *Stomapoda* the ophthalmic and antennular rings are not confounded with the rest of the head, and they even sometimes acquire a remarkable development. As in the other *Podophthalma*, there always exists a Carapace, which is formed by the enlargement of the dorsal arch of the antennary or mandibular rings; but the dimensions of this huckler vary greatly. Sometimes it covers nearly the whole of the thorax, and only leaves exposed a portion of the last ring of that part of the body; sometimes, whilst it prolongs itself above the thoracic rings, it only adheres to those which are near the mouth, and leaves the others free and complete under its lower surface. In other cases it does not reach the four or five last rings of the thorax, which then resemble those of the abdomen. In form it varies too much for general description. The Thorax is generally elongated, and entirely composed of segments moveable upon each other. Sometimes all the rings of this part of the body are united into a single piece. The conformation of the Abdomen varies still more; this portion of the body presents in general nearly the same disposition as in the Macrourous Decapods, and terminates by a great caudal fin composed of appendages of the sixth ring and the following segment; but in some *Stomapods* the abdomen is rudimentary. The disposition of the limbs is equally variable. The Eyes are always carried on a first pair of moveable appendages, the length of which is often very considerable, and whose disposition is essentially the same as in the Macrourous Decapods. The first pair of Antennæ are rather long, and terminate in two or three multi-articulate filaments; their peduncle is always cylindrical, and they can never be bent back under the front as in the Brachyurous Decapods. They are inserted below the eyes, near the median line, or externally to the base of those organs. The second pair of antennæ vary still more; their conformation however generally approaches that in the *Crangonidae*. The basillary joint of their peduncle nearly always carries above a great ciliated blade, and they terminate by a long multi-articulate filament. In the greater part of the *Stomapods* they are inserted outside the first pair, nearly on the same transversal line. The distance which separates the mouth from these appendages is generally very considerable; and the carapace never recurves below, so as to form round that aperture a well determined frame serving to lodge the jaw-feet, as in the greater part of the Decapods. In the majority the buccal apparatus is more simple than in the preceding order, and is only composed of an upper lip, a pair of mandibles, a lower lip, two pairs of jaws, and a single pair of jaw-feet; these last organs are either altogether wanting, or are transformed into natatory feet, and nearly always the seven following pairs of limbs are all so formed as to constitute natatory or prehensile feet. It is also worthy of note, that in the *Stomapods* the second pair of jaws never carry at their base a lamellar appendage analogous to the valvule, which, in the Decapods, fulfils functions so important in the mechanism of respiration; and this modification of structure

is a natural consequence of the absence of a respiratory cavity which includes the thoracic branchiæ, as in the preceding order.

There are generally seven or eight pairs of Feet, often presenting the same mode of conformation. They are nearly always provided with an appendage, which may be considered as the analogue of a palp. There is often found also at the base of many of the anterior feet another soft and vesicular appendage, which has sometimes the form of a galeite, and which represents the flagrum, an organ which, in the greater portion of the Decapoda, is lamellar and of a horny consistence; but which, in certain Shrimps, presents a structure similar to that in the *Stomapods*. Three of the last pairs, or a greater number, are always natatory; the first pair, or even the first four, are often prehensile; but they never terminate in a didactylous pincer, as in the Decapoda: they are subcheliform, that is to say, nothing more than a moveable claw which falls on the preceding joint. The greater part of these organs are approximated to the mouth, or even applied against it; a disposition which has been the cause of the appellation *Stomapods*. The abdominal members present nothing peculiar; their number is nearly always six pairs.

The Branchiæ of the *Stomapods* are always external, and present in general a more complicated structure than those of the Decapods. Instead of being composed of lamellæ, or simple filaments, they are framed of cylinders ranged in parallel order, giving origin to other smaller cylinders, which, in their turn, are equally fringed. Sometimes these ramose branchiæ are fixed at the base of the thoracic feet, and suspended under the thorax; but in general they spring from the basillary joint of the abdominal false feet: in some of the order they are reduced to a rudimentary state; in others nothing is to be seen which can be considered as a special organ of respiration; and, in such cases, there is every reason to believe that this function is exercised by the general surface of the teguments.

Branchiæ of *Stomapoda*.

1, one of the branchiæ of *Thysanopoda*: a, base of the posterior foot; b, branchiæ; c, palp.

2, a branchia of *Squilla*: a, base of the false foot; b, branchiæ; c, d, the two terminal branches of the false foot.

3, a, one of its branches of this ramose branchia; b, the branchlets (ramuscles).

4, one of the abdominal false feet of *Cynthia*: a, basillary joint; b, branchiæ; c, lamellar appendages.

The apparatus of Circulation differs much from that of the Decapods. In the *Squilla*, the only *Stomapods* which have been anatomically examined, the heart, instead of being nearly quadrilateral, and situated towards the middle of the thorax, has the form of a long cylindrical vessel, which extends throughout the length of the abdomen; the arteries which spring from this tubular heart are distributed in a peculiar manner; and the principal venous sinuses, instead of being situated on the thorax, occupy the abdomen.

The Stomach of some *Stomapods* presents vestiges of the solid framework, which, in the Decapods, is armed with teeth serving to bruise the aliments in the interior of the digestive cavity; but in general nothing similar is to be found. The structure of the Liver also varies; and in those species in which the organs of generation have been examined, remarkable peculiarities have been observed in their disposition. The Nervous System in this order presents also modifications which have not been found in the Decapods; but its disposition varies too much to enable M. Milne-Edwards to say anything general of it.

M. Milne-Edwards divides the *Stomapoda*, after the example of Latreille, into three families:—the Caridoides, the Bieuirassés and the Unieuirassés.

I. Caridoid *Stomapoda*.

The Crustaceans arranged by M. Milne-Edwards under this family bear a close resemblance in their general form, he observes, to the family of Salicoques; and indeed till lately their position had been in the order *Decapoda*, where they constituted a small and peculiar family under the name of *Schizopoda*.

The body is thick, and slightly compressed laterally. Head confounded with the thorax, and all the rings of the last-named part (with the exception, sometimes, of the last, or of the last two) completely united together and soldered above with the carapace. Abdomen considerably developed, and terminating by a great fin composed

of five laminae, or blades, disposed in a fan-shape, as in the Macrourous Decapoda. The carapace descends on each side against the base of the feet; covers the whole, or nearly the whole, of the thorax, as well as the head; and presents only a rudimentary rostrum in front; there is no moveable plate in place of this frontal prolongation, as in *Squilla*, and the ophthalmic ring is in general very short and naked. The disposition of the eyes, of the antennae, and of the pieces of the mouth, varies. The thoracic plates are all slender, natatory, and resemble each other; but their number varies much. The abdomen is composed, as ordinarily, of seven rings, the first five of which carry natatory false feet; whilst the seventh forms, with the appendages of the sixth segment, the caudal fin: these last appendages consist each of a small very short basilar joint, and of two great terminal plates disposed as in the Macrourous Decapoda. Finally, the conformation of the respiratory apparatus varies; sometimes the branchiae do not exist; sometimes vestiges of them are found at the abdominal false feet; and sometimes they are, on the contrary, very much developed, and suspended under the thorax. (Milne-Edwards.)

M. Milne-Edwards divides the Caridoids into two small tribes, the Mysians and the Luciferians.

1st Tribe. Mysians.

This tribe resembles the Salicoques so closely, that till lately the species forming it had been arranged under the Macrourous Decapoda, where they constituted the family designated Schizopoda.

The carapace extends to the base of the ocular peduncles, and presenting in general in the middle of the front a rudimentary rostrum. Antennae inserted on two lines, and formed as in the Shrimps, excepting only that the lamellar appendage of the second pair is less. Mouth situated very near the base of these last, and composed essentially of a labrum, a pair of mandibles furnished with a palpiiform stem, a lower lip, and two pairs of lamellar jaws. To this family belong the genera *Mysis*, *Cynthia*, and *Thysanopoda*.

Mysis.—Body narrow, elongated. Carapace covering the anterior extremity of the trunk as well as the greater part of the thorax, and bent down on each side so as to apply itself against the base of the feet. It is free laterally, and does not adhere to the last rings of the thorax; anteriorly it is unwarped considerably, and terminates by a small flattened and very short rostrum; its posterior border is deeply notched. Eyes large, short, and with their base hidden under the anterior part of the carapace. Internal antennae inserted below the eyes, near the median line; peduncle of the same form as in the Shrimps, and carrying at its extremity two multiarticulate and rather long filaments. The second pair of antennae inserted below the preceding, and equally directed forwards; the first joint of their peduncle gives origin to a very elongated lamellar appendage, which is ciliated on the internal border that covers the base of those organs, as in the Shrimps. The two succeeding joints of the peduncle are slender and cylindrical, and the terminal filament is filiform, multiarticulate, and longer than the upper antennae.

There is no vestige of branchiae, either at the vault of the sides or at the base of the feet, or at the lower surface of the abdomen, and the only appendage which would seem to be modified in its structure so as to become more proper than the rest of the body to fulfil the functions of an organ of respiration, is the flagrum of the first pair of jaw-feet, whose disposition, for the rest, is nearly the same as in a great number of crustaceans provided with branchiae.

On account of their peculiar appearance, the species of this genus have been called Oposum Shrimps. The pouch which contains their eggs, and which have secured for them this name, is thus described by Mr. J. V. Thompson:—"Attached to the base of each of the inner divisions of the two posterior pairs of feet in the female, is a large concave scale, strongly pectinate in front, of which the posterior is the outermost, largest, and most concave, lapping considerably over the anterior scale, so as to admit of a considerable extension of the size of the pouch which they form by meeting each other in front, in order to accommodate its capacity to the growth of the ova and young brood. In the male, in place of the valvular pouch of the female, we perceive attached to the inner part of the last pair of feet only, a single small hollow scale on each side, ciliate in front, and provided with a marginal row of slender hooks at the apex; these are probably an appendage of the male organs, which have a similar situation in the Shrimps."

Within this pouch in the female, the eggs, or rather embryos, Mr. Thompson informs us, are received when excluded from the ovary, and enveloped in a mucous or subgelatinous secretion, and gradually developed without any visible attachment to the parent. "The ova when first received into the pouch are considerably more advanced than those of the Shrimps, Crabs, &c., on their first expulsion, and by no means so numerous, a circumstance more than compensated by the rapidity with which one brood succeeds another during the whole of the spring and summer months. The number of broods produced by one individual, as well as the time occupied in their evolution, have not been determined; but the changes which the embryo undergoes in configuration are sufficiently obvious. In the present instance these cannot be considered as metamorphoses, but simply a gradual development of parts; hence the *Schizopoda* may be regarded as one exception to the Crustaceans undergoing trans-

formations, another character by which they are separable from the true Shrimps, &c. The first change which is perceptible in the ova after their reception into the maternal pouch is a slight elongation at one end, and the appearance of two short members on each side; this elongation, which proves to be the tail, increasing in length, shortly after becomes forked at the end, accompanied by a proportional growth in the four lateral members, and which are the rudiments of two pairs of antennae in the perfect animal; the embryo going on thus with a progressional development from day to day, begins to assume a more complete form, and an approximation to that of the parent, in which stages the divisions of the abdomen, the tail, the pedunculate eyes, and the various members are sufficiently distinct; a still more close resemblance to the perfect animal is attained before the young are finally excluded, which is effected by the parent spreading open the valves of its pouch, when the whole brood emerge at once into the ambient element, and, in most of the species, continue associated with the community from which they sprang. The slight differences which they now present (and which are necessary to be known in order to preclude the possibility of their being mistaken for individuals of a different species) affect only the inner rows of feet, the subabdominal fins, the outer antennae, and the tail; the first of these, in place of the multiarticulate termination, have but one or two short joints and a curved claw superadded to the end of the tibiae, and hence this division of the limb is shorter in proportion; the subabdominal fins consist only of a linear joint surmounted by a few bristly hairs; the outer antennae differ in no other respect than in the ciliated scale which is attached to their base being shorter and less developed, as is also the brush of hair in the males; the three intermediate scales of the tail are proportionally shorter, but yet present the character peculiar to the species in their form, indentations, and appendages, so as to testify the acuteness of Dr. Leach in having fixed upon this part to distinguish the species from each other. What is further remarkable in the embryos is the way in which they are arranged within the pouch from the moment they assume an elongated form; their heads being towards the breast of the mother, with the curvature of the tail part suited to that of the outline of the pouch, and the large size and blackness of their eyes."

The species of *Mysis* swim freely in the sea in numerous troops, and are particularly abundant in the north, where, according to Otho Fabricius, they constitute a principal portion of the food of the Whale-Bone Whales (*Balaena*). Captain James Ross, R.N., states that *Mysis flexuosus* (*Cancer flexuosus*, Müll.), though but sparingly found in the seas of Europe, inhabits some parts of the Arctic Ocean in amazing numbers, and constitutes the principal food of the prodigious shoals of salmon that resort thither in the months of July and August, and upon which the inhabitants of Boothia depend, in great measure, for their winter store of provisions. He further observes, that it is also the chief food of the whale, by which such a prodigious quantity of fat is produced in the body of that immense animal.

M. Milne-Edwards divides the genus *Mysis* into the following sections:—

1. Species which have the middle blade of the caudal fin bifurcated.

M. spinulosus, Leach. It is the *Praunus flexuosus*, Leach; *Mysis Leachii*, Thompson ('Zool. Res.'). It is found in the British Channel and the coasts of La Vendée. (Milne-Edwards.)

Mysis Fabricii, magnified.

a, the last ring of its body, or its terminal fin; b, base of a lateral antenna; c, base of an intermediate antenna; d, one of the second pair of jaw-feet; e, one of the first pair. These parts highly magnified. (Desmarest.)

2. Species which have the median blade of the caudal fin entire at the end.

M. vulgaris is common on the Irish coast. It abounds in the Lee, even up to Cork, from the early part of spring to the approach of winter, according to Mr. Thompson, who states that during the still period of the tide at low water, they repose upon the mud and stones at the bottom of the river, and, as the tide rises, may be observed

forming a wide belt within its margin, the youngest swimming nearest to the shore, the oldest farther out and in deeper water. They appear, he adds, to be mostly females, the males being few in proportion, and they swim in a horizontal position, contributing towards the food of various young fish, from which they frequently escape by springing up out of the water.

Mysis vulgaris, magnified. (Thompson.)

Cynthia, Thompson.—Body slender, and of the same form as in *Mysis*; but the carapace of *Cynthia* is smaller, and terminates anteriorly by a small rostral prolongation; behind it a certain number of thoracic rings are exposed. Eyes stout and short, of moderate length. First pair of antennae excavated at their base to make room for the eyes; their peduncle is stout, and they have two terminal filaments. The second pair of antennae are inserted below the preceding, as in *Mysis*, but they are much smaller; the lamellar appendage which covers their base is shorter than the peduncle of the upper antennae. Conformation of the buccal apparatus nearly the same as in *Mysis*; palpiform stem of the mandibles very large; second pair of jaws lamellar, and divided on the internal side into many lobes.

C. Thompsonii, a native of the Atlantic Ocean, between Madeira and the Antilles. (Milne-Edwards.)

Thysanopoda (Milne-Edwards).—External form resembling that of *Mysis*. Body presenting the same divisions as in the Macrourous Decapoda. Carapace, which covers the head, hiding also the whole of the thorax. Abdomen, whose length much exceeds that of the cephalo-thorax, extended backwards, and composed of seven segments, the three median of which present on their posterior and superior borders a small spine, directed backwards. Carapace terminated anteriorly by a small pointed rostrum, which does not reach to the extremity of the eyes, whose peduncles are stout and short. Antennae four in number, inserted on two lines, and nearly equal in length; the upper with a peduncle recurved at its base, to receive the eyes, and composed of three cylindroid joints; they are terminated by two rather long filiform stems. Base of the lower antennae covered by a long lamellar scale, the extremity and internal border of which are ciliated, the terminal stem presenting nothing remarkable. Mouth situated at a small distance from the point of the insertion of the lower antennae, and surrounded, as ordinarily, with a rather stout labrum, a bifid tonguelet, and a pair of mandibles, which are armed on their internal border with some pointed teeth, and carry a short and flattened palp, divided into three joints. Two pairs of jaws are applied on the mandibles and tonguelet.

T. tricuspidata is the only species known. Length about 15 lines. It was found far at sea, in the Atlantic Ocean, by M. Reynaud.

M. Milne-Edwards thinks that the genus *Podopsis*, or Hammer-Headed Shrimp of Thompson, may belong to this family; but he observes, that it is too imperfectly known to warrant the assignment of precise characters to it. This crustacean, which was found in the Atlantic Ocean, and is phosphorescent, is figured and described in the interesting 'Zoological Researches' above quoted.

2nd Tribe. Luciferians.

M. Milne-Edwards observes that the genus *Lucifer*, established by Mr. Thompson, is one of the most singular known. One of the most remarkable traits of this crustacean is the excessive length of the anterior portion of the head; the extreme brevity of the part of the body occupied by the mouth, and constituting the thorax; and the great development of the abdomen.

The general form of the body is nearly linear. Eyes and antennae carried at the extremity of a long, slender, and cylindrical prolongation, which is much longer than all the rest of the cephalo-thoracic portion of the body, and seems to be formed principally by the antennary ring. A small carapace covers the whole of the posterior portion of the cephalo-thorax, and presents nearly the same form as in *Mysis*. The first pair of antennae are slender, short, and terminated by a multi-articulate rudimentary stemlet; the second pair are inserted below, close to the preceding, and are equally slender: near their base is seen a small lamellar appendage, but their mode of termination is unknown. Mouth projecting, and situated behind the base of the prolongation which carries the eyes, &c.

L. Typus. This species differs from the only other *Reynaudii* (which was found in the Indian Ocean by M. Reynaud) in the form of the median piece of the caudal fin, which is lamellar, and without any notch below, in the more considerable length of the middle blades, and in the apparent absence of a separation between the carapace and oculiferous prolongation.

Long-Headed Shrimp (*Lucifer Typus*), magnified, and of its natural size. (Thompson.)

II. Bicuirassid Stomapoda. [PHYLLOSOMA.]

III. Unicuirassid Stomapoda.

The abdomen is well developed, and is composed of seven moveable segments, the last of which constitutes a very large caudal blade. The eyes are stout and convex (renflées) towards the end; the first pair of antennae are inserted below and behind their peduncle, and are composed of a cylindrical peduncle formed of three joints and terminated by three filaments, which are ordinarily multiarticulate. The second pair of antennae are inserted behind and outside the preceding, and are provided with a great lamellar appendage fixed on a stout and cylindrical joint, at the extremity of the first joint of their peduncle, which also carries in front a filament, which is ordinarily multiarticulate. The mouth is rather distant from the antennae, and carried on a nearly triangular eminence, the base of which corresponds with the insertion of the prehensile feet. The upper lip is large, projecting, and semicircular. The mandibles are directed downwards, and terminate by two toothed branches, one of which ascends in the back part of the mouth, towards the stomach; the palpiform stem which carries these organs is small and sometimes null. The lower lip is large, and partially covers the extremity of the mandibles. The jaws are very small, and applied exactly against the mouth; the first pair terminate by a kind of hook directed inwards, and armed with spines

along the internal border of their second joint; there is also a small rudimentary palpiform appendage. The second pair of jaws are lamellar, nearly triangular, and composed of four or five joints placed end to end; nothing resembling a flabelliform appendage is to be seen. The members which belong to the seventh cephalic ring, and which ordinarily constitute the anterior jaw-feet, do not seem to belong to the buccal apparatus. They are very much elongated, and form a pair of slender feet, generally enlarged towards the end, the uses of which are not known.

M. Milne-Edwards divides this family into two small tribes, Erichthians and Squillians.

Tribe 1. Erichthians. [ERICHTHUS.]

Tribe 2. Squillians.

Corresponding with the genus *Squilla* of Fabricius, and the majority of authors, this tribe comprehends, according to M. Milne-Edwards, the genera *Squilla* (containing the *Squilla*, properly so called), *Gonodactylus*, and *Coronis* of Latreille. All these crustaceans have, observes M. Edwards, the greatest resemblance to each other, and the differences upon which these genera are established have not perhaps as much importance as was once thought.

The Squillians are, of all the podophthalmous crustaceans, those in which the various constituent rings of the body are the most equally developed and the most independent of each other. With the exception of those which immediately surround the mouth, all these rings are more or less moveable on each other, and the greater part are complete. The carapace neither covers the first two rings of the head nor the last four rings of the thorax, and constitutes a horizontal buckler nearly quadrilateral, which is divided longitudinally into three lobes, more or less distinct, by two longitudinal furrows. In front of this buckler is a small triangular and moveable plate, which seems to be a dependence of it, and which covers the antennular ring; its form varies, and as it may be an element in specific differences, M. Milne-Edwards terms it the frontal plate. The ring which carries the eyes is small, nearly quadrilateral, and moveable on the succeeding segment; the eyes are large, short, and convex. The antennular ring is also nearly quadrilateral and moveable, but larger, and gives insertion to the internal antennae by its anterior border on each side of the ophthalmic ring. These appendages are directed forwards; their peduncle is long, slender, and composed of three cylindrical joints, and they terminate in three multiarticulate filaments of moderate length. The second pair of antennae are inserted under the anterior border of the carapace, on each side of the antennular ring, and are formed nearly the same as in the Erichthians; the first joint of their peduncle is large and short, and continues itself with an articulation equally stout, which carries at its extremity a great oval blade, analogous to the palp or middle branch of the thoracic limbs, and the basilar scale of the external antennae of the shrimps; the internal branch, which ordinarily is greatly developed, remains here slender, and so small that it only seems to be an appendage of the middle branch; it springs from the anterior angle of the common basilar joint, and presents a peduncular portion, composed of two cylindrical joints and of a terminal multiarticulate filament.

The internal structure of the Squillians differs considerably from that of the Decapods. The heart, instead of being quadrilateral, and inclosed in the middle part of the thorax, has the form of a long vessel, rather enlarged anteriorly, which extends nearly throughout the length of the abdomen as well as of the thorax, and which furnishes laterally in each of the rings which it traverses a pair of arterial branches; by its anterior extremity, this dorsal vessel gives origin to three branches, which seem to be the analogues of the ophthalmic and antennary arteries of the Decapods; and posteriorly it terminates by a small artery which penetrates into the last abdominal segment.

The stomach is very large, and advances into the head very far before the oesophagus, which is vertical and extremely short.

The organs of generation are situated above the digestive apparatus. The nervous system presents nearly the same disposition as in the greater portion of the Macrourous Decapods; in the abdomen the ganglions are well developed, and the cords double; it is the same with the thoracic ganglions of the three last pairs, but all those of the anterior portion of the thorax are united in a single oval mass.

Squilla (Rondeletius).—M. Milne-Edwards points out that the true *Squilla* are probably more carnivorous than the other crustaceans of this tribe, for they are furnished with much more powerful offensive arms. The claw which terminates their raptorial feet has a falcular form, the sharp edge of which is provided with long pointed teeth, and can be received into a groove of the corresponding border of the hand, which is equally compressed, and in general armed with spines on its prehensile border. The three last pairs of thoracic feet carry a slender, cylindrical, and elongated appendage, which represents the palp. The body is in general more slender and narrowed behind the carapace than in the other Squillians.

Squilla are found in the British Channel, but the species which are numerous are abundant only in the seas of warm regions; they keep in general at a distance from the coast, and at considerable depths. Their abdominal false feet are continually in motion, and they swim with great swiftness, striking the water with their powerful tail.

Squilla, seen from above.

M. Milne-Edwards divides the true *Squilla* into two sub-genera:—1, *Squilles Fines-Tailles*; and, 2, *Squilles Trapnes*.

1. Slender *Squilla*.

The species arranged under this sub-genus are remarkable for the narrowing of the posterior portion of their thorax and the gradual enlargement of the abdomen. The sub-genus is divided by M. Milne-Edwards into the following sections:—

a. Species whose abdomen presents above neither crests nor large tubercles, and has its last segment twice and a half as wide as it is long; rounded and hardly denticulated.

S. maculata. Length from 10 to 12 inches. It inhabits the Asiatic seas.

β. Species whose abdomen presents above many longitudinal crests, or large elongated tubercles, and has its last segment in general nearly as long as it is wide.

* Rostral plate not covering the ophthalmic ring.

S. Mantis. Length 6 or 7 inches and upwards. It is found in the Mediterranean.

** Rostral plate entirely hiding the ophthalmic ring.

S. Ferussaci. Length about 4 inches. It is found on the coasts of Sicily.

2. Stout *Squilla*.

This sub-genus has the body very convex, all of a size, without any notable narrowing at the back part of the carapace.

S. stilifera. Length about 3 inches. It is a native of the island of Mauritius.

Gonodactylus (Latreille).—The principal distinction of this genus from the last group lies in the mode of conformation of the raptorial feet. The last joint of these organs, in lieu of having the form of the claw lamellar and strongly denticated, is straight, styliform, more or less convex at its base, and presents at most only vestiges of teeth on its prehensile border, which is enlarged. In general the convexity of the basilar portion is very considerable, and suffices to distinguish these crustaceans at the first glance.

* Rostral plate armed on the median line with a long spiniform tooth.

G. Chiragra. Length about 3½ inches. The species are found in all the seas of warm climates: the Mediterranean, American coasts, Seychelles Islands, near Trincomalee, and Tongataboo.

* Rostral plate rounded and nearly pointed in front.

G. Seyllarus. Length about 4½ inches. It is found in the Indian Seas and on the coasts of Mauritius.

Coronis (Latreille).—This form does not appear to M. Milne-Edwards to differ sufficiently from the *Squilla*, properly so called, to authorise its generic separation; but as he had not observed it himself, he continues to retain it as a genus. The following is Latreille's character:—Lateral and posterior appendage of the third joint of the last six feet (the adactylous and thoracic) in form of a membranous blade or battledore (palette), which is nearly orbicular and a little bordered (rebordée).

C. Scolopendra. (See Guérin, 'Iconographie,' pl. 24, fig. 2.)

STOMATELLA. [HALIOTIDE.]

STOMATES (from the Greek *στόμα*, an 'opening,' or 'mouth'), in Botany, are small longitudinal openings occurring in the epidermis of plants, and usually bounded by two or more lunate or kidney-shaped vesicles.

The first botanist who observed the existence of Stomates was Grew, who, in his 'Anatomy of Plants,' published in London in 1682, gave an imperfect representation of these organs, and stated that they existed on several parts of plants, but he gave them no special name. Malpighi afterwards described their existence in the epidermis of *Marchantiaceae*, where they are very large, but entirely overlooked them in the higher plants. Guettard was the next writer who noticed them, and believing them to perform the office of glands, called them 'glandes miliaires' (glandule miliaires). Saussure also thought them glandular bodies, and called them cortical glands. Hedwig and Gleichen were the first to give accurate drawings of them; and from that time their existence excited general attention, but they received a variety of designations. Hedwig called them Spiraecula and Pori Exhalantes; De Caudolle, Pores Corticaux; Krocke, Rinnes Annulæ; Mirbel, Pores Elongées. Sprengel and other German writers designate them as Spaltöffnungen; Rudolphi called them Pores of the Epidermis; Link proposed the name Stomata, which has since been adopted by De Caudolle, Brongniart, and Mirbel in France, and Lindley and Henslow in England. Link has however since proposed the name of Hautdrüsen (skin-glands), and this term is adopted by Meyen and later German botanists.

The structure of the Stomates is best seen in the monocotyledonous plants, in which they generally occur of a larger size. They are quite imperceptible to the naked eye, but may be discovered by a lens of low power. In general they will be found to consist of two kidney-shaped bodies, which are merely cells of cellular tissue filled with a green matter, and from this circumstance contrast with the transparent cuticle in which they are placed. The kidney-shaped bodies lie with their incurved edges presented to each other, and their extremities unite with each other so that they leave between them a little oval cleft or opening. This opening communicates with the parenchyma of the leaf or other organ underneath the cuticle, and at this point the cellular tissue is loose, and frequently a large cavity is observed, into which the Stomate opens. Nees von Esenbeck, Brown, and others denied at first that the space between the lunate bodies was an opening, but the observation of later writers seems to have proved this point. (Lindley, 'Introduct. Bot.,' p. 52.) This difference among observers may perhaps be explained by the fact that the kidney-shaped bodies have a power of contracting and dilating, and thus closing or opening the space between them. This was first observed by Comparetti, and has since been confirmed by other writers.

The Stomates are not all composed of two cells; those of *Marchantia*, according to Mirbel, are composed of four or five cells, which are arranged circularly, forming an upper outer rim of the Stomate. Sometimes additional cells are found above these, but they differ little, except in their arrangement, from the cells of the tissue by which they are surrounded. This is one of the simplest forms of Stomate. In *Nerium oleander* the Stomates consist of cavities in the cuticle, which are filled up with little hairs. Dr. Lindley has described in *Nepenthes* two sorts of Stomates, "the one oblong, semitransparent, and almost colourless, with numerous pellucid globules in the cavity of the cells; the other roundish, much more opaque, and coloured red." Although the form of the Stomates is most frequently elliptical, they are sometimes quite spherical, as in *Oncidium altissimum*, and Link has noticed them of a quadrangular form in *Yucca gloriosa*.

The Stomates are mostly arranged irregularly upon the surface of the epidermis, occupying generally about equal distances from each other. There are however some remarkable exceptions. In the grasses, for instance, and some other monocotyledonous plants, the Stomates are arranged in regular rows, which run parallel with the bundles of woody tissue which enter into the composition of the leaf. In *Phormium tenax* and in *Pinus* the Stomates are also arranged in a longitudinal series. In *Negonia spathulata* the Stomates on the under surface of the leaves are collected together in the form of little rosettes. The same is seen in *Crassula cordata* and *C. arborescens*.

Stomates are found on plants whenever there is a distinct epidermis, and they exist on nearly all the parts of a plant exposed to the light. In the lower cryptogamic plants, as mosses, *Fungi*, Lichens, and *Algae*, they have never been found. Plants growing in the dark do not possess them, nor are they present on roots or the ribs of leaves. They are

found on the bark of herbs and trees, but in the latter only whilst the bark is herbaceous. In those plants which live under water, as the *Zostera*, *Ceratophyllum*, and *Potamogeton*, they are not found. Those parts of the leaves of some plants which are concealed under the ground, as in the onion, &c., have no Stomates. All the parasitical plants which have not a green colour, as the *Orobanchaceae*, *Lathraea*, and *Monotropa*, are destitute of Stomates, whilst those which are green, as the *Loranthus*, have abundance. They are only rarely found upon the filaments of the stamens, the anthers, or the styles. With the exception of *Canna*, they have not been found on the seeds of plants, nor are they present on fruits, except such as are membranous.

Stomates are not always present on both surfaces of the leaves. They are however much more frequently absent on the upper than on the under surface of the leaf.

The number of stomates contained in a given surface varies very much in different species and families of plants. Many observers have occupied themselves in counting them, and the following table gives the result of some of the observations of Sprengel, Krocke, Thomson, and Lindley on this point:—

Name of Plants.	Observer.	Number of Stomates in a square inch.	
		Under side.	Upper side.
<i>Lilium album</i>	Sprengel	17,280	3,550
<i>L. bulbiferum</i>	Hedwig	83,000	not counted
<i>Tradescantia discolor</i>	Sprengel	9,000	—
<i>Alisma Plantago</i>	Thomson	16,000	12,000
<i>Andromeda speciosa</i>	—	32,000	none
<i>Ilydrangea quercifolia</i>	—	100,000	none
<i>Sempervivum Teetorum</i>	—	6,000	10,710
<i>Rumex acetosa</i>	—	30,000	11,088
<i>Viscum album</i>	—	200	200
<i>Prunus Laurocerasus</i>	Lindley	90,000	none
<i>Orinum amabile</i>	—	20,000	20,000
<i>Stapelia</i> (stem)	—	—	15,000
<i>Cactus</i> (stem)	—	—	15,000
<i>Aloe</i> (leaf)	—	20,000	25,000
<i>Yucca</i>	—	40,000	40,000
<i>Pinus halepensis</i>	Krocke	2,700	—
<i>P. Abies</i>	—	3,600	—
<i>Aloe nigricans</i>	—	7,200	—
<i>Citrus aurantium</i>	—	409,824	—
<i>Solanum sanctum</i>	—	443,704	—

Brown is of opinion that the figure, number, and size of the Stomates might often be made use of to indicate the affinities of genera and natural families of plants, and has proved that this is the case in *Proteaceae*. Schleiden has pointed out the relations and differences of these organs in *Cactaceae*, *Coniferae*, *Piperaceae*, and other orders.

Many different views have been taken of the function of Stomates. That they are organs by which the process of exhalation is carried on as a vital process, there is much reason to suppose. They exist in the greatest abundance in those parts of plants in which this operation is going on, they are also most abundant in membranous leaves, which are known to exhale most, and are deficient in succulent leaves, in which there is little exhalation. It was long ago observed by Comparetti, that the mouths of the Stomates were open by day and closed at night, and this is quite in accordance with what we know of the action of light on the function of exhalation. It is more active in the day, and the mouths of the Stomates are opened to allow of the exit of the vapour. Another argument in favour of this view is derived from the non-existence of Stomates in those families of plants in which no proper transpiration takes place. There is no doubt that the surface of plants absorb moisture when atmospheric conditions are favourable, and it is probable that under those circumstances the Stomates become organs of absorption.

(Meyen, *Pflanzen Physiologie*; Lindley, *Int. Bot.*; De Caudolle, *Organographie Végétale*; Brongniart, *Ann. des Sc. Nat.*, 1834.)

STOMATIA. [HALIOTIDE.]

STOMIAS, a genus of Fishes belonging to the family *Esocidae*. They are distinguished by the muzzle being very short, the mouth very deeply cleft, the opercula reduced to small membranous laminae; the maxillaries fixed to the cheek; the intermaxillary, palatine, and maxillary bones are rather sparingly furnished with teeth, and these are long and hooked, and similar teeth are observable on the tongue. The body is elongated, the ventral fins are placed very far back, and the dorsal fin is placed opposite the anal fin, on the hinder extremity of the body.

Only two species of this genus are known, both of which are inhabitants of the Mediterranean. One, *S. barbatus*, has been so called on account of its having a long barbed on the chin. Both species are of a black colour, but have numerous rows of small silver spots on the abdomen.

STONECHAT. [SAXICOLA.]

STONECROP. [SEDUM.]

STONESFIELD SLATE, a small band of rock separating the Great Oolite from the Inferior Oolite. The accumulation of organic remains in this formation is one of the most remarkable phenomena

known regarding the distribution of the fossils in the Oolitic Rocks. Coniferous, Cycadeous, and Filicoid Plants; Lamelliferous Corals, Conchifers, Gasteropods, Cephalopods, Crustaceans, Insects, Ganoid Fishes, Terrestrial and Aërial Saurians, Marsupial *Mammalia*; all these occur together, and suggest to the naturalist a variety of inferences and speculations. Viewed in their most general relations, the slaty beds of Stonesfield appear to be deposits produced in the sea near the shore in shallow water, at points to which fresh-water currents might send, at intervals, some of the spoils of the land. The Marine Conchifers are often found with valves united, and otherwise in conditions which indicate residence on or near the spot where they are buried; but the broken state of the Land Plants, the scattered elytra of Insects, the detached state of the teeth and bones of Fishes, Saurians, and *Mammalia*, seem the effect of transport from some distance. A great distance cannot well be supposed, for in that case we must imagine the course of a great river, and look for its effects over much wider areas than that of the Stonesfield Fossils. There are several rather similar deposits, and perhaps of the same or nearly the same geological date, in the Oolitic series of Northamptonshire and Yorkshire, but they seem to be due to separate areas of littoral agitation. The Fauna and Flora represented by these fossils is similar to that which now exists in Australia, and has suggested the conclusion that in Australia we have now a condition of the earth's surface such as existed in Europe during the deposition of the Oolitic beds. [OOLITE.]

STORAX. [STRAX.]
STORKS. [CICONIA.]
STRAMONIUM. [DATURA.]
STRAND-WOLF. [HYOENINA.]
STRAPWORT. [CORRIGIOLA.]

STRATA. In Geology, both the separately deposited layers of rock, and the rocks formed of these similar layers, accumulated together, have received the name of Strata. Dr. William Smith uses the term in the latter sense, and in general this is the meaning attached to it in those useful tabular expositions of the 'Series of Strata,' in various districts of the globe, which are now familiar to geologists. In special and local descriptions of rocks, the several beds are commonly enough called Strata (Couches, French). As a general scheme showing the rank frequently assigned to these and other terms, the following view may be useful, the most comprehensive term being to the left:—

Systems, Formations, Strata, Beds, Laminae.

The terms Series and Group are very conveniently employed to collect under one head for purposes of reasoning, any of the laminae, beds, strata, formations, or systems (or parts of one formation and parts of another), without any other limit than that imposed by the principle of grouping. For instance, the Belemnitic Series of strata includes the Lias Formation, Lower, Middle, and Upper Oolite Formations, and the Greensand and Chalk Formations; it includes two systems of Strata: by the Trilobitic Series of strata we may understand the whole of the Palaeozoic Deposits, excepting perhaps the Magnesian Limestone and the oldest of the Slaty Rocks. [STRATIFICATION; GEOLOGY.]

STRATA, ALTERED. [ALTERED STRATA.]

STRATIFICATION. Mineral masses, separately deposited, and arranged into parallel layers under the influence of gravitation, compose a large portion of the known rocky crust of the earth, and are called Stratified Rocks; other masses, in which no such successive deposition and tendency to be bounded by originally horizontal surfaces is traceable, are locally prevalent, and receive the name of Unstratified Rocks. They are generally supposed to be of igneous origin; the former are mostly known to be the fruit of sedimentary aggregation under water. To each class there are exceptions. Parts of certain limestone rocks, formed in water, as modern coral reefs, are really not at all or very slightly stratified; and certain melted rocks which have spread in successive sheets like lava over ancient surfaces, or have been forced by great lateral pressure between really stratified rocks, often assume the stratiform aspect. Without now dwelling on these and several other exceptional cases, it is our purpose to present a general view of the present state of knowledge of the phenomena of stratification, as exhibited in rocks which show clearly the fact of their mineral particles having been separately subject, during the aggregation of the mass, to the influence of gravitation, while partially supported in media lighter than themselves, as water and air, and generally influenced by lateral movements, such as occur in a state of nature in those almost universal fluids.

1. Let us suppose a case of a shower of comminuted mineral matter falling through a limited section of air on the ground. It will be collected in a conical form, the slopes of the cone having reference to the velocity of descent of the sandy particles, the mutual support they yield one to another, and the form of the surface on which they fall. Omitting these sources of variation, the slopes of the conical heap will be generally within moderate limits of uniformity, and the inclination of these slopes constitutes what is called the 'angle of rest.' A second shower of such sandy matters falling uniformly will cover the cone with a parallel sheath, and thus conical strata may result from such operations repeated. (Fig. 1.) The nearest analogy to this type of stratification occurs in a volcanic cone; where however

NAT. HIST. DIV. VOL. IV.

Fig. 1.

the showers of ashes falling not uniformly, but in different quantities in different directions, the result is a streamy or imperfectly concentric stratification, characteristic of the cause, and presenting on a cross-section an appearance as in fig. 2.

Fig. 2.

Horizontal section of strata formed by falling of ashes round a vertical axis irregularly.

2. If further we suppose a shower of ashes or sands to be much affected while falling by horizontal currents of air, in this case the supposed conical heaps of fig. 1 will be drifted so as to show stratification inclined or dipping from the windy quarter. (Fig. 3.) Similar effects might follow the drifting of sand which had fallen into heaps.

Fig. 3.

Laminated deposits of sand by the effect of wind.

If the currents of air changed their direction at intervals, there would arise complication of the strata—oblique stratifications—such as are often seen in sandy rocks and sand-hills; and these would be more or less distinct as the interval between the winds had been marked by vegetation, sediment, or any other cause of consolidation of the surfaces. (Fig. 4.)

Fig. 4.

Oblique lamination in sand and gravel.

3. On surfaces of loose sand once deposited, under whatever of the influences stated, winds have the power of producing other effects: winds eddying among the inequalities of partially grass-grown sand-hills excavate in them circular, oval, or irregular pits, and make ridges and crests of fantastic forms. (Fig. 5.) Winds also wear away by

Fig. 5.

Excavation of cavities in sandhills by wind.

horizontal action the edges of these basins and crests, and make appearances of level stratification, as water which changes level wears its banks in parallel lines. Winds also by their peculiar action on fluid or loose masses, which move with a different velocity from the current of air, produce undulations on the surface of the sand lying across the current, and much resembling the 'ripple or current mark' (which is a secondary phenomenon from the same cause) on the beds of sand below agitated water.

The falling velocity in air of the different sorts of mineral particles which enter into the composition of rocks is not materially different, even if the masses be considerably unequal in size; but both in regard

to falling in water and drifting by wind or water, the specific gravity and the magnitude of the masses require to be taken into account.

For our present purpose it is sufficient to observe that in a mixture of pebbles and sand, subject to drifting, there is an angle of ascent which limits the movement of the pebbles, and yet allows the sands to pass on. Hence, on the sea-coast, the almost stationary pebbly beach is margined on the landward side by parallel ridges of moving sand-hills, and thus a separation is effected of the bases of conglomerates and the bases of sandstones.

If now, instead of comminuted materials falling through air on the land or drifted by wind over its surface, we imagine such materials falling on and sinking in lakes perfectly calm, or the sea always in motion, other effects will follow, and other forms of stratification will result. In a calm lake the sediment may be supposed to fall vertically downwards, and, except the bed of the lake be very irregular, to settle in layers or strata of considerable uniformity. The least lateral movement, by mixing the suspended matter through the water, would tend to widen the deposit, and to fill up the inequalities of the lake-bed, so that by many repetitions a very irregular subaqueous surface would be equalised and levelled. This effect is perhaps actually witnessed in the sediment called *trass* which lies in the valley of Brohl, near Andernach; this is apparently derived from volcanic dust stratified in the water which received the shower of ashes. (Fig. 6.) Besides

Fig. 6.

Arrangement of ashes falling in a lake.

showers of ashes, lakes and the sea receive comminuted mineral substances from shores wasted by tides and storms, and from rivers which transport detritus from the interior of the country. In a very calm lake the sediment from the influx of rivers subsides under the influence of gravitation downward and communicated motion forwards, so that a kind of conical stratification in a delta continually advancing with a level top into the lake is the result. In this delta the arrangement of the strata is probably such as to exhibit successive layers dipping forward into the lake, but there may also be some more horizontal lines depending on the separation of the coarser and finer sediment, owing to their unequal falling velocity in water. Moreover the coarser sediment will fall near the point where the stream enters, and the finer will be longer suspended in water, be transported farther, and rest on more horizontal surfaces, and thus a new complication of the strata will arise, as represented in fig. 7.

Fig. 7.

Deposition of coarse gravel and sand (g) and fine clay (c) in a lake by a river (r).

The earthy materials poured into the sea by rivers follow the same general laws of distribution, but are subject to the additional effects of tides and storms. The effects of these agencies are exhibited in great distinctness on coasts which confront violent winds and the full oceanic flow, and which are margined by pebbles and sands. The sands with ripple-marked surfaces gently inclined extend to some distance below low-water, the pebbles spread upwards in more steeply inclined banks thrown up and left by the breakers in heaps, long parallel ridges, and terraces. A contemporaneous surface of deposition in such cases may be as represented in fig. 8, where clay or sand below

Fig. 8.

Gravel beaches (g), sand beds (s), and fine clay (c) in the sea, under the influence of the tides.

low-water, and pebbles between low and high-water, appear in a continuous layer. Such a surface differs from that found under a calm lake by the concave slope of its pebbly laminae toward the shore, while the lake deposit has convex slopes in the same part.

Such appearances, at least partially, may perhaps be recognised among the strata accompanying coal, and in other groups of rocks where the unequal size of the granular materials and ancient exposure of these to littoral agitation supply the necessary conditions.

Near the shore various causes locally in operation are known to produce on the sea-bed that oblique and variously-directed lamination

which has been already noticed as an effect of wind (fig. 4), and may be seen as an ordinary occurrence in the sections of diluvium, and in the banks of rapid rivers which change irregularly their channel. (Lyell, 'Principles of Geology.') Among the stratified rocks this appearance is common. It occurs in Sussex among wealden strata supposed to be of fluvial origin; at Nottingham in new red-sandstone, which contains no internal evidence of the nature of the water in which it was arranged; in millstone grit of Yorkshire, and in the oolite of Weston near Milton, and Old Down near Bath, which are all deposits from the sea. It is perhaps impracticable to determine by mere inspection of the oblique lamination alluded to, the exact order of phenomena which occasioned it. Tidal agitation, fluvial violence, the force of temporary inundations, sea-currents, each and all of these may have been concerned in the phenomena of this nature, which are so frequent in pebbly sandstones, and in general we may be justified in believing that such appearances may be safely ascribed in most cases to irregular violence of shallow water; while in regard to the more regular and extended parallel lamination of ordinary micaceous sandstones, and still more the fine uniform deposits of clay and argillaceous limestone, must be referred to the wider and gentler influence, and longer suspension due to calmer, that is to say, generally deeper water, farther from shore.

The changes to which the sedimentary deposits, which were the origin of stratified rocks, have been subject since their aggregation, are so considerable, as to gain for them, in extreme cases, the distinctive title of Metamorphic Rocks.

Consolidation of mass is the first of these changes to which we may here allude. It appears to be a phenomenon principally due to pressure: as in the hurried peat of Dartmoor, and the hurried clays of Holderness, the originally light and uncoupled matters have been compressed to some considerable firmness, solidity, and weight; so in respect of ancient clays, mere pressure appears to be a sufficient cause for their condensed, often shaly consistence. But more than this must be appealed to for the induration of slate, coal, limestone, and sandstone. The particles of these rocks cohere with force, by a process of internal molecular arrangement; and it appears to be a fair inference from numerous facts, that among the most influential of the exciting causes of this molecular action is the internal heat of the globe—locally manifested in the induration of stratified masses in the vicinity of trap dykes and other igneous rock-masses, and generally exhibited in the hardness, symmetrical structure, and crystalline aspect of the lower and more ancient strata, which may be supposed to have been more subject, and for a longer time than the others, to the influence of subterranean heat.

Very unequivocal signs of this action of heat appear in the vicinity of the granite rocks of Cumberland, Devon, Cornwall, Wicklow, &c., and perhaps they are seldom absent from such situations. One of the most ordinary of such effects is the development, in the mass of the stratified rocks, of peculiar crystals, as felspar near the granite of Wastdale Head, in virtue of which slates become porphyry; of hornblende and chialotite in those of Skiddaw, just as garnets are developed in argillaceous beds near the trap rocks of Teesdale and Anglesey. [Rocks.]

Some cases of re-arrangement of particles depend on molecular action, not excited by heat, but determined to particular centres by the previous existence there of solidified bodies. Oolite is an example of common occurrence among limestones of the secondary class, and few things are more interesting to examine than a polished slab of the oolite of the mountain limestone of Bristol and Lancashire, or the pisolite of Wilt. In the centre of the spherical grains of the former, and in or near the axis of the less regular nodules of the latter, are grains of sand, bits of shells, or small foraminifera, and round these parallel coats of carbonate of lime are neatly and concentrically arranged. An extremely large and irregular pisolitic nodule gives us the link between these concretionary arrangements and the 'nodules' or 'balls' of limestone and ironstone which inclose pieces of plants, leaflets of ferns, shells, bones, or fish-scales, and lie in parallel layers in the coal-shales, lias-clays, &c. These balls are evidently formed by accretion round the organic objects which they inclose, and the process is the more curious, because the matter of the ball is usually more calcareous or more ferruginous than the surrounding matrix, and seems to have been collected from out of it by some peculiar elective attraction depending on the nature of the organic body. (Fig. 9).

Fig. 9.

Re-arrangement of deposited matter in nodules, round organic or inorganic masses: a, one of these cracked as in *Septaria*.

In addition to this process, it has frequently happened that the 'ball' has been cracked internally across by subsequent contraction during consolidation, and the cracks are filled by carbonate of lime

iron pyrites, silica, &c., introduced through the apparently solid texture of the external parts according to the peculiar circumstances of the operation. Thus by a peculiar species of electrical transfer, analogous to what is supposed in the case of mineral veins, the internal cavities become filled, and the result is the septarium, for whose formation internal heat was once deemed necessary by the advocates of the Huttonian hypothesis. (Playfair, 'Illustrations,' p. 30.) Derived from sources so various, and aggregated under aqueous agencies so diversified in respect of power and direction, it is not surprising that the stratified rocks present themselves in a variety of appearances. It is clear that in the same bed of the ancient sea, or on the same basin of the actual sea, contemporaneous surfaces of deposition might extend over calcareous, argillaceous, arenaceous, and pebbly deposits: that in different basins contemporaneous deposits might be extremely unlike; and that metamorphism, more or less important, must be allowed to have often further increased such original diversity. Yet, notwithstanding these limitations, it appears to be a fact sufficiently established that there are general characters of mineral composition and structural aggregation which are associated with the strata of each great period of the earth's history, so as more or less completely to distinguish one period from another. [GEOLOGY.]

STRATIOTES, a genus of Endogenous Plants belonging to the natural order *Hydrocharidaceæ*. It has a 3-parted calyx and 3 petals. The male flower has 12 or more stamens surrounded by numerous abortive ones. The female has 6 deeply bifid styles. The berry is inferior, 6-celled, and many-seeded.

S. aloides, Water-Soldier, has sword-shaped triangular ciliate spinous leaves. The root creeps extensively in the mud, and sends out rigid leaves like those of an alga. The stalk is compressed, 5 or 6 inches high, with two leaves near its summit. The flower is white and delicate. It is a very ornamental aquatic plant, and is found in ditches in the east of England. It remains under water during the greater part of the year, but raises itself to the surface on special stalks during the season for fertilising the seeds.

STRAWBERRY, the English name of the fruit and plant of the *Fragaria*, a genus of Plants belonging to the natural order *Rosaceæ*. The fruit of the *Fragaria* is one of the most delicious of our summer fruits. The name *Fragaria* is derived from the Latin *Fragum*: and the English name from the practice in this country of cultivating the plant with straw surrounding it.

The genus *Fragaria* is known in its family by possessing a calyx with a concave tube, the limb of which is 10-parted, and the outer 5 segments accessory; 5 petals; stamens and carpels indefinite, the latter placed upon a fleshy and succulent receptacle, forming the juicy and succulent part of the fruit.

The species are perennial plants, throwing out runners; the leaves are trifoliate, each leaflet being coarsely toothed; the receptacle on which is seated the carpels, and which is called the fruit, is round, and assumes a variety of colours from a scarcely perceptible pink to a dark red.

Several species of this genus have been described. Linnæus gave only two; but Willdenow admitted eight; and Don, in 'Miller's Dictionary,' enumerates fourteen. Duchesne, who is followed by many French botanists, makes only two species, and makes the species of other writers varieties of these. All of them are natives of temperate or cold climates; and are found in Europe, America, and the mountains of Asia.

F. vesca, Wood or Alpine Strawberry, has plicate leaves, pilose beneath; the sepals reflexed, and the hairs on the peduncle pressed down. It is found wild in woods and on hill-sides throughout Europe, and is abundant in Great Britain. Duchesne describes eight varieties of this species, mostly characterised by the different form of the fruit or fleshy receptacle. Many of these produce the cultivated varieties which are known in gardens. The *F. v. semperflorens* produces the Red, the White, the American, and Danish Alpine strawberries, all of which are of a fine flavour, and greatly valued. *F. v. minor* produces the Red Wood-Strawberry, or Frasier d'Angleterre, and the White Wood-Strawberry, both very fine kinds. To the *F. v. elatellii* belongs the Red and White Alpine Busb-Strawberry, but these do not produce so good fruit as the last.

F. collina, the Hill Strawberry, has the sepals erect after flowering, and the hairs on the peduncles and calyx erect. This species is a native of Switzerland and Germany, and is characterised by its producing green fruit. The varieties of strawberries which are called Green are the produce of this species. In flavour and size they are only a second-rate strawberry.

F. Majaufea, the Majaufe of the French.

F. elatior, the Hautbois Strawberry, has the sepals reflexed on the peduncle, the hairs of the peduncles and petioles extending horizontally. It is a native of North America, and is occasionally found in groves in the south of England. The shape, size, and colour of the fruit of the Hautbois are subject to great varieties, according to its mode of cultivation. It is the parent of a great number of sorts known in gardens, most of which, when properly managed, produce fruits of a first-rate kind.

F. Virginiana, the Virginian Strawberry.

F. grandiflora, Large-Flowered Strawberry, is a native of Surinam,

and has furnished our gardens with the sorts called Pine Strawberry.

F. Chilensis, Chili Strawberry, is a native of South America, both in Chili and Peru.

STRAWBERRY-TREE. [ARBUTUS.]

STREPSICERUS. [ANTILOPEÆ.]

STREPSILAS. [CHARADRIADÆ.]

STREPSIPTERA, an order of Insects, remarkable for having the anterior wings transformed into a pair of short, slender, contorted appendages, whilst the posterior are very large, and fold in the manner of a fan. The mouth is armed with two slender acute jaws and two 2-pointed palpi. The tarsi are 2-3- or 4-jointed. The larva is vermiform, and has no feet. The pupæ are inactive. They are all very small creatures, the largest not so long as a quarter of an inch. The larvæ are parasitic on the bodies of wasps and bees. The perfect insects are very short-lived, but very active.

These insects are the *Rhipiptera* of Latreille (*Diptera Rhipidoptera* of Lamarck). Their systematic position has been much debated.

They were first observed by Mr. Kirby, who gives the following account of his discovery:—Observing acarid-like animals infesting the abdomens of various *Andrena*, he attempted to remove one, and to his surprise drew from the body of the bee a white fleshy larva a quarter of an inch long, the head of which he had mistaken for an acarid. "How the animal receives its nourishment seems a mystery. Upon examining the head under a strong magnifier, I could not discover any mouth or proboscis with which it might perforate the coriaceous covering of the abdomen, and so support itself by suction; on the under side of the head, at its junction with the body, there was a concavity; but I could observe nothing in this but a uniform unbroken surface. As the body of the animal is inserted in the body of the bee, does that part receive its nutriment from it by absorption? After I had examined one specimen, I attempted to extract a second; and the reader may imagine how greatly my astonishment was increased, when, after I had drawn it out a little way, I saw its skin burst, and a head as black as ink, with large staring eyes, and antennæ consisting of two branches, break forth and move itself briskly from side to side. It looked like a little imp of darkness just emerging from the infernal regions. I was impatient to become better acquainted with so singular a creature. When it was completely disengaged, and I had secured it from making its escape, I set myself to examine it as accurately as possible, and I found, after a careful inquiry, that I had not only got a nondescript, but also an insect of a new genus, whose very class seemed dubious." ('Monographia Apium Angliæ,' vol. ii. p. 111.)

Stylops and *Xenos* are the only two genera belonging to this order.

(Westwood, *Families of Insects*.)

STREPTAXIS (J. E. Gray), a genus of *Mollusca*, separated from *Helix* on account of the eccentricity of the penultimate whorl. [HELICIDÆ.]

STREPTOSPONDYLUS, H. Von Meyer's name for an extinct genus of Reptiles belonging to the Colospondylus tribe of the Crocodilian order in the arrangement of Professor Owen, who thus defines the vertebral characters of this highly-interesting form, the *Stenosauros rostro-major* of Geoffroy, and the Crocodile d'Honfleur of Cuvier:—

"The distinguishing vertebral characters are a ball-and-socket articulation of the bodies of the vertebrae; but the positions of the ball and cavity are the reverse of those in the existing crocodiles, the convexity being on the anterior part of the vertebra, and the concavity directed backwards. In the anterior vertebra, which have the ribs articulated with the body, there is a deep pit behind the costal articular surface; the transverse process rises by four salient ridges, one from each oblique process, and the two inferior and principal ones from the base of the neuropophysis; these ridges converge at an acute angle as they ascend, and meet at the under part of the transverse process, so as to include a triangular space, which is deeply concave. A third salient ridge ascends from the fore part of the base of the neuropophysis to the anterior oblique process, nearly parallel with the posterior of the two last mentioned ridges, so that the side of each neuropophysis appears as if marked with the letter N in high relief. In the cervical and anterior dorsal vertebrae there are, instead of a single inferior spinous process, two ridges, which terminate each in front by a tubercle." ('Report on British Fossil Reptiles,' British Association.)

Portions of the remains of this animal have been found in the Oolite in the vicinity of Chipping Norton, among which the anterior half of an anterior dorsal vertebra belonging to this animal, and in the collection of Mr. Kingdon of that town, is minutely described in Professor Owen's report. Other vertebrae were also found.

A portion of a compressed conical hollow tooth, with a brown dense glistening dentine, resembling that of the *Megalosaurus*, was associated with the vertebra. The length of this fragment is 2 inches 4 lines, but both ends are wanting. The breadth is 8 lines; the thickness 5 lines.

"If it really belongs to the *Streptospondylus*," says Professor Owen, "it confirms the view of the affinity of that genus to *Megalosaurus*, which has been suggested by the characters of the vertebra."

Professor Owen notices a posterior dorsal vertebra from the jet-rock

(lias shale) near Whitby (much more complete than the preceding specimen, and nearly corresponding in size with the dorsal vertebrae of the Honfleur *Streptospondylus* described by Cuvier), in the collection of Mr. Ripley of Whitby; and informs us that the third British formation in which he has determined the remains of the genus is the Wealden, specimens having been obtained from three localities, namely, Tilgate Forest, in Sussex, and Brook Point and Culver Cliff, in the Isle of Wight. The specimens, he observes, differ in size, being larger than the *Streptospondylus Cuvieri* from the Oolite, and he strongly suspects that they indicate a different species; indeed he names it *Streptospondylus major*, but remarks that the means of comparison for the satisfactory establishment of the distinction are as yet wanting. Professor Owen also makes mention of a cervical vertebra associated, as in the Mantellian Collection, with vertebrae of the *Iguanodon* and *Cetiosaurus*, which had been washed out of the submarine Wealden beds at the south side of the Isle of Wight, and thrown on shore near Culver Cliff and Brook Point. Some idea of the size of this reptile may be derived from Professor Owen's measurements, which give 5 inches as the transverse diameter of the posterior concave articular surface in the Wealden, and 6 inches in the Culver Cliff specimen, whilst the transverse diameter of the body across the inferior transverse processes is 6 inches in the Tilgate, and 6 inches 6 lines in the Culver Cliff specimen, the height of the latter from the lower surface of the centrum to the hind part of the base of the spine being 7 inches 9 lines.

The foreign localities in which remains of *Streptospondylus* have been found are the Oxford clay formation at Honfleur, and the Kimmeridge clay at Havre (Cuvier); and the Lias of Altdorf (H. Von Meyer).

The form of this extinct Saurian is highly interesting, for it presents those transitional characters which, while they beautifully manifest the passage, so to speak, from one specific form to another, are too apt to lead a superficial observer to wild speculations. Professor Owen, in his luminous argument at the close of the valuable Report above quoted, against the transmutation theory—fallacy, we would venture to call it—of Maillet, Lamarck, the less learned author of the 'Vestiges of the Natural History of Creation,' and their followers, observes that if the three forms of extinct Saurians, *Ichthyosaurus*, *Plesiosaurus*, and *Teleosaurus*, whose changes of specific and generic characters have thus been speculated upon, had actually succeeded each other in strata successively superimposed in the order here set forth, some colour of probability might attach itself to this hypothesis, and there would be ground for searching more closely into the anatomical and physiological possibilities of such transmutations. Those genera however, he observes, appeared contemporaneously on the stage of vital existence; one neither preceded nor came after the other. How the transmutation theory is to be reconciled to these facts is not, he justly observes, obvious, nor to these other, namely, that the *Teleosaurus* ceases with the oolite, while the *Ichthyosaurus* and *Plesiosaurus* continue to co-exist to the deposition of the chalk, and disappear together alike unchanged; the *Ichthyosaurus* manifesting as little tendency to develop itself into a *Plesiosaurus* as this to degrade itself into the more fish-like form of the *Enaliosaurian* type.

"If," says Professor Owen, "it were urged that the *Streptospondylus*, or crocodile with ball-and-socket vertebrae, of which the remains occur in later secondary strata, when the *Teleosaurus* had ceased to exist, might be a modification of the apparently extinct Amphicoelian Crocodile, in which the vertebrae had undergone a progressive development analogous to that by which the biconcave joints of the vertebrae of the tadpole are actually converted into the ball-and-socket joints of those of the mature Frog, the facts of both geology and anatomy again oppose themselves to such an hypothesis; for the remains of the *Streptospondylus* occur likewise in the Whitby Lias, which is the earliest formation characterised by remains of the *Teleosaurus*; and the modification of the vertebral structure by which the *Streptospondylus* differs from its ancient contemporary, and which it retains unaltered throughout the whole series of oolitic strata, is no approximation to the ball-and-socket structure of modern crocodiles, which first appears in the *Mosasaurus* and the Eocene Crocodiles, but is the very reverse. As reasonably might we infer that the *Teleosaurus* was an intermediate form between the *Streptospondylus* and modern crocodiles, and that the anterior ball had first subsided, and a sub-biconcave type of vertebra had been produced before the posterior ball which characterises the vertebra of recent crocodiles was finally developed. If the present species of animals had resulted from progressive development and transmutation of former species, each class ought now to present its typical characters under their highest recognised conditions of organisation; but the review of the characters of fossil reptiles taken in the present Report proves that this is not the case. No reptile now exists which combines a complicated and thecodont dentition with limbs so proportionally large and strong, having such well-developed marrow-bones, and sustaining the weight of the trunk by synchondrosis or ankylosis to so long and complicated a sacrum, as in the order *Dinosauria*. The *Megalosaurs* and *Iguanodons*, rejoicing in these undeniably most perfect modifications of the Reptilian type, attained the greatest bulk, and must have played the most conspicuous parts in their respective characters as devourers of animals and feeders upon vegetables that this earth has

ever witnessed as oviparous and cold-blooded creatures. They were as superior in organisation and in bulk to the crocodiles that preceded them as to those which came after them."

There is not the slightest ground for affirming that the procolian gavia of the present day is in any respect more highly organised than the opisthocelarian gavia of the oldest lias. If the differences of vertebral structure in these crocodilians were contrasted in reference to their relative approximation to the vertebral structure of the higher animals, the resemblance of the ball-and-socket joints of the spine of the *Streptospondylus* to those of certain mammals would give precedence in organic perfection to the primæval gavia. If therefore the extinct species, in which the Reptilian organisation culminated, were on the march of development to a higher type, the *Megalosaurus* ought to have given origin to the carnivorous *Mammalia*, and the herbivorous should have been derived from the *Iguanodon*. "But where is the trace of such *Mammalia* in the strata immediately succeeding those in which we lose sight of the relics of the great Dinosaurian Reptiles; or where indeed can any mammiferous animal be pointed out whose organisation can by any ingenuity or licence of conjecture be derived, without violation of all known anatomical and physiological principles, from transmutation or progressive development of the highest reptiles? If something more than a slight inspection be bestowed upon the organic relics deposited in the crust of the globe, we learn that the introduction of *Mammalia* on that crust is independent of the appearance of the highest forms of reptiles. The small insectivorous mammals of the lower oolite are contemporary with the most ancient *Dinosaurius*, and are anterior to the *Iguanodon*. The period when the class of reptiles flourished under the widest modifications, in the greatest number, and of the highest grade of organisation, is passed; and since the extinction of the Dinosaurian order it has been declining. The *Reptilia* are now in great part superseded by higher classes. Pterodactyles have given way to Birds; *Megalosaurs* and *Iguanodons* to carnivorous and herbivorous *Mammalia*; but the sudden extinction of the one and the abrupt appearance of the other, are alike inexplicable on any known natural causes or analogies." (Owen.)

STREPTOSTACHYS. [GRAMINACEÆ.]

STRIGATELLA. [VOLUTIDÆ.]

STRIGIDÆ, a family of Birds, including the Nocturnal Birds of Prey commonly known as Owls.

This natural family have large heads and great projecting eyes directed forwards, and surrounded with a circle or disc (more or less developed according to the nocturnal or comparatively diurnal habits of the species) formed of loose and delicate feathers; a raptorial beak; crooked claws; and a downy plumage, generally spotted, powdered, or barred with different shades of brown and yellow.

Mr. Yarrell, in his paper on the 'Anatomy of Birds of Prey' ('Zool. Journal,' vol. iii.), points out the diminished extent of surface and power in the sternum of the Owls as compared with that of the Pere-

Sternum of Wood-Owl (*Strix Stridula*). (Yarrell.)

grine Falcon. [FALCONIDÆ.] And he observes, that from the loose and soft nature of the plumage in these birds, as well as their deficiency in muscle and bone, rapid flight is denied them as useless, if not dangerous, from the state of the atmosphere at the time they are destined to seek their food; but, he adds, they are recompensed for this loss, partly by their acute sense of hearing, from an extension of the posterior edge of the cranium forming a conch, coupled with a very large external orifice; and partly by the beautifully serrated exterior edge of the wing primaries, which, allowing them to range without noise through the air, enables them to approach unheard their unsuspecting victim, which falls a prey to the silent flight and piercing eye of an inveterate enemy. He further remarks, that some increase and variation will be found in the strength and form of such of the Owls as depart from the type of the true nocturnal bird. In the Screech Owl and Short-Eared Owl, which are described as occasionally taking their food by day, the furcula, Mr. Yarrell observes, is stronger and less angular in proportion than in the Wood- and Barn-Owls. The trachea, he tells us, of the different species of Owls so nearly resembles the same part in the Falcons, that a separate description is unnecessary, and the same may be said generally of the oesophagus, stomach, and intestines, as the similarity of food would appear to require. Mr. Yarrell found the two caecal appendages considerably developed in the species of *Strix*; in the Barn-Owl (*S. flammea*), as

well as in the Short-Eared Owl, they are, he states, small at their origin, afterwards dilated, and each one inch and three-quarters in length. The crop is large, and the stomach or gizzard is considerably muscular notwithstanding the nature of their living prey. The brain is well developed in this family, and the senses of sight, hearing, taste, and smell, especially the two former, are enjoyed in a considerable degree of perfection. Mr. Yarrell observes (loc. cit.) that the external form of the bony ring in the Golden Eagle [FALCONIDÆ] will be found to extend through all the species of every genus of British birds, except the Owls, in all of which it is concave. The bony ring of the Snowy Owl has fifteen plates forming the circle, and they are considerably lengthened. The transparent cornea being placed as it were at the end of a tube is thus, he remarks, carried forward beyond the intervention of the loose and downy feathers of the head. It is this

1, bony ring of a Snowy Owl; 2, crystalline lens of the same bird; a, the anterior surface, less convex than the posterior one. (Yarrell.)

position of the eyes, observes the same author, giving a particular fulness and breadth to the head, which has gained for the Owl the intellectual character universally awarded to it. The concave facial disc of feathers with which they are surrounded materially aids vision by concentrating the rays of light.

Head of Barn-Owl (*Strix flammea*).

The sense of hearing appears to be very acute in the *Strigidae*: they not only look, but listen for prey.

Head of a young White or Barn-Owl (*Strix flammea*).

The down pressed backwards and forwards, to expose the auditory passage and operculum. a, cranium; b, bill perforated by the nostril; c, neck; d, eye; e, termination of external skin surrounding the orifice of the ear; f, anterior flap or opercular fold of the ear; g, part of the tympanic or quadrate bone; h, membrana tympani. ('Cat. Mus. Coll. Chr.,' vol. iii.)

Smell, taste, and touch appear to be developed nearly as they are in the *Falconidae*. Preparations of the structure of the *Strigidae* are to be seen in the Museum of the Royal College of Surgeons of England in London.

Foot of White or Barn-Owl (*Strix flammea*).

'Zoologists are generally agreed in the position assigned to the Owls. In Belon and Gesner we find them next to the diurnal birds of prey. In the work of the former the Cuckoo indeed intervenes; but the external similitude between that species and the birds of prey accounts for the intervention. In Gesner the Shrikes come between the diurnal and nocturnal predacious birds.

Willughby divides the birds of prey into the diurnal and the nocturnal, placing in the last subdivision of the former the Butcher-Birds and Birds of Paradise. The latter he separates into two sections—1, the horned, or eared; 2, those without horns.

Brisson places the Owls in the second section of his third order, which consists of birds with a short and hooked bill. This second section is defined as comprising species the base of whose bill is covered with feathers directed forwards.

The genus *Strix* stands among the *Accipitres* in the 'Systema Naturæ,' between the genera *Falco* and *Lanius*, which last concludes that order of Linnæus.

Latham places the Owls at the end of the birds of prey, and so do Lacépède, Duméril, and Meyer. Illiger, on the contrary, makes the *Nocturni* the first of his order *Raptatores*. Cuvier makes them follow the *Diurnes*; and they immediately precede the *Passeræaux*, among which last the Butcher-Birds hold the first place in the first family, *Dentirostres*. Vieillot arranges the Owls with the family name of *Ægoliæ*, under his second tribe (*Nocturni*) of his first order *Accipitres*.

M. Temminck places them at the end of his first order (*Rapaces*); and, in his 'Manuel' of European birds, divides the family of Owls into two divisions—1st, the Chouettes, properly so called; 2nd, the Chouettes Hibous.

The first division, or Chats-Huants, he subdivides into two sections, placing in the first section the *Accipitrine* Owls, or those which see well and pursue their prey by day; and in the second section the *Nocturnal* Owls, which hunt in no light stronger than twilight or moonlight, and conceal themselves during the day.

In the first section of the first division M. Temminck places the following species:—*Strix Lapponica*, *S. nyctea*, *S. Uralensis*, and *S. funerea*.

In the second we find *S. nebulosa*, *S. Aluco*, *S. flammea*, *S. passerina*, *S. Tengmalmi*, and *S. Acadica*.

Under the second division, Chouettes Hibous, distinguished by two tufts of feathers situated more or less forward upon the front, and capable of erection (whence their English appellation of Horned Owls), he arranges *Strix brachyotus*, *S. Bubo*, *S. Otus*, and *S. Scops*.

Mr. Vigors, who makes his first order (*Raptatores*) consist of the families *Vulturidae*, *Falconidae*, *Strigidae*, and *Gypogeranidae*, says, that if we search for the connection between the *Falconidae* and the *Strigidae*, we shall not fail to find their affinity apparent, as is usual, in the less typical part of the two groups.

Mr. Swainson states that the divisions of the *Strigidae* made by modern ornithologists can all be referred to one or other of the following groups:—1, Typical Owls, having the facial disc very large and complete, with large ears and (in general) an ample operculum; 2, Horned Owls, furnished with egrets and a large facial disc, but having only small or moderate-sized ears; and 3, Diurnal or Hawk-Owls, where the conch of the ear is comparatively small, and is destitute of an operculum: the head has no egrets, and the facial disc is imperfect or obsolete. The first he considers the typical group; the second the subtypical; and the third the aberrant group.

The following table gives Mr. Swainson's arrangement of the entire family:—

Strigida.—The Owls.

- | | |
|--|------------------------|
| 1. Typical Group.—Ears large, operculated, no egrets | Genera. <i>Strix</i> . |
| 2. Subtypical.—Ears smaller, no operculum, egrets | Asia. |
| Ears small, no egrets or operculum, disc imperfect. | |
| 3. Aberrant.—Head small, claws feathered, tail short | <i>Nyctea</i> . |
| Head large, claws naked, tail moderate | <i>Nyctipetes</i> . |
| Head small, claws feathered, tail wedged | <i>Surnia</i> . |

Mr. G. R. Gray makes the *Accipitres Nocturni* the second sub-order of his first order *Accipitres*. His third family, the first of that sub-order, is formed the *Strigida*, which are thus subdivided by him:—

Sub-Family 1.—*Surnina*.

Genera.—*Surnia*, Dum. (*Surnia*, Steph., *Strix*, Gm.); *Accaba*, Wagl. (*Surnia*, Cuv., *Strix*, Shaw); *Nyctea*, Steph. (*Noctua*, Cuv., *Nyctia*, Sw.); *Athene*, Boie (*Nyctipetes*, Sw., *Strix*, Daud.); *Hukua*, Hodgs.

Sub-Family 2.—*Bubonina*.

Genera.—*Scops*, Sav. (*Scops*, Sav., *Asio*, Briss., *Otus*, Less., *Strix*, Linn.); *Lophostrix*, Less., *Kelupu*, Less. (*Cultrunguis*, Hodgs., *Strix*, Gm.); *Bubo*, Sibb. (*Feliceps*, Barr., *Asio*, Antiq., *Ulula*, Bonap., *Heliap-ter*, Sw., *Ascalaphus*, J. Geoff., *Strix*, Linn.).

Sub-Family 3.—*Uulina*.

Genera.—*Syrnium*, Sav. (*Scotiapterx*, Sw., *Ulula*, Briss., *Strix*, Linn.); *Otus*, Ray (*Asio*, Briss., *Brachyotus*, Gould, *Strix*, Linn.); *Urrua*, Hodgs.; *Nyctalops*, Wagl.; *Ulula*, Cuv. (*Strix*, Gm.); *Glaucidium*, Boie (*Strix*, Linn., *Noctua*, Cuv., *Athene*, Boie); *Nyctale*, Brehm (*Scotophilus*, Sw., *Nudipetes* and *Ptilipetes*, Less., *Strix*, Bechst., *Athene*, Boie); *Ninox*, Hodgsou.

Sub-Family 4.—*Strigina*.

Genera.—*Strix*, Linn.; *Pholidus*, J. Geoff. (*Strix*, Horsf.); *Bulaca*, Hodgsou.

The geographical distribution of this family is very wide; extending as high as the Polar Sea, where *Strix Nyctea* is recorded by Sabine as having been seen on the islands in the summer months, and by James Ross as having been observed about Victoria Herhour throughout the winter, where several pairs had bred in the preceding autumn; and as low at least as Port Famine in the Straits of Magellan (*Strix rustipes* and *S. nana*, &c., King). Species are found in Europe, Asia, Africa, America, and in Australia.

They feed on birds and quadrupeds, and even fish (in the case of *Strix nyctea* and *S. flammea*), according to the size of the species. Hares, partridges, grouse, and even the turkey, are attacked by the larger horned owls of Europe and America; while mice, shrews, small birds, snakes, and crabs suffice for the inferior strength of the smaller *Strigida*. Mr. Yarrell states that the Short-Eared Owl (*Strix brachyotus*) is the only bird of prey in which he ever found the remains of a bat.

The species are numerous, and the British Museum contains a very fine collection of them. Our limits will not permit us to do more than notice a very few. The larger horned owls are described in the article *Bubo*.

Strix flammea, the common White or Barn-Owl, is the Effraie, Fressie, and Petit Chathuant Plombé of the French; Barbagianni, Alloco Comune e Bianco of the Italians; Schloierkauz, Perlshlierkantz, and Perl-Enle of the Germans; De Kerkuil of the Netherlands; Barn-Owl, White Owl, Church-Owl, Gillihowlet, Howlet, Madge-Howlet, Madge-Owl, Hissing-Owl, and Screech-Owl of the English; and Dylluan Wen of the Welsh. The upper parts are bright yellowish, varied with gray and brown zig-zag lines, and sprinkled with a multitude of small whitish dots; face and throat white; lower parts in some individuals rusty-white, sprinkled with small brown dots; in others bright white, marked with small brownish points; in others again without the slightest appearance of spots; feet and toes covered with a very short down, more scanty on the toes; iris yellow. Length about 13 inches. In the female all the tints are brighter, and more developed. The young are covered with a thick white down, and remain long in the nest. Mr. Blyth states that the first set of feathers grows very slowly, and is not moulted till the second autumn.

Varieties.—Whitish, or entirely white.

This bird is common in England and Ireland, less common in Scotland. Not common in the Orkneys, but present in some of the islands. Found in Denmark, but said not to inhabit Sweden or Norway; generally spread over temperate Europe; found in Madeira; common in Lorraine; extending in Africa from the north to the Cape of Good Hope; met with in India, Japan, and Australia.

Montagu says that this species is never known to hoot. Mr. Yarrell states that it screeches, but does not generally hoot. Sir W. Jardine declares that he shot one in the act of hooting; and that at night, when not alarmed, hooting is their general cry. It snores and hisses, and, like other owls when annoyed or frightened, snaps its bill loudly. Rats, mice, shrews, young birds, and beetles, form their food, and the mice especially suffer when the White Owl has a young brood to sustain. It has been seen to catch fish. This owl frequents

churches, old buildings, and barns, often breeding in the latter, as well as in hollow trees near farmyards and villages. The nest is but a rough one, and the female lays three or four white eggs more oval than those of the Brown or Ivy-Owl, and not so large. Young have been found so late as July, September, and even December. Mr. Blyth, in the 'Field Naturalist's Magazine' (vol. i.), throws some light upon this. "A nest of the Barn-Owl last summer," says he, "in this neighbourhood (Tooting), contained two eggs, and when these were hatched two more were laid, which latter were probably hatched by the warmth of the young birds; a third laying took place, after the latter were hatched, and the nest at last contained six young owls of three different ages, which were all reared." Mr. Yarrell states that he has been frequently told by boys in the country, that they had found eggs and young birds at the same time in this bird's nest. The food is generally swallowed whole, and the bones and fur or feathers rejected in pellets called castings, as indeed is generally the case with this family.

In captivity the Barn-Owl is sociable with other birds, but will sometimes, like the dogs, hide what remains of its meat.

Barn-Owl (*Strix flammea*).

Surnia Uralensis, the Ural Owl, is the *Strix Uralensis* of Pallas; *S. liturata*, Retz; *S. macroura*, Natterer; *S. macrocephala*, Meisner; La Chouette des Monts-Urals, Sonnini; Die Ural Hablehtseule, Bechstein; Hablehtseule, Naumanu; Uralischer und Grossköpfiger Baumkauz, Brehm.

The face is whitish; tail much graduated, much longer than the wings; all the plumage striped with large longitudinal spots and streaks.

Old of both Sexes.—The head is of considerable size; face very large, well feathered, grayish-white, marked with some blackish hairs; a large circle of white feathers spotted with brownish-black, takes its origin on the forehead, and frames in the whole face; top of the head, nape, back, and wing-coverts, marked with great longitudinal spots, which are disposed on a whitish ground; throat, front of the neck, and all the lower parts whitish, marked on the middle of each feather with a large longitudinal brown stripe; quills and tail-feathers banded with brown and dirty white alternately; seven of these bands may be counted on the tail; beak yellow, nearly hidden in the long hairs of the face; iris brown; tarsi and toes covered with white hairs marked with small brown points; claws very long, yellowish. Length of tail 10 inches and some lines; total length about 2 feet.

Young of the Year.—All the ground-colour of the plumage bright brownish-gray; the spots and stripes on all the lower parts ashy-brown; upper parts irregularly spotted with ashy-brown and light red, and variegated with oval white spots; wings and tail transversely banded with grey, the seven bands of the tail whitish-ash.

It is found in the arctic regions of the Old World, Lapland, North of Sweden, Norway and Russia, Livonia and Hungary, and Japan. Very rare in the eastern parts of Germany; very accidentally found elsewhere. Mr. Gould regards it as one of the rarest European Owls.

It eats leverets, cats, mice, ptarmigan, and small birds. The nest is formed in the holes of trees, often near the habitations of man. Mr. Gould states that the number of eggs is two; M. Temminck says three or four: they are pure white.

Ural Owl (*Surnia Uralensis*).

Surnia funerea, the Canada Owl. It is the *Strix Ulula*, Linn.; *S. funerea*, Gm.; *S. Hudsonia*, Gm.; *S. Canadensis* et *Frati Hudsonis*, Brisson; *S. Hudsonia*, Wils.; *S. nisoria*, Meyer; Chouette de Canada et Chouette Epervière, on Caparacoch, and Chouette à Longue Queue de Siherie, Buffon ('Eul.' 463, a very good figure of this species, under the erroneous name of the Ural Mountain Owl); Chouette Epervière, Sonn.; Sperebule, Meyer; Naum.; Habichtseule, Bechst.; Plattköpfige and Hochköpfige Habichtseule, Brehm.; Hawk-Owl of Pennant and Wilson; Little Hawk-Owl of Edwards; Paypaw Theecawsew, or Cobadecootch of the Cree Indians; Theechazza of the Copper Indians and Chepewyans; and Ood no Hæoot of the Esquimaux.

The forehead is dotted with white and brown; a black band takes its origin behind the eyes, includes the orifice of the ears as in a frame, and terminates on the sides of the neck; upper parts marked with brown and white spots of various forms; on the borders of the wings are similar white spots disposed on a brown ground; throat whitish; the other lower parts white, transversely striped with ashy-brown; at the insertion of the wings a great spot of blackish-brown; tail-feathers ashy-brown, striped at considerable distances with transversal narrow zigzags; bill yellow, varied with black spots according to age; iris bright yellow; feet feathered to the claws. Length of tail 6 inches and some lines. Total length upwards of 14 inches (Temminck); Richardson says 18 inches.

Profile of Hawk-Owl (*Surnia funerea*).

The colours of the female are less pure than those of the male, and she is rather larger.

It is found in the Arctic Circle and Arctic regions of both continents; sometimes seen as a bird of passage in Germany, more rarely in France, but never in the southern provinces.

The visual organs of this species are more able to hear the light of day, at least in dull weather, and, like the Snowy Owl, it hunts frequently in the day-time. The smaller head and less perfect facial disc, combined with these habits, have obtained for it the name of Hawk-Owl.

Hawk-Owl (*Surnia funerea*).

Surnia nyctea, Snowy or Ermine Owl. It is the *Strix nyctea*, Forster, Latham, and Gmelin; *S. candida*, Latham; *S. nivea*, Daudin; Chouette Harfang, Buffon; Chouette Blanche, Le Vaillant; Alucco Diurno, 'Stor. degl. Ucc.'; Schneekauz, Bechst.; Sneuwuil, Sepp.; Nordicher Schneekautz and Schnee Eule, Brehm; Great White Owl, Edwards; Snow-Owl, Wilson; Wapow-Keetho or Wapohoo of the Cree Indians; and Ookpeegwak of the Esquimaux.

Head small in proportion; bill black, entirely hidden by the hairy feathers at its base; plumage snow-white, but more or less variegated with transverse brown spots or stripes; the younger the bird is, the larger and more numerous are these spots and stripes; very old individuals are pure white, without any brown spot; iris fine orange-yellow; feet very well covered, so as to look almost woolly to the claws; tail rounded, not much exceeding in length the extremity of the wings. Length 24 or 25 inches. Female considerably larger than the male.

Young at the time of departure from the nest covered with brown down; the first feathers bright down.

It is found in the Arctic regions of the Old and New World, Iceland, Sweden, Norway, Lapland, and the north of Europe generally.

Specimens in different stages of plumage are generally to be seen in the garden of the Zoological Society in the Regent's Park.

The following are also European species:—*Bubo maximus**, *B. Acalaphus*, *Otus vulgaris**, *O. brachyotus**, *Scops Aldrovandi**, *Surnia cinerea*, *Ula nebulosa*, *Syrnium Aluco**, *Noctua nudipes** (Gould—*Strix nudipes*, Auct.), *Noctua Tengmalni**, and *N. passerina** (Gould—*Strix passerina*, Auct.).

(Those marked * are in the 'Catalogue of British Birds.' Mr. Yarrell gives *Strix passerina* and *Noctua nudipes*, Gould, as synonyms.)

Strix badia, Horsf., Wowo-wiwi, or Kalong-wiwi of the Javanese, is an Asiatic species. Dr. Horsfield states that this species, whose head is proportionally large, has a general resemblance to *S. flammea* in the distribution of its colours and external marks. The upper parts are, he observes, generally dark, and the lower of a paler hue. The neck is surrounded by a loose ornamental collar; the plumes encircling the eyes are rigid, and disposed with perfect regularity, and the legs are entirely covered. A resemblance also exists, he adds, in the lustre of their covering. It is a native of Java, in the closest forests of the district of Pugar, and the ranges of low hills south of the capital of Surakarta. (Horsfield.)

The habits of this species are nocturnal. Dr. Horsfield speaking of *S. Javanica* (which, he says, his specimens show to be merely a variety of *S. flammea*), remarks, that it is the only species of this division

which is occasionally found near villages and dwellings. "It is not however a favourite with the natives; various superstitious notions are also in Java associated with its visits; and it is considered in many parts of the island as protending evil. The other species of this division are by no means common, and the *S. badia* is one of those that are most rarely met with. It never visits the villages, but resides in the closest forests, which are the usual resort of the tiger. The natives even assert that the Wowo-wiwl approaches this animal with the same familiarity with which the Jallak (the Pastor Jalla of our catalogue) approaches the Buffalo, and that it has no dread to alight on the tiger's back." Dr. Horsfield adds, that it is never seen in confinement.

The same author states that eight species of owls from Java have been arranged in the museum at the India House; three eared-owls, and five smooth-headed.

S. Capensis, Smith, the Cape Owl. It is red brown above, scantily sprinkled with small white spots, pale ochreous red below, marked with small heart-shaped spots; face yellow-brown; cervical collar pale buff-orange, with many of the feathers, particularly on its inferior portion, tipped with brown; quills subochreous, banded with brown; eyes brownish-black; bill and feet livid or straw-yellow; legs long, upper half of the tarsi covered with feathers, lower half and toes covered with small flat circular scales, upon which are a few strong rigid bristles, claws long, dark brown-colour, slightly covered and pointed. Length 16 inches. The whole of the plumage has a silky gloss. Female considerably larger than the male, and with the colours less clear. The down of the nestling is dull cream-yellow, plumage of the upper parts during the first year darker than in adult birds. (Smith.)

Dr. Smith states that the few specimens which he saw were obtained near Cape Town, close to Table Mountain, in the rocky precipices of which they were said to have concealed themselves during the day. He adds, that the colonists recognise this bird as distinct from the Doodvogel (*Strix flammea*), which occurs abundantly throughout the whole of South Africa, and that it is at once to be distinguished by its size from the *Strix badia* of Horsfield, the species to which it is by colours most nearly allied.

Dr. Smith also figures and describes another Typical Owl (*Athene Capensis*), and an Eared Owl (*Otus Capensis*).

Noctua.—It is brown above, with a few yellowish-white spots; white beneath, varied with ferruginous spots; toes hairy.

N. Boobook (*Strix Boobook*, Boobook Owl of Latham) is an Australian species. According to Mr. Caley, "the native name of this bird is Buck-Buck. It may be heard nearly every night during winter uttering a cry corresponding with that word. Although this cry is known to every one, yet the bird itself is known but to few; and it cost me considerable time and trouble before I could satisfy myself respecting its identity. The note of the bird is somewhat similar to that of the European cuckoo, and the colonists have hence given it that name. The lower order of the settlers in New South Wales are led away by the idea that everything is the reverse in that country to what it is in England; and the cuckoo, as they call this bird, singing by night, is one of the instances which they point out."

N. maculata, described by the same authors, much resembles the species just noticed, but they are inclined to consider it distinct.

STRIGOCEPHALUS, a genus of Fossil Brachiopoda.

STRINGY-BARK TREE. [EUCALYPTUS.]

STROBILITES, a genus of Fossil Fruits.

STROBILURUS. [IGUANIDÆ.]

STROMATOPORA. [MILLEPORIDÆ.]

STROMBIDÆ, a family of Marine Gasteropodous Mollusca, belonging to the *Alata* of Lamarck and the *Angustomata* of De Blainville.

The genus *Strombus* of Linnaeus is placed in the 'Systema Naturæ' between *Buccinum* and *Murex*.

Cuvier arranges *Strombus* next to *Turbinella* and at the end of his 'Pectinibranchiate Gastropoda.' He defines the genus *Strombus*, Linn., as comprising shells with a canal which is either straight or inflected towards the right, the external border of whose aperture dilates with age, but always preserves a sinus towards the canal, under which the head of the animal passes when it extends itself. The greater part have, he adds, this sinus at some distance from the canal.

Mr. Swainson defines the *Strombidae*, Wing-Shells, which, in his arrangement, stand between the *Turbinellide* and the *Volutide*, thus:—

"Outer lip dilated, or thickened internally, or detached from the preceding whorl by a sinus; operculum small."

He makes the family consist of the following sub-families:—

1. Strombinae.

Genera:—*Aphorrais*, Da Costa (*Aporrhais*, we suppose is meant); *Pteroceras*, Lam.; *Strombus*, Linn.; *Strombidea*, Sw.; *Rostellaria*, Lam.

2. Coninae.

Genera:—*Terebellum*, Lam.; *Coronaria*, Sw. (with the sub-genera, *Coronaria*, Sw.; *Puncticulus* (l), Sw.; *Tuliparia*, Sw.; *Cylindrella*, Sw.; and *Comilithes*, Sw.); *Conus*, Linn. (with the sub-genera *Conus*, Linn.; *Dendroconus*, Sw.; *Textilia*, Sw.; *Theliconus*, Sw.; and *Lepticonus*, Sw.); *Conella*, Sw.; and *Conorbis*, Sw.

3. Columbellinae.

Genera:—*Conidea*, Sw.; *Columbella*, Lam.; *Pusiosoma*, Sw.; *Crasispira*, Sw.; *Nitidella*, Sw.

4. Pleurotominae.

Genera:—*Brachytoma*, Sw.; *Pleurotoma*, Lam.; *Clavatula*, Sw.; *Clavicantha*, Sw.; *Tomella*, Sw.

5. Cerithinae.

Genera:—*Potomis*, Brong.; *Pirena*, Lam.; *Terebralia*, Sw.; *Rhino-clavis*, Sw.; *Cerithium*, Lam.

Dr. J. E. Gray makes the *Strombidae* (the first family of his section *Ctenobranchiata*, Order 1, *Zoophaga*) include the following genera:—*Strombus*, *Terebellum*, *Pteroceras*, *Rostellaria* and *Scaphys*.

In this article the *Strombidae* will be confined to the genera and sub-genera *Strombus*, *Pteroceras*, and *Rostellaria*.

Strombus.—Animal spiral, slightly compressed, furnished with a proboscis, at the extremity of which is the mouth opening longitudinally, and containing a lingual riband furnished with sharp points curved backwards. Tentacles cylindrical, obtuse, and short. Eyes carried upon two peduncles, which are cylindrical and stout, longer than the tentacles, and placed at their external side. Foot rather small, but enlarged forwards. Mantle forming in front a canal, which is generally rather short. Orifices of the anus and oviduct behind. Shell thick, oval-oblong, sub-involved, conical in front and behind; spire moderately elevated; aperture long and narrow, terminated anteriorly by a canal more or less long or removed; right lip dilated, and with a sinus a little behind the canal; columellar or inner lip simple, but sometimes callosus. Operculum horny, long and narrow, with a terminal summit and composed of elements imbricated, as it were. (Rang.)

Animal of *Strombus lambis* (*Pteroceras lambis* of modern authors). Female.

a, the foot seen in its anterior part, with its groove; b, the operculum fixed at its posterior division; c, e, ocular tubes with their tentacles; d, the proboscis open to show the tongue; e, the cerebral ganglion, behind which are two long salivary glands; f, digestive tube entering a large stomach; g, the stomach partially opened, and showing the orifices of the esophagus; h, the intestine become filiform before it forms the very voluminous rectum; i, the first part of the uterus; k, second part of the uterus, forming meanders before opening into the groove which leads on the right side of the foot; l, the groove which does not exist in the murex; m, follicles of viscosity; n, respiratory siphon; o, large branchia and its vein which goes to the heart; p, small and rudimentary branchia; q, the heart; r, the liver and the ovary united to the extremity of the tortillon, or turbinate part of the body. ('Voyage of the Astrolabe.')

M. Rang considers that the variations in the shell lead to the establishment of two sub-genera, *Strombus* and *Pteroceras*.

M. De Blainville divides the genus *Strombus* into the following sections:—

a. Species whose external lip becomes much dilated with age, and offers a number of digitations variable in number. Genus, *Pteroceras*, Lam. Ex. *S. Scorpis*.

β. Species whose right lip is much dilated, but without digitation. Ex. *S. tricornis*.

γ. Species whose external lip is thick, and but little or not at all dilated. Ex. *S. Auris Dianæ*.

δ. Species whose right lip is not dilated, and very delicate, which makes them resemble the Concs. (Non-adult *Strombi*.)

The species are extremely numerous, and many of them are gigantic in size, the well-known *S. gigas* of the West Indies for example. Like some others of the Turbinate Testaceans, the animals of the genus *Strombus* occasionally produce pearls. Mr. Wood, in his 'Zoography,' relates that he saw a pink pearl which was taken from the body of the animal of *S. gigas*, which is fished for the table off the island of Barbadoes. The pearl was discovered by chance, while the men were employed in cleaning the fish. Its weight was 24 grains, but it would have been more valuable if it had been round. The same author states that only four of these pearls had been discovered in the vast number of shell-fish that are annually brought to market in that part of the world, though he has reason to believe that this is in some measure owing to the carelessness of the negroes, who clean their fish without consideration, and have probably in their hurry returned many a pearl to its native element with the refuse of the animal. This pearl was exactly of the same colour as the interior coat of the shell, and like it in every respect except in figure. Immense quantities of this shell are imported into this country from the Bahamas: 300,000 were imported into Liverpool alone in the year 1850. They are used in making cameos, and in the manufacture of porcelain.

The species are found in the seas of warm climates; many from those of India, and some from those under and near the equator. They are carnivorous. Species have been found at depths varying from the surface to 13 fathoms.

S. latissimus has the shell turbinated, ventricose, smooth on the back, somewhat wrinkled on the wing, brown-orange spotted with white; the spire short and nodulous; the external lip very broad, rounded above, projecting beyond the spire; the anterior margin sharp, but the side of it very thick; the aperture smooth and white, tinged with rose colour.

It is found in the East Indian seas.

Strombus latissimus.

a, seen from above; b, seen from below.

This fine and somewhat rare species grows to a large size, from 5 to 10 or more inches in length.

NAT. HIST. DIV. VOL. IV.

There are about 60 recent species of *Strombus* described. Five fossil forms have been described from the Chalk and three from the Miocene beds of the Tertiary.

Pteroceras.—Shell with the wing digitated, and furnished forwards with an elongated canal. There are 10 recent species, inhabitants of the Indian seas, and 100 fossil species, found from the Lias beds up to the Chalk.

P. Scorpius. Shell ovate oblong, gibbous, tuberculate, transversely rugose and knotty, 7-fingered, white spotted with rufous; the fingers rather slender, and knotted at intervals throughout their length; the anterior ones and the tail the longest, and curved; aperture violaceous-red wrinkled with white.

It is a native of the East Indian seas.

Pteroceras Scorpius.

Rostellaria.—Animal imperfectly known, but bearing a considerable resemblance to that of *Murex*, according to Cuvier.

Shell fusiform or subturriculate, with an elevated pointed spire; aperture oval, canal projecting, and terminating in a pointed beak; external lip simple, dectated, digitated, or very much dilated, furnished with a sinus near the canal, and having generally a second canal ascending upon part of the spire.

The species are found in the Asiatic seas, if we except *Rostellaria Pes Pelecani* and *R. Pes Carbonis* (genus *Aporrhais*), which are found in the Mediterranean and other European seas. A very fine specimen of *Rostellaria rectirostris* was brought up in the mud lying on the fluke of an Indiaman's anchor, in the Straits of Macassar. They are carnivorous.

There are 7 recent species, and 70 fossil species. The latter range from the Neocomian beds to the Chalk.

R. curvirostris (*Strombus fusus*, Linn.), the Spindle of collectors, is by far the most common of the Asiatic species. We illustrate the

Rostellaria rectirostris.

genus by *Rostellaria rectirostris*, Lam., a name which suits this rare species well when the beak is curtailed, as it most frequently is. In

a very fine specimen, as far as the beak is concerned, now in the British Museum, that usually mutilated part is much longer and better preserved than it is generally seen, and from its recurvature the name of *recurvirostris* would be more apt. Indeed it is by no means clear that there are not two species of this long-beaked kind of *Rostellaria*, one much darker than the other, and not so slender.

STROMBODES. [POLYPIFERA.]

STROMEYERITE, a Mineral consisting of Sulphuret of Silver and Copper.

STRONGYLUS. [ENTOZOA.]

STRONTIA, the name of an Earth, composed of Oxygen and the metal Strontium. Neither strontium nor its oxide is found pure in nature. The Salts of Strontia have a high specific gravity, varying from 3.6 to 4.0. In this respect they resemble Baryta. Two are found in the form of minerals.

Celestine—Sulphate of Strontia—occurs in modified rhombic prisms. Crystals sometimes flattened, often long and slender. Massive varieties:—Columnar or fibrous, forming layers half an inch or more thick, with a pearly lustre; rarely granular. Colour generally a tinge of blue, but sometimes clear white. Lustre vitreous, or a little pearly; transparent to translucent. Hardness 3.0 to 3.5. Specific gravity 3.9 to 4.0. Very brittle. It contains—Sulphuric Acid, 43.6; Strontia, 56.4. Decrepitates before the blow-pipe, and on charcoal fuses rather easily to a milk-white alkaline globule, tinged the flame red. Phosphoresces when heated.

It resembles heavy spar, but is distinguished by its specific characters and behaviour under the blow-pipe. It is distinguished from the carbonate by not effervescing with acids. It is found in the United States of America. Sicily affords very splendid crystallisations associated with sulphur.

The pale sky-blue tint so common with the mineral, gave origin to the name Celestine.

Celestine is used in the arts for making the nitrate of strontia, which is employed for producing a red colour in fire-works. Celestine is changed to sulphuret of strontium by heating with charcoal, and then by means of nitric acid the nitrate is obtained.

Strontianite—Carbonate of Strontia—occurs in modified rhombic prisms. It occurs also fibrous and granular, and sometimes in globular shapes with a radiated structure within.

The colour is usually a light tinge of green; also white, gray, and yellowish-brown. Lustre vitreous, or somewhat resinous. Transparent to translucent. Hardness 3.5 to 4. Specific gravity 3.6 to 3.72. The analysis gives—Strontia, 70.1; Carbonic Acid, 29.9. It fuses before the blow-pipe on thin edges, tinged the flame red; becomes alkaline in a strong heat; effervesces with the acids.

Its effervescence with acids distinguishes it from minerals that are not carbonates; the colour of the flame before the blow-pipe, from witherite; and this character and the fusibility, although difficult, from calc spar. Calc spar sometimes reddens the flame, but not so deeply.

Strontianite occurs in limestone at Schoharie, New York, in crystals, and also fibrous and massive. Strontian in Argyleshire was the first locality known, and gave the name to the mineral and the earth strontia. It occurs there with galena in stellated and fibrous groups and in crystals. It is also used for making nitrate of strontia.

(Dana, *Manual of Mineralogy*.)

STROPHODUS, a genus of Fossil Fishes. [FISH.]

STROPHOMENA. [BRACHIOPODA.]

STROPHOSTOMA. [HELICIDÆ.]

STRUTHIOLARIA. [SIPHONOSTOMATA.]

STRUTHIONIDÆ, a natural family of Terrestrial Birds, in which the locomotive energy is thrown into the lower extremities, the wings being in no case adequate to raising the body into the air, and in the majority of instances merely rudimentary. In this respect the genera which compose it are the very reverse of the Humming-Birds, Swallows, Albatrosses, Tropic-Birds, and Man-of-War Bird; for in the latter the moving power resides in the highly-developed wings, whilst the feet, especially in the Man-of-War Bird, are feeble.

The *Struthionida* consist of the Ostrich, American Ostrich (*Rhea*), Cassowary, Australian Cassowary, or Emu, and that extraordinary bird the Kivi-Kivi, or *Apteryx*, of New Zealand.

The anatomy of these animals is referred to in great detail by

remarkable modifications of the skull in this family occur in the Asiatic Cassowary and the *Apteryx*. In the former the bony crest

Skull of Asiatic Cassowary (adult).

which is so highly developed in the adult, is hardly perceptible in the young bird, but increases with age, as in the Hornbill and the Guinea-Hen. [PAPONIDÆ.]

In *Apteryx*, according to Professor Owen, the skull is chiefly remarkable for its smooth expanded elevated pyriform cranial portion, the total absence of supra-orbital ridges, the completeness and the thickness of the inter-orbital septum, the great development of the ethmoid, the small size of the lachrymal bones, and the expansion of the nasal cavity behind these bones. The tolerably semicircular occipital region differs from that of other *Struthionida* in the greater relative extent of its base, and in the comparatively slight lateral sinuosities due to the temporal depressions. There is no vertical notch at the upper part of the single hemispherical tubercle in the basi-occipital for articulation with the atlas, as in the Ostrich and Emu, but it is entire, as in *Rhea*; the plane of the occipital foramen also has the same aspect as in that bird, in which it is more nearly horizontal than in the Ostrich. The supra-occipital plate forms a somewhat angular projection, corresponding with the small cerebellum, and is bounded on each side by a vertical vascular groove terminated by a foramen above and below; the ex-occipitals extend outwards and downwards external to these grooves in the form of obtuse processes compressed in the antero-posterior direction, and are slightly convex behind and concave in front, where they form the back part of the wide meatus auditorius externus. The occipital bones, and also the surrounding bones, are ankylosed together. The angle between the posterior and superior regions of the cranium can hardly be said to be produced into a ridge. The superior region is smooth, convex, and separated from the temporal depressions by a narrow ridge, rather more marked than the occipital ridge. The sagittal suture crosses a little behind the middle of the upper part of the cranium. In one cranium Professor Owen found the left half of this suture persistent; but in another, that of a male, all the sutures were obliterated. The persistent sutures were more denticulated than those in the skull of a young ostrich. The superior region is continued into the lateral regions by a continuous curvature, so that the upper part of the small orbital cavity is convex, and its limits undefinable, there being no trace of supra-orbital ridge, nor of antorbital, or postorbital processes. This structure, Professor Owen observes, is quite peculiar to the *Apteryx* among birds, but affords a very interesting resemblance between it and the monotreme *Echidna*.

The base of the skull of *Apteryx* exhibits all the peculiarities characteristic of the Struthious Birds. The body of the sphenoid sends out two processes on each side externally; the posterior of these abuts against the tympanic bone, and the anterior one by a flattened oval articular surface against the pterygoid bone. Professor Owen points out that the latter processes exist, but are much more feebly developed in the Ibis, and that in most other birds, including the *Gralla*, they are wanting, whilst they are well developed in the Lacertine *Sauria*.

The usual ornithic characters, with the Struthious modifications traceable in the individual peculiarities, are presented in the lower jaw of *Apteryx*. "The transversely expanded angular and articular extremities offer the inwardly extended process for the attachment of the pterygoidei muscles; the superior transverse plate, behind the articular surfaces, is thin and concave towards the meatus auditorius externus, and is lined by the mucous membrane of that passage, of which it forms part of the bony parietes. There are two distinct narrow oblique articular surfaces, concave in the longitudinal, and convex in the transverse directions; the internal one is the largest, and behind this there is a small excavation, into which a small process of the air-sac lining the tympanum is continued; and this is the only part of the skeleton not immediately concerned in the formation of the organs of hearing or smelling into which air is admitted. The entry to the air-cells, in the lower jaw of the Ostrich,

Skull of Asiatic Cassowary (young).

Professor Owen in his paper on the 'Anatomy of the *Apteryx*,' in the Transactions of the Zoological Society, London. The most

is situated in the part corresponding to the above depression or sinus in the jaw of *Apteryx*. Traces of the compound structure of the lower jaw are very evident in that of the *Apteryx*, and the limits of the angular, articular, and coronoid pieces may be in part defined. There is a linear vacancy, bounded by the surangular and angular pieces behind, and by the bifurcate commencement of the mandibular or dentary piece in front; the surangular is compressed, and sends upwards a very slightly elevated coronoid ridge. A second narrower fissure occurs between the thick opercular or splenial element and the upper fork of the mandibular piece. The opercular piece reaches to the posterior part of the symphysis, as in the Ostrich, and the rest of the lower jaw in front of this part is formed by the two ankylosed mandibulars. In the extent of this ankylosed symphysis the *Rhea* makes the nearest approach to the *Apteryx* among the *Struthionidæ*, and the two impressions which diverge from the back part to the front of the symphysis are present in both the *Rhea* and *Emeu*, as in the *Apteryx*. The lower jaw of the *Apteryx* differs from that of the *Ibis* in its greater posterior expanse, its more depressed form, the lower coronoid plate, the narrower fissure between the angular and surangular pieces, and the absence of the mesial furrow, extending in the *Ibis* to the end of the symphysis."

The number of the cervical vertebrae in the Ostrich is 18, in the Cassowary 16 (true), in *Rhea* 16 (not 14, as Cuvier states), in the *Emeu* 19, in the *Apteryx* 15 only; and in the latter there are 9 dorsal and 22 remaining vertebrae in the lumbar, sacral, and caudal regions: the spinal column of *Apteryx* is relatively stronger, especially in the cervical region, than it is in the larger *Struthionidæ*.

In the *Struthionidæ* we look in vain for the deep crista or keel which so strongly marks the well-developed ornithic character, especially in the diurnal birds of prey, the larger sea-birds above alluded to, and the Humming-Birds. Such a foundation would be worse than useless where there is none of the machinery of flying to be worked, and the utmost demand on the anterior extremities goes no farther than their aid in balancing the body when the bird runs. We accordingly find that in the larger *Struthionidæ* (Ostrich, Cassowary, &c.) the breast-bone presents a plane and uniformly arched shield-like surface, not unlike, in some of the family, the Cassowary and *Emeu* for instance, to a Highlander's target on a reduced scale. But in the *Apteryx* this low development is reduced to its lowest grade. In its small size, and in the total absence of a keel, it resembles, Professor Owen observes, that of the Struthious Birds generally, but differs in the presence of two subcircular perforations on each side of the middle line, in the wide anterior emarginations, and in the much greater extent of the two posterior fissures. The anterior margin, he tells us, presents no trace of a manubrial process, as in the Ostrich; on the contrary, the wide interspace between the articular cavities of the coracoid is deeply concave; in the extent of this interspace, he remarks, the *Rhea* most resembles the *Apteryx*, but its contour is almost straight; whilst in the Cassowary the space is narrower, but deeply notched. The articular surface for the coracoid is an open groove, which in the fresh state is covered with articular cartilage; and, external to the groove, the anterior angles of the sternum are produced into two strong triangular processes with the apex obtuse. The thickened costal margin, when viewed anteriorly, presents an undulating contour, from the presence of the four articular convexities, for the sternal ribs and the intermediate excavations. The sternum of the *Emeu*, Professor Owen remarks, presents a similar appearance. The breadth of each sternal perforation is, he adds, nearly equal to that of the intervening osseous space, and in the specimen described they were not quite symmetrical in position. The posterior notches equal in extent one half the entire length of the sternum, and the external boundaries of these notches curve towards each other. These notches exhibit a slight want of symmetry in form, position, and extent.

There is no true furcula in the *Struthionidæ*, but the Ostrich and Cassowary have on each side of the front of the chest an elongated flat bone consisting of a rudiment of the furcula, with the clavicle and scapula consolidated into one piece. The two branches of this rudimentary furcula are very short, and never united in the African Ostrich, but ankylosed with the bones above mentioned. In the Cassowary there are merely two little processes from the side of the clavicle; these are the rudiments of the branches of the fork. In the *Emeu* two very small thin bones are attached to the anterior edge of the dorsal end of the clavicles by a ligament, and are directed upwards towards the neck; there they are fastened to each other by a ligament, but have no connection with the sternum. In the *Apteryx* the scapula and coracoid are ankylosed; and a small perforation anterior to the articular surface of the humerus indicates the separation between the coracoid and rudimental clavicle, of which, Professor Owen states, there is not otherwise the least trace. The coracoid, he adds, is the strongest bone; and its inferior expanded extremity presents an articular convexity, adapted to the sternal groove before described. The third rib is reached by the scapula, which is a simple narrow plate of bone, an inch in length, slightly curved, and expanded at both ends, chiefly at the humeral articulation.

The true wing bones are best developed among the Struthious Birds in *Rhea*; the next best development is in the Ostrich; in the Cassowary, *Emeu*, and *Apteryx*, the lowest development of these bones

is exhibited. In the latter the humerus is a slender cylindrical styloid bone, 1 inch 5 lines in length, and slightly bent. At the two extremities it is slightly expanded, but most at the proximal end, which supports a transverse oval articular convexity, covered with smooth cartilage, and joined by a synovial and capsular membrane to the scapulo-coracoid articulation. Beyond each end of the humeral articular surface is a small projecting tuberosity. The distal end of the humerus is articulated by a true but shallow ginglymoid joint with the rudimental bones of the antibrachium, and both the external and internal condyles are slightly developed. The slender radius and ulna, each 9 lines in length, are almost straight and cylindrical. Above the articular surface of the ulna a feebly-developed olecranon is projected. A minute carpal bone, two metacarpals, and a single phalanx, which supports the long curved obtuse alar claw, complete this rudimentary hand, which is 7 lines in length, including the claw, and that measures $3\frac{1}{2}$ lines. To the ulna and metacarpus a few short and strong quill-feathers are attached by ligament.

Skeleton of Ostrich. (Pender and D'Alton.)

Skeleton of *Apteryx*. (Owen.)

Strongly contrasted with the flattened sternum and the dwindled anterior extremities are the strongly developed pelvis and posterior limbs of the *Struthionidæ*. The pelvis of the ostrich bears some resemblance to that of the extinct quadrupedal *Myodon*, of which there is a noble skeleton in the Museum of the Royal College of Surgeons. In this part of the osseous system we have ample fulcra for those powerful muscles which render the larger *Struthionidæ* swifter than the swiftest. The iliac bones of *Apteryx* resemble those of the rest of the tribe in size and shape, and are four inches and three lines in length. There is a slight anterior concavity on the outer surface, and this concavity passes into a convexity posteriorly, the two surfaces, not being separated by the transverse elevation which exists above the acetabulum in the four large *Struthionidæ*. Between the posterior extremity of the ilia and the first three caudal vertebrae, a distinct epiphyseal piece of bone is wedged in. The ischium extends backwards parallel with the sacrum, in the form of a thin plate of bone, which slightly expands to its free and truncated extremity. The pubic element is a slender bony style, connected by ligament to the end of the ischium, but attached by bone at its acetabular extremity only. A short pointed process extends from the anterior margin of the origin of the pubis. In comparing the pelvis of *Apteryx* with that of the large *Struthionidæ*, Professor Owen observes that the ischia do not meet below the sacrum, as in the *Rhea*, but are more distant from that and the iliac bones than in any of the *Struthionidæ*; the pubic bones, he remarks, are not joined together at their distal extremities, as in the Ostrich; nor are the extremities of the ischia ankylosed to the superincumbent ilia, as in the Cassowary. It is the Emeu, he adds, that comes nearest to the *Apteryx* in the structure of the pelvis, but it also differs in the complete bony boundary of the foramen, which transmits the tendon of the obturator internus, and which is completed posteriorly by ligament in *Apteryx*. The acetabulum, he observes, communicates, as usual, by a wide opening with the pelvis, and a surface covered with a cushion of thick cartilage is continued from its posterior and upper part.

The great length of leg in the *Struthionidæ* is produced, as in the true wading-birds, by the tibia and common bone of the tarsus and metatarsus; for the femur is comparatively of short dimensions.

The fibrous capsule of the hip-joint of *Apteryx* is very strong; the synovial membrane is reflected from it upon the upper margin of the trochanter and upper part of the short neck of the femur, as well as upon the ligamentous bridge, continued from the upper and extended margin of the acetabulum to its anterior part. The very large ligamentum teres is short, and consists of an infundibular process of synovial membrane, reflected from the circumference of the acetabular perforation to that of the depression on the head of the femur: this synovial sheath incloses two distinct ligaments, which are twisted about each other like the crucial ligaments of the knee-joint. One of the ligamentous bands passes from the upper margin of the acetabular perforation to the lower edge of the femoral depression.

The femur, tibia, patella, fibula, and other parts of the osseous system of the legs of these birds are not less characteristic of their habits.

The number of the toes varies in these birds. In the Ostrich the number of toes is two only; the Cassowary and Emeu have each three. The *Apteryx* has a fourth. In the *Apteryx* the number of phalanges of the three greater toes follows the ordinary law; the inner toe having three, the middle four, and the outermost five phalanges.

The crop in the *Struthionidæ* is of great size. The bulbus glandulosus or proventriculus is situated before the entrance of the oesophagus into the proper stomach, and is so large and so modified in form in some of the species, the Ostrich for example, as to give it the appearance of a second stomach; indeed Valisnieri, in his 'Anatomy of the Ostrich,' calls it the first stomach. Mr. Lawrence found the oesophagus of an ostrich which he dissected dilated into an immense bag capable of holding several pints of water, and five or six times larger than the gizzard itself, which was placed on the right and anterior part of this dilatation. The glands did not surround the tube, so that, Mr. Lawrence observes, the term 'zone' would be here inapplicable. They formed, he tells us, a long but narrow band, commencing at the termination of the oesophagus, and running along the front of the bag towards the gizzard. This band measured about twelve inches in length and not more than three inches at its greatest breadth. The size of the individual glands varied: they were largest in the middle, and decreased towards either margin of the band. Some of them equalled a large pea, and their openings were in proportion. They were arranged in close apposition to each other, and the inner surface of the pouch was covered by a continuation of the insensibile lining of the gizzard, which separated very easily from the surface. The caeca in the ostrich are characterised by a remarkable spiral valve, and the villi in its small intestine are rather flat than laminae than villi; but they are at the same time long and numerous, presenting a very elegant structure. The large intestine of the ostrich presents a remarkable deviation from the structure usually seen in birds; for the surface of that intestine is in them generally uniform on its surface, whereas in the Ostrich the large intestine, which are very long, have numerous transverse folds, like the valvulae conniventes of man.

In the Museum of the College of Surgeons in London is a series of

preparations admirably illustrative of the internal anatomy of the *Struthionidæ*.

The tongue of the *Apteryx* is short; but short as it is, it is more developed than in other *Struthionidæ*. The lining membrane of the pharynx, behind the glottis, forms two elongate, square-shaped, smooth, thick, and apparently glandular folds or processes, the obtuse free margins of which project backwards like lappets into the pharynx; beyond which the living membrane is produced into close-set, narrow, somewhat wavy, longitudinal folds; the oesophagus is continued through the thorax and diaphragm to the proventriculus without forming any partial dilatation or crop. The proventriculus is a narrow elongated cylindrical cavity in the axis of the oesophagus, of which it is an immediate continuation. The gastric glands, narrow elongated follicles, are developed around its whole circumference, and are closely packed together; they are mostly bilobed, but sometimes more subdivided at their caecal or outer extremities. The longitudinal rugae of the lining membrane gradually subside at the entry of the proventriculus, where they run into each other, and so form a general reticulate surface, in the meshes of which the orifices of these glands are situated. The epithelium lining the glandular part of the stomach is gradually condensed towards its lower part into a cuticle, which, as it passes into the muscular compartment, assumes a brown colour and a callous hardness, and forms a stratum about one-third of a line thick. In the Cassowary and Emeu, observes Professor Owen in continuation, the proventriculus is marked off from the stomach by a circular strip of epithelium, whiter and thinner than the rest, from one to two lines in width, as is well shown in Sir Everard Home's 'Comparative Anatomy' (pl. li, lii). In this structure the *Apteryx*, though it resembles these species in the arrangement of the gastric glands, does not participate. Its muscular stomach does not present the characteristic sub-compressed shape of a gizzard; but in its regular oval rounded form resembles the membranous stomach of carnivorous birds. It is small for the size of the bird in its contracted state, but when distended with food Professor Owen found that it measured two inches and a half in length, and two inches across at the widest parts. The muscular fibres are not digastric and lateral, as in the true gizzard; but, instead of being arranged in well-defined masses, radiate from two tendinous oval centres, measuring about two-thirds of an inch in the longest diameter. The pyloric passage is narrow, leading from the left side of the muscular stomach into the duodenum. A transverse crescentic ridge of the lining membrane defends the pylorus, but there is no distinct sphincter. The cuticle is continued into the duodenum about three lines beyond the pylorus, but the Professor found no dilatation of this part constituting a pyloric pouch, as in the Emeu and Ostrich. In one *Apteryx* there was a very short caecum, the remnant of the ductus vitello-intestinalis, attached to about the middle of the small intestine; and from the same relative position of the intestinal tube in a small female specimen there extended an obliterated duct three lines long, which expanded into a still persistent sub-globular vitelline sac, about an inch in diameter, but collapsed, and with wrinkled parietes. In a large male the intestinal canal measured four feet, independently of the caeca, each six inches in length: the rectum was four inches long. The lining membrane of the rectum, which is beset with minute short villi or points, together with glandulae solitariae, that become numerous and large at the terminal half of the rectum, is thrown, when it is contracted, into longitudinal folds; but there is no trace of the transverse or spiral valvulae conniventes, characterising the caeca and rectum of the Ostrich and *Rhea*; and in this respect the *Apteryx* resembles the Cassowary and Emeu. The liver presented nothing extraordinary. In two of the specimens there was a gall-bladder, as in the Emeu and Cassowary; in the third it was wanting, as is usually the case in the *Rhea* and Ostrich. In the *Apteryx* without a gall-bladder there were two long ducts terminating in the same part of the duodenum. The pancreas consisted, as usual, of two elongated subtriangular lobes; and the spleen was about the size and form of a hazel-nut.

In the preparations in the College of Surgeons the peculiarities of the circulating and respiratory systems of these birds are well displayed. The *Apteryx* possesses a complete and well-developed diaphragm.

Professor Owen, after adverting to the long recognised existence of a diaphragm in a rudimentary condition in birds, and Hunter's beautiful figure of the costal portion of that of the Ostrich ('Cat. Mus. Coll. Chir.', vol. ii., pl. xxvi., 'Physiol. Series'), observes that in this, as well as in the other large *Struthionidæ*, there is also a pars vertebralis, or analogue of the lesser muscle of the diaphragm, which rises by two tendinous crura from the last dorsal vertebra, and in the Emeu, by a double origin on each side. Nevertheless, he remarks, their diaphragm is incomplete; first, by reason of an arrest of its centripetal development, which leaves a permanent defect of union in the mesial plane; and, secondly, by the large perforations for the abdominal air-cells.

Professor Owen found the mechanism of respiration in the *Apteryx* essentially the same as in other birds, and he states that a more muscular diaphragm than it possesses would be unnecessary as a part of the mechanism. As in the *Mammalia*, the abdominal surface of the diaphragm is principally in contact with the liver, spleen, and stomach; but its thoracic surface does not support the heart, and it

is separated from the lungs by the interposition of a series of small but well-marked air-cells. No thoracic serous sac or pleura could be traced. "Thus," says Professor Oweu, "although the respiratory organs are confined to the chest, and the *Apteryx* offers the only known instance in the feathered race of a species in which the repectacular part of the lungs is not continued into the abdomen, yet the Struthious type is strictly preserved, and the march of development has only been restricted, not changed."

The brain and nervous system appear to be, generally speaking, well developed in the Struthious Birds.

The senses of Touch, Taste, Smell, and Hearing are well developed.

The Eye is well formed, and the Sight piercing in the *Struthionidæ* generally; but, in the *Apteryx*, the eye has less development than appears in the rest of the family, the reasons for which are above assigned. It presents a remarkable deviation from the construction characteristic of birds generally, in the total absence of the pecten or marsupium, a privation compatible with the nocturnal habits and restricted locomotion of this species. "The eyeball," says Professor Owen, "is relatively much smaller than in other birds; its antero-posterior diameter is three lines; its transverse diameter four lines. The cornea transparens is very convex, and two lines in diameter. The sclerotic is thin, but the margin supporting the cornea is strengthened by a circle of small osseous plates. The choroid is a delicate membrane; its pigment is of a light brown colour. The ciliary processes commence at the ciliary ring, each process baving at its origin a slight linear rising, which becomes gradually wavy and tortuous as it approaches the lens, anterior to the circumference of which it projects freely to a small extent. The iris in the specimeu examined was one-third of a line in breadth. The optic nerve terminates by a small round aperturo. The lens is two lines in breadth, and nearly one line at the thickest part, being thus more convex than in other birds. The external appendages of the eye presented no peculiarities, except the very great strength of the orbicularis palpebrarum; the membrana nictitans had the usual trochlear muscles: its free margin was black."

The place assigned to the Struthious Birds by zoologists generally will be found in the articles BIRDS and GRALLÆ. The position of the Dodo in this family is doubtful. [DODO.]

Mr. G. R. Gray makes the *Struthionidæ* the first family of the order *Cursores*, Temm., the sixth order in Mr. Gray's arrangement, and includes under it the following sub-families and genera:—

Sub-Family 1. *Struthionidæ*.

Genera:—*Struthio*, Linn.; *Casuarius*, Briss.; *Dromaius*, Vieill.; and *Rhea*, Briss.

Sub-Family 2. *Apteryginæ*.

Genus:—*Apteryx*, Shaw.

Sub-Family 3. *Didinæ* (?).

Genus:—*Didus*, Linn.

Sub-Family 4. *Otinæ*.

Genera:—*Otis*, Linn.; *Tetrax*, Leach; *Sypheotipes*, Less.; *Chlamydotes*, Less.; and *Eupodotis*, Less.

The *Struthionidæ* are placed in Mr. Gray's arrangement between the *Tinamidæ*, the last family of his *Rasores*, and the *Charadriadæ* the first family of his *Grallatores*.

Amongst the *Mammalia* the *Marsupiatæ* make the nearest approximation to the *Ovipara*; and amongst the birds the *Struthionidæ* approach the most closely to the *Mammalia* and the *Reptiles*.

This approximation of the Struthious Birds to the *Mammalia* especially cannot fail to strike the physiologist. In the first and typical genus, *Struthio*, it is strongly manifested.

Struthio (Linn.).—Bill moderate, obtuse, straight, depressed at the point, which is rounded and unguiculate; mandibles equal and flexible; nasal fossæ longitudinal, prolonged half way down the bill, open. Feet very robust; toes two only, stout and strong, directed forwards, and connected at their base by a strong membrane, the internal toe considerably larger than the external, and furnished with a thick and hoof-like claw, external toe clawless. Wings useless for flight, furnished with long soft undulating plumes, and armed with two spurs, or rather two plumeless shafts, not unlike a porcupine's quill. Head and upper half of the neck scantily covered with a thin down, through which the colour of the skin is visible. There is but one species, the *S. Camelus*.

It would be a needless occupation of space to give a minute description of a bird which is so well known in these days of zoological societies and menageries. The Ostrich is generally understood to be the bird designated by the terms Joneh, or Jaanah, and Rinonim, in the Scriptures (Levit., xl. 19; Deut., xiv. 15; Job, xxx. 29; Isai., xlii. 21; xxxiv. 13; xliii. 20; Jer., l. 39; Lament., iv. 3; Mic., i. 8; Job, xxxix. 13). In many of these passages, Jer., l. 39, and Isai., for instance, our version reads 'Owls,' and in Levit. does not mention the Ostrich, but the general opinion seems to be in favour of the Ostrich being intended. It is the Neamah of the Arabs, Thar Edsjanmel (Camel-Bird) of the Orientals, Στρουθοκαμηλος of the Greeks, *Struthiocamelus* of Pliny and the Romans, Struzzo and Struzzolo of the Italians, Strauss of the Germans, Autruche of the French.

Head and Foot of Ostrich.

The approximation in the digestive organs of the Ostrich to the structure of some of these parts in the *Ruminantia*, especially in the additional ventricle of the bird, is still further strengthened by the bisulcous foot, which may not be inaptly compared to that of the camel, and probably led in no small degree to its appellation of Camel-Bird, to which, moreover, its height, lengthened neck, habit of frequenting the desert, and patience under thirst may have contributed.

The food of the ostrich consists of vegetable substances only, but seeds and grain appear to be preferred, and it is consequently a most unwelcome neighbour to the cultivator of the soil, on whose crops the bird commits great devastation. Its iron-eating propensities have long been celebrated, and indeed it picks up and swallows any mineral substance, metallic or not, with indiscriminating voracity. Nor is this propensity confined to the devouring of minerals; for leather, hair, cordage, and wood do not seem to come amiss. In the stomach of one of these birds Valisnieri found a farrago of grass, nuts, cords, stones, glass, brass, iron, tin, copper, lead, wood, and among the stones one weighing more than a pound.

Perrault took from an ostrich's stomach 70 doubles, the greater part of which were worn down three-fourths of their substance by collision against each other or the pebbles found with them: those which were bent were worn and polished on the convex side, while they remained entire on the concave surface. These copper pieces had tinged everything in the stomach with green. This eagerness for picking up everything, whether or not it can be assimilated or can assist in the grinding down of the food by the action of the stomach, to which no doubt the polishing and wasting of the pieces of money mentioned by Perrault were due, is often fatal to the Ostrich. Too great a quantity of copper or iron thus taken into the stomach has caused the death of the bird. Valisnieri saw one killed by swallowing a quantity of quick-lime; and one kept in the gardens of the Zoological Society of London was first deformed and afterwards died from swallowing part of a parasol. Some of the heterogeneous contents found in the stomachs of these birds are preserved in the Museum of the Royal College of Surgeons.

Their speed is great. The swiftest grayhound cannot overtake them; and even the Arabian and his horse are obliged to have recourse to cunning as well as speed to close the chase, by throwing a stick dexterously between its legs, or otherwise to disable it. In its flight it spurns the pebbles behind it like shot against the pursuer. Nor is this its only mode of annoyance. Dr. Shaw, who gives a pretty account of the airs which the Ostrich plays off in a domesticated state, fanning itself with its expanded wings, and seeming to admire its own shadow, states, that though tame and tractable to those familiar with them, these birds were often very fierce to strangers, especially those of the poorer sort, whom they would try to run down and attack with their feet. They are capable of striking with great force, and the same author gives a melancholy account of a person whose belly was ripped up by a stroke from the pointed and angular claw. The European sportsman, after riding so that the bird shall pass within shot, dismounts and brings it down with the rifle.

The strength of the Ostrich is great. Adanson mentions the rapidity with which a large tame one ran, first under the weight of two little blacks, and afterwards under two full-grown negroes, while a smaller bird carried with equal facility one full-grown negro.

The general opinion is that the Ostrich is not polygamous. The number of eggs does not seem to be correctly ascertained. From 20 to 30, and 33 with 13 others scattered around the inartificial nest—a mere pit in the sand, which is thrown up so as to form an elevated edge round it, about three feet in diameter—have been found together. Some have made the number 80; others reduce it to 10. This is the number that Le Vaillant would assign to a single female, although he disturbed one from the nest containing the 33 eggs surrounded by the 13 others. This nest he watched, and saw during the day the four females successively sit upon them; and towards the close of the evening a male took his turn of incubation. This then was probably a common nest in which several females had laid their eggs.

The passage in Job (xxxix. 14) will occur to every one, and there is no doubt that within the torrid zone the heat of the sun's rays renders the incubation of the female unnecessary, excepting perhaps at night; but in cooler latitudes she performs the maternal office with assiduity, and even in the warmer climates, where an officious determination to sit would in all probability endanger the vitality of the eggs, she watches over them; and indeed the hunters have learned from her actions, and doubling back in her flight to one particular spot, where to seek for the nest. If, as has been asserted, the outlying eggs are intended to serve for the nourishment of the young, it is a proof of provident care for her offspring on the part of the mother.

The flesh of the Ostrich when young is good and palatable, and the eggs are considered a great delicacy. Both Europeans and natives agree in this last opinion. The Hottentot, who abstracts the egg from the nest with a long stick, that the hen may not take alarm at the human touch, and not abandon the nest, but go on laying, as the common hen will do to a great extent when her nest is robbed, buries them in hot ashes. They are said to be excellent when eaten with a sufficient quantity of butter. The brains of hundreds of these birds not unfrequently made a dish at the insane Roman suppers; and Firmus is said to have eaten a whole ostrich at a meal. The flesh of the bird was prohibited by the Mosaic law as unclean, and the Arabs regard it in the same light; but many of the barbarous tribes of the interior of Africa feed on it without scruple. The well-known plumes form a material article of commerce for the head-dress of European ladies, &c.

There is in the noble and admirably arranged zoological gallery of the British Museum a fine and well-preserved series of young ostriches. Not the slightest trace of a nail is observable on the external toe of any of them, any more than on that of the adult bird. The usual height of the ostrich is from 7 to 8 feet, but it has reached 11 feet.

The ostrich is a native of Africa, and is scarcely known beyond the limits of the Arabian deserts.

Casuarus (Brisa).—Bill straight, carinated above, rounded and bent at the point; upper mandible slightly vaulted; the edges depressed, and notched or jagged towards the extremity; the lower mandible rather angular below towards the point; nasal fossæ nearly as long as the bill. Head helmeted. Front of the neck naked, and furnished with two wattles. Toes three. Wings entirely unfit for flight, furnished with five rounded naked pointed quills.

C. Emeu has the bill compressed laterally, the head surmounted with a bony prominence covered with a horny substance; skin of the head and the upper part of the neck naked, tinged with cerulean blue and flame colour, with pendent wattles like those of a turkey-cock; wings furnished with some stiff featherless quills; nail of the internal toe much the strongest. "It is," says Cuvier in continuation, "the largest of the birds after the ostrich, from which it differs sufficiently in its anatomy, for it has short intestines and small cæca, wants the intermediate stomach between the crop and the gizzard, and its cloaca does not exceed that of other birds in proportion."

This well-known bird was named Emeu by the early Portuguese navigators. It is the *Emeu* vulgo *Casuaris* (the latter appearing to be the Malayan appellation) of Bontius, the *Struthia Casuarus* of Linnæus, *Casuarus galeatus* of Vieillot, and Cassowary of the British naturalists, who now apply the term Emeu to the Australian Cassowary (*Dromaius*, Vieill.). Its height when erect is about 5 feet.

It is a native of the peninsula of Malacca and the great chain of islands to the south and east. Bontius notes it from Ceram and the other neighbouring Molucca Islands. M. Lesson observes that it is very common in the islands of the Asiatic Archipelago, and especially at New Guinea. It is frequently seen alive in our menageries, and is common in museums.

This species, which is characterised by M. Lesson as "stupid and massive," feeds on seeds and herbage according to him; but Cuvier says that it eats fruits and eggs, but no grain. Bontius states that he does not think it should be placed among the birds: "Alio enim ad currendum pro velo, non ad volandum inserviunt." He adds, that when irritated, it does not rush forward to the attack, but turns itself obliquely, kicking backwards at the enemy. Cuvier observes that the featherless quills serve the bird for offensive weapons. Bontius remarks that the eggs are very different from those of the Ostrich, by reason of their thinness and colour, for their shell is greenish, ornamented with numerous tubercles of a deeper green (*saturè viridibus*); he adds that they are eaten by the natives. Cuvier relates that the

bird lays a small number of green eggs, which it abandons, like the Ostrich, to the heat of the climate.

Head and Foot of Cassowary.

Rhea (Brisa).—Bill straight, short, rather soft, furnished at its base with an obliterated membrane, slightly depressed, moderate, the point rounded, bent, and unguiculated: upper mandible with its back elevated, notched towards the end; lower mandible flat below; nostrils large, longitudinal. Wings improper for flight, the phalanges furnished with plumes and terminated by a spur. Head completely feathered. Feet three-toed, all the toes furnished with claws.

Foot of Rhea.

In this genus the wing is better developed than in any of the Struthious Birds, but it is still useless as an organ of flight.

Till lately the only species known was *Rhea Americana*, the Nhandu-Guacu of the Brazilians. (Marcgrave; Piso.) It is described as haunting the banks of rivers and having the same propensity for swallowing iron and stones as the African Ostrich, running so swiftly and cunningly, aided by its wings, as not only to evade the pursuit of dogs, but the weapons of the barbarians. The females are said to lay eggs like other ostriches, but smaller, in the sand; and it is added that the males sedulously perform the function of incubation. "Salaces sunt admodum, mentulanque aliquantum aduncam vibrant sæpe, donec reperta femella eam rigidissime incant, suppressamque diu immobilem teneant." (Piso.) The same author states that these American Ostriches are fond of flesh, the best fruits, and the little fishes washed to the bank; nor do they spare the gray amber, if they can gain possession of it on the shore. He adds that their flesh is approved of and solid, equalling that of our swans and geese.

This American Ostrich is the *Struthio Rhea* of Linnæus, the Tuiju of Lacépède; but we owe the perfect knowledge of a second species to Mr. Darwin, who has given a figure and ample descriptions of the bird and its habits in the 'Zoology of the Beagle,' and in his 'Researches in Zoology and Natural History;' but before we proceed to notice

Rhea Darwinii, we must give his valuable account of the habits of *Rhea Americana*.

"This bird," says Mr. Darwin, "is well known to abound on the plains of La Plata. To the north it is found, according to Azara, in Paraguay, where however it is not common; to the south its limit appears to be from 42° to 43°. It has not crossed the Cordillera; but I have seen it within the first range of mountains on the Uspallata plain, elevated between six and seven thousand feet. The ordinary habits of the Ostrich are well known. They feed on vegetable matter, such as roots and grass; but at Bahia Blanca I have repeatedly seen three or four come down at low-water to the extensive mud-banks, which are then dry, for the sake, as the Gauchos say, of catching small fish. Although the Ostrich in its habits is so shy, wary, and solitary, and although so fleet in its pace, it falls a prey, without much difficulty, to the Indian or Gaucho armed with the bolaa. When several horsemen appear in a semicircle, it becomes confounded, and does not know which way to escape. They generally prefer running against the wind; yet at the first start they expand their wings, and like a vessel make all sail. On one fine hot day I saw several ostriches enter a bed of tall rushes, where they squatted concealed till quite closely approached. It is not generally known that ostriches readily take to the water. Mr. King informs me that in Patagonia, at the bay of San Blas and at Port Valdes, he saw these birds swimming several times from island to island. They ran into the water, both when driven to a point, and likewise of their own accord, when not frightened: the distance crossed was about two hundred yards. When swimming very little of their bodies appear above water, and their necks are extended a little forward: their progress is slow. On two occasions I saw some ostriches swimming across the Santa Cruz River, where it was about four hundred yards wide, and the stream rapid.

"The inhabitants who live in the country readily distinguish, even at a distance, the male bird from the female. The former is larger and darker coloured, and has a longer head. The Ostrich, I believe the cock, emits a singular deep-toned hissing note. When first I heard it, standing in the midst of some sand-hillocks, I thought it was made by some wild beast, for it is a sound that one cannot tell whence it comes or from how far distant. When we were at Bahia Blanca in the months of September and October the eggs were found, in extraordinary numbers, all over the country. They either lie scattered single, in which case they are never hatched, and are called by the Spaniards 'huachos,' or they are collected together into a shallow excavation which forms the nest. Out of the four nests which I saw, three contained twenty-two eggs each, and the fourth twenty-seven. In one day's hunting on horseback sixty-four eggs were found; forty-four of these were in two nests, and the remaining twenty scattered huachos. The Gauchos unanimously affirm, and there is no reason to doubt their statement, that the male bird alone hatches the eggs, and for some time afterwards accompanies the young. The cock when on the nest lies very close; I have myself almost ridden over one. It is asserted that at such times they are occasionally fierce, and even dangerous, and that they have been known to attack a man on horseback, trying to kick and leap on him. My informant pointed out to me an old man, whom he had seen much terrified by one chasing him."

Rhea Darwinii, Gould, is smaller, and the general tinge of the plumage is light brown in place of gray; each feather being conspicuously tipped with white. The bill is considerably smaller, and especially less broad at its base; the culmen is less than half as wide, and becomes slightly broader towards the apex, whereas in the *R. Americana* it becomes slightly narrower: the extremity of both the upper and the lower mandible is more tumid in the latter than in *R. Darwinii*, and there are other differences.

R. Americana has been exhibited alive in the Gardens of the Zoological Society of London, and specimens of both species are to be seen in the museum of that Society and in the British Museum.

Dromaius (Vieill.).—Bill straight, with the edges very much depressed, rounded at the extremity, slightly carinated above; nostrils large, protected by a membrane, and opening above about the middle of the bill; head feathered; throat nearly naked; feet three-toed.

This is also the genus *Dromiccius* of Vieillot, *Tachsa*, Flem., and the form is placed by Latham under the genus *Casuarus*, and by Temminck under *Rhea*.

The Emeu, Emu, or Australian Cassowary, *Dromaius Novæ Hollandiæ* of authors, *D. ater* of Vieillot, and *Dromiccius Australis* of Swainson, Parembang of the natives, has become quite familiar to us from the frequency of its exhibition in menageries, and its breeding so readily in a state of domestication.

The food of the Emeu consists of vegetables and seeds, but chiefly of fruits, roots, and herbage. In a state of nature it is very fleet, and affords excellent sport in coursing with dogs, which are however rather shy of their game, in consequence of the powerful kicks that the bird can inflict, so powerful that the settlers say it can break the bone of a man's leg by striking out with its feet. Well-trained dogs therefore, to avoid this infliction, run up a-breast and make a sudden spring at the neck of the bird. Though the Emeu has bred so frequently in captivity, the mode of making the nest in the wild state does not appear to be well known, though it is generally supposed to be a mere hollow excavated in the earth. The dark green eggs are

six or seven in number. The birds appear to be tolerably constant in pairing, and the male bird sits and hatches the young, whilst the female watches and guards the nest. The Emeu can produce a hollow drumming sort of note, well known to those who have attended to its manners in captivity. These birds will, like the *Rhea*, take water. Captain Sturt, when descending the Murrumbidgee, in Australia, saw two of them in the act of swimming. They appear to be gregarious, and not very shy in some localities, for Major Mitchell in his excursion towards Port Phillip found them very numerous on the open downs, and their curiosity brought them to stare at the horses of the party, apparently unconscious of the presence of the riders. In one flock he counted thirty-nine, and they came so near him that the gallant traveller, having no rifle with him, was tempted to discharge a pistol at them, but without effect.

Rhea Darwinii.

Foot of Emeu.

This bird is widely diffused over the southern part of Australia and the neighbouring islands; but gradually disappearing before the encroachment of civilised man. They have also been observed on the west coast (Swan River). Captain Flinders found them in abundance at Port Phillip and King George's Sound, and D'Entrecasteaux at the latter place. Flinders and Péron saw them in numbers at Kangaroo Island.

The flesh of the Emeu, particularly the hind quarters, is generally described to be good and sweet eating.

Apteryx (Shaw).—In 1812 Captain Barclay, of the ship Providence, brought a specimen from New Zealand, and presented it to Dr. Shaw. When Dr. Shaw died, this specimen came into the possession of the late Earl of Derby. M. Temminck placed it with the Dodo among the *Inertes*, but still hardly anything was generally known of the bird till Mr. Yarrell, in 1833, described and figured the Earl of Derby's original specimen, collecting in his paper, in the first volume of the

'Transactions of the Zoological Society,' all that had been previously made known on the subject.

Mr. Gould, who has given beautiful and accurate figures of the bird in his grand work 'The Birds of Australia,' states that since Mr. Yarrell wrote he had become acquainted with five additional specimens, and had obtained further information respecting the history of the species. Two of these, from which his figures are taken, were presented to the Zoological Society by the New Zealand Company; and that society possesses a third but imperfect specimen, presented by Alexander M'Leay, Esq., of Sydney. Two others were afterwards added to the collection of the Earl of Derby, one of which his lordship liberally presented to Mr. Gould. A specimen is now (1855) alive in the gardens of the Zoological Society, Regent's Park.

The following is Mr. Gould's description:—Face and throat greenish-brown; all the remainder of the plumage consisting of long lanceolate hair-like feathers of a chestnut-brown, margined on each side with blackish-brown; on the lower part of the breast and belly the feathers are lighter than those of the upper surface, and become of a gray tint; bill yellowish horn-colour, its base beset with numerous long hairs; feet yellowish-brown.

This is the *Apteryx Australis* of Shaw; *Apteryx* of Temminck; Apterous Penguin of Latham; and Kivi-Kivi, or Kiwi-Kiwi, of the aborigines of New Zealand.

The length from the point of the bill to the end of the tailless body is about thirty-two inches; but the bill is much longer in some individuals than in others, and it is not satisfactorily made out whether this difference of length is to be attributed to difference of age or sex; but it has been supposed that the female has the longest bill.

Bill of *Apteryx*. (Owen.)

The toes are four in number; the three anterior ones are unconnected. The hind toe is placed on the inner flattened surface of the tarsus, is directed backwards, and almost perpendicularly downwards;

Foot of *Apteryx*.

it measures only one inch and one-eighth, and of this the claw or spur measures three-quarters of an inch. In the size and position of this toe the *Apteryx* corresponds with the Dodo.

Worms, insects, especially the larvæ of *Lepidoptera*, and probably snails, appear to be the food of this species. Mr. Gould states that the favourite localities of the bird are those covered with extensive and dense beds of fern, among which it conceals itself, and when hard pressed by dogs, the usual mode of chasing it, it takes refuge in crevices of the rocks, hollow trees, and in the deep holes which it excavates in the ground in the form of a chamber. In these latter situations, Mr. Gould tells us, it is said to construct its nest of dried fern and grasses, and there deposits its eggs, the number and colour of which have not been clearly ascertained.

Its habits are exclusively nocturnal, and the natives usually hunt it by torchlight, seeking for it with the utmost avidity, the skins being so highly prized for the dresses of the chiefs, and indeed the natives can be rarely induced to part with them. The feathers are also used for artificial flies in angling, after the European manner. When attacked it vigorously defends itself, striking rapidly and dangerously with its powerful feet and sharp spur, with which it is also said to beat the ground, in order to disturb the worms, on which it feeds, seizing them with its bill the instant they make their appearance.

The *Apteryx* inhabits all the islands of New Zealand, particularly the southern end of the middle island. ('Birds of Australia.') A second species, *A. Oweni*, has been described.

Apteryx Australis. (Gould.)

STRUVITE, a Mineral consisting of a Phosphate of Ammonia and Magnesia, with water.

STRYCHNOS (from *στυχνος*), a name applied by Theophrastus and Dioscorides to a kind of Nightshade, and adopted by Linnaeus for a genus of Plants belonging to the natural order *Apocynaceæ*. This genus has been made the type of a distinct order by Blume, who has been followed by Link, D. Don, and others. The principal difference that it presents from the order *Apocynaceæ*, to which it is referred by Von Martius, Brown, and Lindley, is in its peltate seeds and simple succulent fruit. This genus is composed of trees or shrubs, which do not yield a milky juice, and have opposite usually nerved leaves and corymbose flowers. Some of the species are possessed of tendrils, and are climbing plants. The calyx is 5-parted; corolla tubular, funnel-shaped, with a 5-parted spreading limb, which is valvate in æstivation; the stamens are 5, inserted into the throat of the corolla; ovary 2-celled, with a single stylo and capitate stigma; fruit a berry, pulpy inside, with a hard rind; seeds peltate, numerous, attached to a central placenta, with copious albumen, and foliaceous embryo. The species are not numerous, and are found principally in the tropical parts of Asia and America. One has been described by Mr. Brown a native of Australia.

S. Nuxvomica, Poison-Nut or Ratsbane, is characterised by its oval shining leaves 3-5-nerved, and its round smooth berries containing many seeds. The flowers are small, of a greenish-white colour, and are arranged in terminal corymbæ. The fruit, when ripe, is of the size and colour of an orange. Although the seeds of this plant yield an alkaloid, which is a deadly poison, the pulp of the fruit is greedily eaten by many kinds of birds. The wood of this plant is very hard and durable, and on that account is applied to many purposes by the natives on the coast of Coromandel and other places where it grows.

S. potatorum, Clearing-Nut, has ovate or oval glabrous pointed leaves; a deeply-fissured bark; and berries containing only one seed. It is an abundant plant in the woods and mountains of the East Indies. It has shining fruit, which is black when ripe. When full grown it attains a height of from 15 to 20 feet, and, like the last species, has a very hard wood, which is used for various economical purposes. The English name is derived from the use which is made of the seeds, which, when dried, are sold by the natives for the purposes of clearing muddy water.

S. St. Ignatii, St. Ignatius's Bean, has ovate acute glabrous leaves; pyriform fruit with many seeds, and 4-flowered axillary peduncles. It is a climbing shrub, without tendrils, bearing long drooping white flowers, which have the scent of jasmine. This species is the *Ignatia amara* of Linnaeus, but has been referred to the present genus by later botanists. It is a native of Cochin-China, the Philippine Islands, and other parts of Asia. This plant is called Papeeta in India, and is used by the native doctors as a remedy in cholera, but is administered in conjunction with Jehirree (*Cocos Maldivica*). When given in overdoses the symptoms are those of poisoning by strychnia, as vertigo, convulsions, &c., and the remedy used for these effects is lemonade in large quantities, which is said to afford relief speedily.

S. colubrina, Snake-Wood, or Snake-Poison-Nut, is a climbing plant with simple tendrils; leaves oblong or oval, obtuse, 3-nerved, shining; ovaries many-seeded. It is a native of the coast of Coromandel and of Silihet. It has small greenish-yellow flowers, and fruit as large as an orange, of a yellowish colour. It is called by the Telingas Naga Musadi, and is considered by the Indian doctors as an effectual remedy for the bite of the Nagra, or Cobra di Capella, a well-known poisonous snake; for this purpose it is used both externally and internally. It should however be stated as the result of the observation of the most intelligent travellers, that these vegetable remedies are not to be depended on in cases of bites of serpents, and that where danger is apprehended the only effectual remedy is excising the wound. The wood of this and other species of the genus is brought to this country, and is known under the name *Lignum colubrinum*.

S. Tiente, Tjetek, or Upas Tiente, has elliptical, acuminate, 3-nerved, glabrous leaves, and simple tendrils which are thickened opposite the solitary leaves. This plant is a climbing shrub, and is a native of Java, and is said to be the true Upas-Tree of that country. It is undoubtedly the most poisonous species of the genus, and yields the greatest quantity of strychnia. There are several other plants which are called by the name of Upas in various parts of Asia. The natives of Java prepare from this species one of the most deadly of the various poisons that are used by barbarous nations for producing death by the wounds occasioned by their arrows.

S. toxifera, Woorsly, Urari, or Poiseu-Plant of Guyana, has a climbing stem, thickly covered with long spreading reddish hairs; coarsely rough, 5-nerved, ovate, or oblong, shortly acuminate leaves; large round fruit. This plant is a native of Guyana, and was brought to this country by Sir Robert Schomburgk. It had long been suspected that the poison used by the American Indians for their arrows was a species of Strychnos, but such is the secrecy with which they gather the plant and prepare the poison, that all inquiries had been frustrated. Sir Robert's long stay in Guyana has enabled him to decide this point: by bribing some of the natives, he induced them to guide him to a spot where their famous Urari flourished, and on arriving at the place, found it to be the species of Strychnos above described. In the preparation of the poison, the Urari is not the only ingredient, but forms about half of the bulk of the ingredients used. For a full account of the discovery of this plant, and the mode of making the poison, with its effects on the animal economy, the reader is referred to Sir Robert Schomburgk's account of the Indian arrow-poison. ('Annals of Natural History,' vol. vii. p. 467.) It is remarkable that the poison prepared from this plant, though destroying life so rapidly when applied to a wound, may be taken into the stomach in doses of several grains without producing any ill effects, and it has even been proposed as a remedy in many diseases. It must be admitted however that it is a dangerous remedy to administer, as by coming in contact with the slightest abrasion of surface or ulceration, it might immediately destroy life.

S. pseudo-quina, Quina do Campo, has short-stalked, ovate, quintupled-nerved leaves, which are scissous at the edge, and smooth or nearly so above. It is a native of Brazil, and forms a scrubby plant about 12 feet high, with a corky bark. Its fruit is a smooth shining berry of a yellow colour, containing only four seeds. This plant is not poisonous, and is remarkable for its bitterness, which gives it a resemblance to the Gentiana and Cinchona. The fruit of this species is eaten by the native children. The fruit also of another species, *S. brachiata*, is eaten by deer in Peru, and that of *S. spinosa*, a Malagash plant, is greedily devoured by swine.

STRYGOCEPHALUS. [BRACHIOPODA.]

STURGEON. [STURIONIDÆ.]

STURIONIDÆ, a family of Fishes belonging to the section *Chondropterygii*, the species of which are distinguished from others of the section by the gills being free, as in ordinary fishes, thus differing from the second great division of the fishes having a cartilaginous skeleton, such as the Sharks and Rays, in which the gills are fixed, and have their outer margin attached to the skin. The *Sturionidæ*, or Sturgeon Tribe, have moreover but one opening to the gills, and this is protected by an operculum.

Four genera are contained in this family, *Acipenser*, *Spatularia*, *Chimæra*, and *Callorhynchus*. To the first of these genera belongs the Common Sturgeon (*Acipenser Sturio*, Linn.), which is not unfrequently met with in mouths of English rivers. It is of an elongated form, and has the body protected by numerous indurated plates, which are arranged in longitudinal series; the head is entirely covered by bony plates; the muzzle is elongated, and more or less

pointed; and the mouth, which is placed on the under side of the head, is tubular, and destitute of teeth: on the back is a single dorsal fin, which is placed on the hinder third of the fish; the tail is forked, and the upper lobe is the largest, as in the Sharks.

"In the northern part of Europe," observes Mr. Yarrell, "this fish is much more numerous than with us, and extensive fisheries are established for its destruction. Caviar is made of the roe of the female; isinglass is obtained from the dense membrane forming the air-bladder; and the flesh, besides being preserved by salting and pickling, is in request for the table while fresh, being generally stewed with rich gravy, and the flavour considered to be like that of veal. The flesh, like that of most of the cartilaginous fishes, is more firm and compact than is usual among those of the osseous families."

Two species of Sturgeon have long been distinguished by the fishermen of the Solway Frith, the one with a blunt nose, and the other with a sharp nose: the latter is the more common of the two; the former has been described by Dr. Parnell, in the 'Transactions of the Royal Society of Edinburgh' (vol. xiv. pl. 4), and is introduced by Mr. Yarrell, in the Supplement to his 'History of British Fishes.'

Several very distinct species frequent the rivers of Russia, and will be found described and figured by M. A. Loretzky, in the third volume of the 'Transactions of the Imperial Society of Naturalists at Moscow.' Three species are found in the rivers which flow into the Black Sea, and moreover North America possesses species which are peculiar.

The genus *Spatularia* is distinguished by the enormous prolongation of the muzzle, the sides of which are dilated. The general form of the body nearly resembles that of the Sturgeon; but the gills are more open, and the operculum is prolonged into a membranous point behind; the mouth is deeply cleft, and well provided with small teeth; the lobes of the tail are very nearly equal. But one species of this curious genus is known (*Squalus Spatula*, Mauduit), and that is an inhabitant of the Mississippi.

Chimæra, Linn.—Although placed in the present section, the *Chimæra* differ considerably from the Sturgeons, and are in fact very nearly allied to the Sharks. "Though in these fishes there is but one apparent gill-opening," observes Sir John Richardson, in his 'Fauna Boreali-Americana,' "the gills in reality adhere by a large part of their borders, and there are consequently five holes communicating with the external gill-opening." They have a rudimentary operculum concealed by the skin; and their jaws, still more reduced than those of the sharks, are furnished with hard plates, four above and two below, in place of teeth. The males are distinguished by trifid horny appendages to the ventral fins. The eggs are large and of a coriaceous texture, and have flattened and hairy margins. The snout, supported like that of the shark, projects forwards, and is pierced with pores arranged in tolerably regular lines; the anterior dorsal fin is armed with a strong bony spine, and is placed over the pectorals.

In the genus *Chimæra*, as at present restricted, the snout is conical; the second dorsal fin commences immediately behind the first, and extends to the tip of the tail, which is elongated and pointed, and terminates in a long filament: on the under side the tail is also furnished with a long but narrow fin. Only one species is known, the Northern *Chimæra* (*C. monstrosa*, Linn.). This fish inhabits the European seas, and is said to be frequently caught following the shoals of herrings, on which it preys. It is usually two or three feet in length, and the general colouring of the body is silvery-white, but the upper parts are mottled with brown.

The next genus differs from *Chimæra* chiefly in having the snout terminated by a largish fleshy appendage. The second dorsal fin is placed over the ventrals, and terminates opposite the commencement of the lower tail-fin. The only species known until very recently was the Antarctic *Chimæra* (*C. Callorhynchus*, Linn.), an inhabitant of the South Seas. A second species of *Callorhynchus* is described by Mr. Bennett under the name of *C. Smythi*, in the zoological appendix to Beechey's 'Voyage;' and more recently Sir John Richardson describes a species of the present genus (*C. Tasmanicus*), which he regards as distinct. It is from Port Arthur, Van Diemen's Land.

STURMIA, a genus of Plants belonging to the natural order *Orchidaceæ* and the tribe *Malazideæ*. It has a patent perianth; lip anterior, erect or oblique, entire, dilated, much larger than the sepals; stigma roundish; rostellum obsolete, but with an appendage consisting of two tubercles; anthers terminal, deciduous, moveable like a lid, with two distinct cells; column elongated; germeo on a twisted stalk.

S. Loeselii has the leaves oblong-lanceolate; stem triangular; lip obovate, longer than the petals; flowers from 6 to 12, in a lax spike, yellowish in colour; the sepals lanceolate; petals linear; the hypanthium is large, ovate, inclosed in the whitish sheaths of the decayed leaves. It is the *Liparis* of some authors. It is found in spongy bogs in Norfolk, Suffolk, and Cambridgeshire, but is very rare.

(Babington, *Manual of British Botany*.)

STURNIDÆ, Mr. Vigors' name for the Starling Family, belonging to his order *Insectores*.

Linnaeus placed his genus *Sturnus*, consisting of only five species, among which the Water-Ouzel appears as *Sturnus Cinclus*, between *Alauda* and *Turdus*, in his order *Passeres*. Cuvier arranges the Starlings between the Cassiquea (*Cassicus*) and the Crows (*Corvus*).

Mr. Vigors, who assigns to the *Sturnidæ* a place between the *Fringillidæ* and the *Corvidæ*, in his *Conirostres*, observes that this family embraces a considerable number of groups, approaching each other in their gregarious and migratory habits. They are, he remarks, found in every part of the globe united in large flocks, carrying destruction among the cultivated fields, and following herds of cattle for the sake of the insects or grains which they may pick up from their bodies or in their neighbourhood. "In addition to the American genus *Icterus*," continues Mr. Vigors, "and the contiguous genera *Cassicus* and *Xanthornus* of M. Brisson, together with *Pendulinus*, Vieillot, and several corresponding groups, we may observe the genus *Amblyramphus*, Leach, united to the family, as also the *Buphaga*, Linnæus, and *Pastor* and *Lamproternis*, which M. Temminck has separated from the *Thrushes*. The whole of the family, united by their manners and the straight and conical form of the beak, the ridge of which passes back to some extent over the forehead, may be observed, by those who cast even a casual glance over the three adjoining groups, to hold an intermediate rank between the weaker conformation of the *Fringillidæ* and the more powerful structure of the *Corvidæ*." And he passes into the family of *Corvidæ* by the genus *Nucifraga*. [NUCIFRAGA.]

Mr. Swainson divides the family into five groups or sub-families.

Sturnidæ. Starlings.

Size smaller than that of the *Corvidæ*. Stature less robust. Bill angulated at the base; the upper mandible entire. Lateral toes equal. (Sw.)

Sub-Family *Sturninæ*.

Bill in the form of a lengthened cone, longer than the head; the commissure with an acute angle at the base.

Sturnus, Linn.—Bill depressed from the base as far as the tip, which is slightly inflexed, and obsoletely notched; culmen convex and rounded. Wings lengthened, pointed; the first quill minute and spurious; the second and third longest. Tail short, divaricated. Feet moderate, terrestrial; the lateral toes equal; the middle toe as long as the tarsus; hinder toe shorter. The *Conirostral* type. (Sw.)

S. vulgaris, the Common Starling, the Starc. This bird is too well known in Great Britain to need description. It is one of the handsomest of our birds, and is a general favourite. It is intelligent, sprightly, has a retentive memory, and when kept in confinement the males learn to whistle tunes and imitate some of the sounds of the human voice. They are social, living in flocks throughout the greater portion of the year. The Starling builds in church steeples, under eaves, and in holes of houses, towers, or ruins. The nest is made of slender twigs. The eggs are four or five in number, of a delicate pale blue, 1 inch 2 lines in length by 10 lines in breadth. Their food consists of worms, insects, and snails. They are frequently seen in meadows searching for food amongst cattle and sheep. They sometimes eat berries and grain. They occasionally congregate together in prodigious numbers in shrubberies and plantations.

The Starling is common in almost every part of the United Kingdom. It is found in the north of Europe, and as far east as Nepaul, the Himalaya Mountains, Calcutta, China, and Japan. It has been seen in Africa as far south as the Cape of Good Hope.

Head and Foot of Starling (*Sturnus vulgaris*).

Pastor, Temm.—Bill depressed only at the base, compressed beyond; culmen slightly bent; tip of the upper mandible deeply notched; commissure distinctly angulated at the base; nostrils large, feathered. Wings moderate in length, ample in breadth; first quill very minute, the second nearly equal to the third. Tail short, broad, rounded. Feet very large and strong; middle toe as long as the tarsus; hinder shorter; lateral toes equal; claws somewhat slender, acute, but not much curved.

P. roseus, the Rose-Coloured Ouzel. This bird is an accidental visitor in the British Islands. Like the Common Starling, it has a wide geographical range. It is very numerous in various parts of

hindistan. It inhabits Syria, Egypt, and Africa. It flies in flocks, and has many of the habits of the Common Starling.

The adult male has a beak of a yellowish rose-colour; the head, neck, wugs, and tail black, glossed with violet-blue; the feathers on the head elongated so as to form a flowing crest; the back, scapulars, and rump of a delicate rose-colour; the chin, throat, and front of the neck, black; breast, sides, and abdomen, like the back, of rose-colour; thighs and under tail-coverts black; legs and toes yellowish-brown; claws darker brown. (Yarrell.)

Gracula, Auct. [CORACIAS.]

Acridotheres, Vieill.—General structure of *Pastor*; but the whole of the head entirely naked, and furnished with fleshy crests and wattles; nostrils large, naked. Feet moderate. Tail even. Bill very wide at the base. The *Tennirostral* type. (Swainson.) Ex. *A. carunculatus*.

Oryzotomus, Sw.—Bill much lengthened, longer than the head; the sides are compressed; culmen flattened, nearly straight, and angulated on each side, the base advancing very far upon the head and dividing the frontal feathers; nostrils placed in a large depression towards the base of the bill. Wings very short and considerably rounded. Tail moderate, rounded; all the feathers, and the secondary quills, ending in setaceous points. Legs long and robust; tarsus much longer than the middle toe; lateral toes unequal, the inner shortest. It is a native of the Pacific Islands. The *Scansorial* type. (Sw.) Ex. *O. carunculatus*.

Sub-Family *Lamproterninæ*. Grakles.

Bill thrush-like, compressed; the culmen curved from the base. Lateral toes unequal.

Ptilonorhynchus.—Size large. Bill short, very thick, convex above; both mandibles distinctly notched; nostrils placed half-way between the gape and the tip, partly concealed by the short thick-set feathers of the front, which lie on the basal half of the bill. Wings rather short, rounded; the first and second quills graduated; the third shorter than the fourth and fifth, which are the longest. Tail moderate; the feathers broad, their tips truncated. Feet ambulating, large, and very strong; middle toe and tarsus of equal length; hinder toe very strong, but much shorter; lateral toes unequal, the outer longest, and united to the middle as far as the first joint. It is a native of Australia. (Sw.) Ex. *P. holosericeus*.

Lamproternis, Temm. (Grakle).—Bill thrush-like, compressed its whole length; culmen curved from the base to the tip; upper mandible notched; commissure slightly curved; nostrils midway between the tip and the gape, naked, but with the frontal feathers reaching to their base. Wings long, ample; the first quill spurious; the third, fourth, and fifth of equal length, and longest. Tail short, even, rounded, or (as in the *Rasorial* type) considerably lengthened and cuneated. Feet very large and strong; middle toe and tarsus equal; hinder strong, but much shorter; lateral toes unequal. (Sw.) Ex. *L. ptilonorhynchus*. ('Birds of West Africa,' i. 140.)

Sub-Family *Scaphidurinæ*. Boat-Tails.

Bill of a very lengthened conic shape, entire, and compressed; the culmen slightly curved. Tail graduated, the sides reflected upwards, or boat-shaped. Feet strong. (Sw.)

Astrapia, [CORVIDÆ.]

Scaphidura, Sw.—Bill longer than the head, conic; both mandibles equally thick; the base of the culmen broad, flattened, and advancing very far on the front of the head; commissure angulated at the base, and situated on the sides; nostrils basal, placed in a small triangular hollow on the sides, the membrane obsolete. Wings lengthened, pointed; the first quill longest. Tail moderate, graduated, boat-shaped. Feet strong; middle toe and tarsus of equal length; hinder toe much shorter; inner toe hardly shorter than the outer. It is a native of South America. (Sw.) Ex. *S. Barita*.

Quiscalus, Vieill.—Bill longer than the head, compressed. Both mandibles equally thick. Culmen slightly curved, and compressed from the base, where it simply divides the frontal feathers, without being dilated. Commissure considerably sinuated. Nostrils broad, naked; the aperture round. Wings moderate, somewhat pointed; the first two quills slightly shorter than the third and fourth, which are the longest. Tail rather lengthened, much graduated, boat-shaped; tips of the lateral feathers truncated. Feet large, strong. Middle toe and tarsus equal; hinder toe shorter; inner toe scarcely shorter than the outer. America. (Sw.) Ex. *Q. versicolor*.

Scolecophagus, Sw.—Bill shorter than the head, straight, slender; the margin inflexed, but not sinuated. Wings moderate, pointed; the first quill rather shorter than the second. Tail divaricated, flat, and slightly rounded. Legs lengthened, slender, formed for walking. Middle toe and tarsus of equal length; hinder toe shorter; lateral toes of equal length. Claws slender, acute, slightly curved. (Sw.) Ex. *S. ferrugineus*.

Sub-Family *Icterinæ*. Hang-Nests.

Bill completely conic, entire, rather shorter than the head, either straight or with both mandibles slightly bent. Feet formed for grasping. The claws thick, broad, and much curved. (Sw.)

Cassicus, Dandin (Cassicans).—Bill rather longer than the head the base thick, very convex, and enlarged into a broad oval plate

which advances very far on the front, and divides the frontal feathers. Nostrils oval, naked, basal, pierced in the solid substance of the bill, and close to the margin of the upper mandible. Commissure straight, but angulated at the base. Wings rather long; the first and second quills graduated. Tail graduated. Feet short, very strong. Hind toe and claw nearly as long as the tarsus. It is a native of Tropical America. (Sw.)

Xanthornis (*Xanthornis*), Cuv.—Bill not longer than the head, generally shorter, perfectly straight; the culmen not dilated at the base, but simply dividing the frontal feathers. Wings moderate, pointed; the first three or four quills generally or nearly equal. Tail moderate, rounded. Feet moderate, but with the hinder toe manifestly longer than the tarsus; lateral toes unequal. It inhabits America. (Sw.) Ex. *X. Baltimorei*.

Icterus, Cuv.—Bill somewhat lengthened, as long as the head, or longer; both mandibles slightly curved, and considerably attenuated. Nostrils basal, rather large, covered above by a membrane; the aperture lateral and oval. Wings moderate; the first and second quills rather shorter than the third. Tail somewhat lengthened, graduated. Feet moderate; inner toe shorter than the outer; hinder toe shorter than the tarsus. Ex. *I. castaneus*.

Chrysomus, Sw.—Bill resembling *Xanthornis* (*Xanthornis* must be meant); but the margin of both mandibles inflexed. Wings moderate; the first quill rather shorter than the second. Tail rounded. Feet formed for walking. Toes large, very long and slender; middle toe longer than the tarsus; lateral toes equal; hinder toe shorter than the tarsus. Claws long, very slender, and but slightly curved. (Sw.) Ex. *C. icterocephalus*.

Sub-Family Aglainæ (*Agelaius*?). Maizers.

Bill short, thick, entire, completely conic, sometimes depressed, and rounded at the tip. Culmen rather broad, and flattened at the base. Legs long, slender, formed for walking.

Dolichonyx, Sw.—Bill very short, finch-like, conic, entire, shorter than the head; the commissure sinuated. Wings pointed; the first and second quills longest and nearly equal. Tail slightly graduated, subscansorial; the tips acuminate, and somewhat rigid. Legs long, slender; middle toe longer than the tarsus; lateral toes unequal, the inner longest; hind toe of equal length with the tarsus. Claws long, very slender, and slightly curved. (Sw.) Ex. *D. oryzivorus*. [BOBOLINK.]

Agelaius, Vieill.—Bill short, very conic, entire; the tips compressed; the culmen flattened towards the base; sides of the mandibles inflexed. Wings lengthened; the first two quills longest. Tail slightly rounded. Legs long, slender; middle toe nearly as long as the tarsus. Claws long, very slender, and but slightly curved. It is a native of America. (Sw.)

A. phæniceus, the Red-Winged Starling. It is the *Sturnus prædatorius*, *Icterus phæniceus*, Red-Winged Maize-Bird and Red-Winged Blackbird of authors. This bird is a native of America, but a few specimens have been taken in Great Britain. In America it is called Marsh Blackbird, where they are very destructive to the corn crops. They are sociable like the starling, and not unfrequently vast numbers of them assemble together.

Leistes, Vigors.—Bill lengthened, conic, very straight; the culmen depressed from the base to the tip, which is flattened. Wings moderate; the first quill rather shorter than the three next, which are the longest. Tail rounded. Legs large, strong; middle toe longer than the tarsus; hinder toe shorter; lateral toes unequal, the outer one smaller than the inner; the hinder claw much stronger and more curved than the middle one. (Sw.) Ex. *L. erythrocephalus*.

Molothrus, Sw., Cowpen. Ex. *M. pecoris*. [MOLOTHRUS.]

Sturnella, Vieillot.—Bill long, equal to the length of the head, conic, much depressed towards the tip, where it is broader than high; culmen dividing the frontal feathers, where it is depressed and flattened. Wings moderate; first quill rather shorter than the second. Tail short, rounded; the feathers rather narrow. Feet large, but slender; tarsus longer than the middle toe; lateral toes unequal, the inner shortest; hind toe not much shorter than the middle. Anterior claw small, and of equal size; hinder claw (typically) twice as long as the others. (Sw.) Ex. *S. collaris*. ('Classification of Birds.')

The family is immediately succeeded in Mr. Swainson's arrangement by the *Fringillidæ*, to which some of the species placed by him among the *Sturnidæ*, but by others among the *Finches* (*Dolichonyx*, for example), would seem rather to belong.

Prince Bonaparte, in his 'Birds of Europe and North America,' places the *Sturninæ* in his family *Corvidæ*, next to *Corvinæ*, and arranges under the *Sturninæ* the genera *Acridotheres*, *Quiscalus*, *Scolecophagus*, *Sturnella*, *Icterus*, *Agelaius*, *Molothrus*, and *Dolichonyx*.

Mr. G. R. Gray ('Genera of Birds') makes the *Sturnidæ*, which are immediately succeeded by the *Fringillidæ*, as they are in Bonaparte's method, follow the *Corvidæ*.

Mr. Gray divides the *Sturnidæ* into the following sub-families:—

1. *Lamprotorninæ*.

Genera:—*Ptilonorhynchus*, Kuhl (*Pyrrhocorax*, Vieill.; *Kitta*, Kuhl); *Chlamydera*, Gould (*Ptilonorhynchus*, Jard.; *Calodera*, Gould); *Lamprotornis*, Temm. (*Turdus*, Lath.; *Lamprotornis*, Temm.); *Jaida*,

Less. (*Lamprocolius*, Sundev.; *Lamprotornis*, Temm.); *Megalopterus*, Smith; *Spreo*, Less. (*Turdus*, Gm.; *Lamprotornis*, Sw.); *Aplonis*, Gould (*Turdus*, Lath.); *Coccoa*, Hodgs.

2. *Buphaginæ*.

Genus, *Buphaga*, L.

3. *Sturninæ*.

Genera:—*Pastor*, Temm. (*Psaroides*, Vieill.; *Boscis*, Brehm; *Turdus*, L.); *Acridotheres*, Vieill. (*Cossyphus*, Dum.; *Gracula*, Gm.); *Psarolophus*, Jard. and Selby (*Pastor*, Gould; *Oriolus*, Hodgs.); *Cutia*, Hodgs.; *Dilophus*, Vieill. (*Sturnus*, Lath.; *Pastor*, Temm.; *Acridotheres* (Vieill.), Swains.; *Gracula*, Gm., Cuv.); *Creadion*, Vieill. (*Sturnus*, Lath.; *Oxytornus*, Swains.; *Philesturnus*, J. Geoff.; *Philedon*, Cuv.; *Icterus*, Less.); *Sturnus*, L.; *Sturnella*, Vieill. (*Cassicus*, Daud.; *Aldaia* and *Sturnus*, L.); *Amblyrhynchus*, Leach (*Oriolus*, Gm.; *Sturnella*, Vieill.; *Leistes*, Sw.).

4. *Quiscalinæ*.

Genera:—*Astrapia*, Vieill. (*Paradisea*, L.; *Lamprotornis*, Temm.); *Scolecophagus*, Sw. (*Gracula*, Wils.; *Quiscalus*, Bonap.; *Chalcophanes*, Wagl.); *Quiscalus*, Vieill. (*Icterus*, Temm.; *Quiscalia*, Licht.; *Chalcophanes*, Wagl.; *Scaphidura*, Sw.); *Cassidix*, Less. (*Oriolus*, Gm.); *Scaphidura*, Sw. (*Gracula*, Gm.; *Quiscalia*, Licht.; *Icterus*, Temm.; *Chalcophanes*, Wagl.).

5. *Icterinæ*.

Genera:—*Cassicus*, Briss. (*Icterus*, Temm.; *Xanthornus*, Pallas; *Psarocolius*, Wagl.; *Oriolus*, L.); *Cassidix*, Swains. (*Icterus*, Bonap.; *Xanthornus*, Jard. and Selby); *Xanthornus*, Briss. (*Psarocolius*, Wagl.; *Yphantos* and *Pendulinus*, Vieill.; *Oriolus*, L.); *Icterus*, Briss. (*Oriolus*, L.; *Pendulinus*, Vieill.; *Psarocolius*, Wagl.); *Chrysomus*, Sw. (*Pendulinus*, Vieill.; *Oriolus*, L.).

6. *Aglainæ*.

Genera:—*Molothrus*, Swains. (*Emberiza*, Gm.; *Passerina*, Vieill.; *Psarocolius*, Wagl.; *Agelaius*, Swains.); *Leistes*, Vigors (*Agelaius*, Vieill.; *Psarocolius*, Wagl.; *Xanthornus*, Quoy and Gaim.; *Icterus*, Licht.); *Agelaius*, Vieill. (*Oriolus*, L.; *Sturnus*, Wils.; *Icterus*, Briss.; *Psarocolius*, Wagl.); *Dolichonyx*, Swains. (*Emberiza*, L.; *Passerina*, Vieill.; *Icterus* and *Emberizoides*, Bonap.; *Psarocolius*, Wagl.).

STYLARIA, a genus of Annelida.

STYLE. [PISTIL.]

STYLIDIACEÆ, *Styleworts*, a natural order of Plants belonging to the epigynous group of Monopetalous Exogens. They are herbaceous plants, or under-shrubs, with aqueous juices, sometimes having hairs, which are simple, acute, or capitate; the stem and branches are round, or sometimes they have a scape; the leaves are entire, without stipules, mostly scattered, sometimes whorled, the radical ones clustered in the

Stylidium lanicifolium.

a, cutting showing corymbose flowers and leaves; b, flower showing irregular corolla, tubular calyx, and capitate hairs; c, filaments and style, forming a single column, with anthers covering stigma; d, 2-celled ovary; e, section of seed with minute embryo.

species which possess a scape; the flowers are solitary, or arranged in spikes, racemes, or corymbs, mostly terminal; the pedicels have three bracts; the tube of the calyx is attached to the ovary; the limb is 2-6-parted, bilabiate, or regular and persistent; the corolla is monopetalous, irregular, 5- or 6-cleft, imbricated in maturation, and late in falling off; there are two stamens, the filaments of which are united

with the style, the whole forming a single elongated column; the anthers are 1- or 2-celled; when the latter, they lie over the stigma; the pollen is globose, simple, sometimes angular; the ovary is 2-celled, or sometimes 1-celled from a contraction of the dissepiment, many-seeded, with a single gland in front, or two opposite ones; the style is one with the filaments, and the stigma, which is simple or bifid, is inclosed and hidden by the anthers. The fruit is a capsule, with two valves and two cells; the seeds are indefinite, small, erect, sometimes stalked; the embryo is minute, and inclosed within a fleshy somewhat oily albumen. This curious order of plants is allied to *Campanulaceæ* and *Goodeniaceæ*, but the peculiar union of its filaments and style into a single column distinguishes it at once. This column possesses a considerable degree of irritability. [STYLIDIUM.] There are only two genera of this order known besides *Stylidium*. They are chiefly found in Australia, but species have been discovered on the Himalayas, Ceylon, and the South Sea Islands. Their properties are unknown.

STYLIDIUM (a diminution of 'stylus,' a column), the name of a genus of Plants, the type of the natural order *Stylidiaceæ*. The essential characters of this genus are: Calyx 2-lipped; corolla irregular, 5-parted, form of the segments equal, the fifth smaller, forming a labellum, which is deflected; column consisting of filaments and style, reflexed, with a double curve; anthers with two lobes widely separated; stigma obtuse, undivided; capsule bilocular, with the dissepiment sometimes superiorly incomplete. This is chiefly an Australian genus of plants, and is remarkable for its gynandrous structure, and for the irritability of the column formed by the union of filaments and style. Irritability is seen in many genera allied to this, as in the indusium of *Goodenia*. The part which exhibits movement on being excited is the curved column, and the irritability is confined to a small portion only of the column near its base. In the natural state the column projects from beyond the flower, and hangs down over the smaller petal or labellum, and the irritable part of it is in contact with the labellum. The movement of the column consists in raising itself from this deflected position to that of perfect uprightness. In the bud, the column does not possess this power, but as the anthers develop, this property of the column increases, and is at its greatest intensity at the time of the dehiscence of the anthers, and entirely ceases when the impregnation of the ovules has taken place. During this process the anthers also undergo a change; previous to dehiscence, they entirely cover the stigma, but after this process has taken place, the stigma is fully exposed, and remains so. The irritability is then developed with the anther: it is at its greatest height whilst the anther is performing its function, and ceases with the function of that organ. The movement of the column is produced by external stimulants or the application of a solid body. Exposure to heat will erect the column, and its withdrawal will cause it to return to its natural position. After returning to this state, it requires ten or fifteen minutes' rest before it will again exhibit irritability. When elevated, the column cannot be made to return by force to its bent position. When the movement takes place naturally, it is slow and regular, and when under the influence of artificial excitants, it occurs suddenly and by jerks. The final cause of these movements is evidently connected with impregnation, and it seems that the pollen is conveyed to the stigma whilst the column is upright, which could not be the case whilst it was dependent.

The species of this genus described by Mr. Brown, in his 'Prodromus Floræ Novæ Hollandiæ,' are forty-five in number; besides these there are two or three natives of the East Indies.

STYLIFER, or STILIFER (Broderip), a family of Pectinibranchiate Mollusca. The shell is hyaline, turritated, the apex of the spire mucronate. The aperture subovate, acuminate above. The external lip acute and sinuated. Animal with the mantle thick, fleshy, and cup-shaped, covering the last whorls of the shell. The proboscis very long and retractile. The tentacles round, thick, subacuminate, and situate at the base of the proboscis. Eyes very small, sessile at the base of the tentacles. Stem of the branchia solitary. Animal marisque, penetrating into the integument of the star-fish.

S. Astericola (Brod.).—Mr. Broderip states that the arrival of this species with the soft parts had afforded data for a generic character, indicating a distinct family among the Pectinibranchiata, the form of whose mantle differs from any other genus of that order. This mantle, which is of a green hue, is thick, fleshy, and cup-shaped, with a small aperture at its base, and a free posterior margin, enveloping the soft parts and the last volutions of the shell, which has thus somewhat the appearance of a small acorn set in its cup. On the ventral aspect of the mantle is the rudiment of a foot, and from the small basal aperture a retractile proboscis (which, when exerted, is as long as the whole animal) is protruded. At the base of the proboscis are two thick, round, somewhat pointed tentacula; and at the base of them are the eyes, or rather, ocular specks without pedicles. The branchia is placed on a single stem. At the base of the proboscis is a spherical muscular stomach, and the intestine ascends into the spire of the shell, where it becomes attached to the liver, which in *S. Astericola* is of an orange colour.

Mr. Cuming found this elegant parasite burrowed in different parts of the rays of the oral disc of *Asterias solaris*. It was almost hidden from sight, so deeply does the animal penetrate into the substance of the star-fish, in which it makes a comfortable cyst for itself, and

wherein it most probably turns by the aid of its rudimentary foot. All the specimens infested with these testaceous molluscs appeared to be in the best health, though there is reason to believe that they feed upon the juices of the star-fish. Mr. Broderip observes that *Stylifer* (with that instinct of self-preservation which is imparted to all parasites whose existence depends upon that of their nidus) appears, like the larvæ of the ichneumon tribes among insects, to avoid the vital parts; for in no instance did Mr. Cuming find it imbedded anywhere save in the rays, though some of the individuals had penetrated at their base, and very near the disc. When extracted, the older shells have the appearance of a milky-clouded glass-bubble; the younger shells Mr. Broderip found of an unclouded transparency.

Stylifer Astericola. (Sowerby's 'Genera.')

a, a portion of *Asterias solaris*, showing *S. astericola* in its cyst; b, a fine specimen of the shell; c, d, views of the upper and under side of the same, magnified.

Mr. Broderip remarks that Dr. Turton, in the second volume of the 'Zoological Journal,' p. 367, pl. 13, describes and figures a shell under the name of *Phasianella stylifera*, adding that he found a dozen attached to the species of *Echinus esculentus* dredged up in Torbay. Mr. Broderip observes that it is clear that Dr. Turton's shell is not a *Phasianella*, for it is described as having no operculum, and the similarity of the shell leaves no doubt, when joined to the parasitic habits of the animals, that it is one of the congeners of *Stylifer Astericola*. Mr. Broderip therefore names Dr. Turton's specimen *S. Turtoni*.

Stylifer Turtoni, natural size and magnified. ('Zool. Journ.')

Mr. G. B. Sowerby furnished Mr. Broderip with a third species, which, though its habits were unknown to the latter, he considers to be referrible to this genus, and he names it *S. subulatus*; it is so beau-

Stylifer subulatus, natural size and magnified. (Sowerby's 'Genera.')

tifully transparent, that in fine specimens the columella can be as distinctly seen as if there were no intervening medium; and its long apex, which consists of many close-set whorls, is generally out of the perpendicular.

(Broderip, in Sowerby's *Genera of Recent and Fossil Shells*, Number xxxviii.)

STYLINA. [MADREPHYLLIÆ.]

STYLOCERUS. [CERVIDÆ.]

STYLOPORA. [MADREPORÆ.]

STYLOPS. [STREPSIPTERA.]

STYRACEÆ, *Storax* woods, a small natural order of Plants, placed by Lindley in his Polycarpous group of Monopetalous Exogens. The

species are trees or shrubs, with alternate leaves without stipules, usually turning yellow in drying. The flowers are axillary, and are either solitary or clustered with membranaceous bracts. The calyx is persistent, and has five divisions; corolla with divisions, frequently differing from the calyx, and with imbricated aestivation; stamens varying in number, arising from the tube of the corolla, with 2-celled anthers; ovary 3-5-celled, with few ovules, a simple style, and capitate stigma; fruit a drupe; seeds solitary, with the embryo lying in the midst of albumen. This order is nearly allied to *Ericaceae*, from which it differs in habit, its definite seeds, and its frequently inferior ovary. It differs from *Ebenaceae* in its stamens being perigynous, in the insertion of the ovules, and its simple style. It is however an order on which there are many different opinions, some referring all its genera to *Ebenaceae*, whilst others separate from it the genera *Symplocos* and *Halesia* as types of distinct orders.

The species are found in the temperate and tropical parts of North and South America, and also in Nepal and China. This order is chiefly remarkable, in an economical point of view, for furnishing the Storax and Benzoin of commerce, which contain a peculiar acid called the Benzoic Acid. Some of the species are used for dyeing yellow, and a species of *Alstonia* is employed as a substitute for tea. The various species of *Halesia* are the Snow-Drop Trees of the Carolinas. [HALESIA.]

Styrax officinalis.

a, branch showing leaves and clustered flowers; b, corolla opened with perigynous stamens and pistil; c, fruit covered with tomentum; d, transverse section of ovary, showing three cells; e, section of seed, showing embryo in the midst of albumen.

STYRAX (from *στυράξ*), a genus of Plants forming the type of the natural order *Styraceae*. It has a persistent campanulate 5-toothed calyx; monopetalous deeply 3-7-cleft corolla; 10 stamens monadelphous at the base, with linear 2-celled anthers; superior ovary with indefinite ovules, with simple style and 3-lobed stigma; fruit a dry drupe; seed with a double testa, inverted embryo, and fleshy albumen. The species are elegant trees and shrubs, mostly covered with hairs having a stellate form, with entire leaves, and white or cream-coloured racemose flowers. They are principally natives of America and Asia; one is found in Europe and one in Africa.

S. officinalis, Official Storax. Leaves ovate, downy beneath, shining above; racemes 5-6-flowered, simple, shorter than the leaves. It is a native of Syria, Italy, and most parts of the Levant. It is common all over Greece and the Peloponnese, where Dr. Sibthorp found it retaining almost the same designation as that given it by Theophrastus and Dioscorides, the modern name being *Στυράκη*. It was first cultivated in England by Gerard, but is still a rare plant in this country. One of the finest specimens is in the Botanic Garden at Chelsea, and is annually covered in May and June with a profusion of rich blossoms. This is the species which yields the Storax which is admitted into the *Materia Medica* of the London Pharmacopoeia. [STYRAX.] There is however another Storax known in commerce, with which this must not be confounded, and which is the produce of the *Liquidambar styraciflua*, a plant belonging to the natural order *Balsamaceae*.

S. Benzoin, Benjamin Storax, or Gum-Benjamin Tree. Leaves ovate-oblong, pointed, glabrous above, downy beneath; racemes compound, almost the length of the leaves. It is a native of Sumatra and Java. It is the plant which produces the Benzoin, or Gum Benjamin, of commerce; and which, as well as Storax, is used in medicine.

[BENZOIN.] The great consumption however of these resins is not as medicines, but in their use as incense in the worship of the Roman Catholics and Mohammedans. Though older botanists, as Garcias, Grim, and others, were acquainted with the tree that yielded Benzoin, Ray confounded it with the genus *Laurus*, and Linnaeus with the genera *Croton* and *Terminalia*. Dryander gave a correct account of the plant in 1787, and referred it to its present position.

S. grandifolius, Large-Leaved Styrax. Leaves broad, obovate, pointed, slightly serrated, green above, downy beneath; lower peduncles 1-flowered, solitary, axillary. It is a native of North America, in woods and on the banks of rivers from Virginia to Georgia. It is a handsome shrub, bearing white flowers, opening them in June and August.

S. lavigatus and *S. pulverulentus* are North American species, and are natives of the woods of the Carolinas and Virginia.

Several other species are described from South America, mostly from Brazil.

SUBAPLYSIA/CEA, M. De Blainville's name for the first family of his *Monopleurobranchiata*.

SUBEL. [QUERCUS.]

SUBMARINE FORESTS. Under this term geologists class very numerous accumulations of vegetable matter, involving roots, stems, branches, leaves, and fruits of trees, rarely in the attitude of growth, sometimes in the condition of having fallen, and locally with the appearance of having been drifted from some distance, but all occurring on the margin of the sea, below the level of high-water, and extending not unfrequently much beyond the low-water line.

Subterranean Forests is another term for similar phenomena, not limited however to any particular level, nor to a close proximity with the sea. The circumstances as to level, and physical condition of the neighbouring regions, when these hurried forests either grew on or were drifted to their present repositories, and the changes in these respects which may have since occurred, are extremely worthy of consideration.

If we take, as a mode of classifying these phenomena, the relative levels of the hurried forests and the surface of the sea, we find a series of instances, beginning on high ground, and ending below the sea. On parts of the very high ground at the head of Glencoe, we see yet rooted in peaty soil the bases of enormous trunks of trees, while far around, and even in much lower levels, and warmer and more sheltered situations, large trees are altogether wanting. On the moderate elevations between Kirby Lonsdale and Kendal are small dried basins of ancient lakes, in which portions of fir-trees abound; on the course of many rivers, in flat parts of valleys, and especially when they approach the sea, as at Ferrybridge on the Aire, and at Stockton on the Tees, vegetable accumulations, peaty plants, and lacustrine shells, hazel-wood, nuts, and large trees abound. In situations where the tides cease to have power, along the sides of rivers, the accumulations of this nature are locally enormous, as over the large area of Hatfield Chase and Thorn Waste in Yorkshire, Sedge-moor in Somersetshire, and the fens of Huntingdon and Cambridge. Finally, on reaching the actual sea-shore, whether along the course of a great river, as the Humber or the Mersey, or on the bare coast, as in Lincolnshire, Yorkshire, Norfolk, and many parts of the coast of Great Britain, we find narrow or extensive deposits of like nature, both above high-water and below low-water mark. Generally in all these situations, the trees, even though not now growing in the neighbourhood, are of sorts that belong to the same latitude and the same region. What might be the circumstances which encouraged their growth in ancient times is not easy to be determined. Instead of supposing any elevation of land since the growth of trees in the high valleys about Glencoe, which, by raising the surface to a temperature too low, prevented their continued existence, it appears better to suppose that the duration of forests under some constant conditions is limited. It is only by mutual protection in some cases that trees rise to perfection. Arriving from this cause nearly at once to maturity, and passing by equal stages to decay, it may easily happen, in a limited area, that a whole forest of trees should perish and be followed by no successors. Such an occurrence might be accidentally caused by the alteration of the supply of water, the growth of peat, addition of sediments, and other causes of injury. Violent tempests might prostrate a forest, and affect the drainage of the country, and thus convert the area where the forest grew into a marsh, a peat-bog, a buried forest.

Suppositions of this nature have commonly been suggested by the phenomena observed in various parts of Europe. De Luc adopts such views regarding the buried pine-forest of Bornholm, which is covered by peat and surrounded by sand-hills. The trees lie prostrated from the circumference toward the centre, not by the force of inundations, but by the violence of winds. ('Hist. de la Terre,' v. 222.) A similar opinion has been entertained concerning some part of the extensive levels of Hatfield Chase in Yorkshire, where in places the trees appear as if prostrated in a particular direction. Moreover, in examining the deposits of this nature on the shores of the Firth of Tay, Dr. Fleming found the clay below the peat penetrated by numerous roots, which are either carbonised or pyritised.

But there are other cases in which the accumulations of hurried timber and peat may better be supposed to have been drifted. This

appears to be the fact in the eastward prolongation of the great levels of Hatfield Chase along the estuary of the Humber, and much below its level. De Luc supposes the same thing in regard to the peaty deposit of Rotterdam, which rests on silt, as that reposes on sand. He regards the whole as drifted by the river currents, and as accumulated below the river waters.

There are many examples of the occurrence in one deposit of sand, clay, peat, timber, lacustrine shells, and bones of quadrupeds. It is rather characteristic of such combinations that there is only one layer of peat with trees, that it lies upon the clay, and that in this clay are the lacustrine shells and the bones of quadrupeds. This general rule applies to numerous small deposits on the coasts of Yorkshire and Lincolnshire, including bones of deer, and to the larger area of the Irish peat, which yields the bones of the gigantic elk; and is exemplified in the American deposits which contain the mastodon. Beneath the whole of these deposits frequently lie the gravelly clays and sands, with boulders of distant rocks, commonly called Diluvium. The shells are usually of existing species, the trees of existing kinds, but the quadrupeds (Beaver and Irish Elk for instance) often of races locally or universally extinct.

It has been thought necessary in some cases to appeal to a local change of the relative level of land and sea for an explanation of the submerged forests of the English and European coasts: sometimes this may be avoided by assuming in ancient times a different condition of the tides; and sometimes it is unnecessary, because the trees may be supposed to have been transported. It should seldom be granted, because, in the very same district, the diluvium with its marine shells may be thought to be a 'raised beach,' and the submarine forests to mark a real subsidence of the land. This is the case in Holderness.

The antiquity of these buried forests is often beyond the reach of inference, but in many inland districts the condition of the trees is such as to have led observers to believe they were cut down or burned down. In Hatfield Chase ('Phil. Trans.' 1701) many of the trees were thus destroyed; some were evidently worked by the woodman's tools of stone or wood. Roman coins were gathered from among the roots; and in one situation the ground below seemed to have been ploughed in ridge and furrow.

Examples of accumulations such as have here been generalised, are abundant round all the shores of Britain, and are common in the interior of the island.

(De la Beche, *Geological Manual*; Lyell, *Principles of Geology*; Phillips, *Treatise on Geology*, vol. ii.; De Luc, *Histoire de la Terre*; De la Puyne, in the *Philosophical Transactions*, abridged by Hutton; *Transactions of the Cornish Geological Society*, &c., may be consulted for details of phenomena and reasoning on the causes and dates of their occurrence.)

SUBMYTILACEA, M. De Blainville's name for his sixth family of *Lamellibranchiata*.

The following is a definition of the *Submytilacea*.—Mantle nearly as in the *Mytilacea*, that is to say, adherent, and slit throughout its lower part, with a distinct orifice for the anus and a commencement of a tube for respiration by means of a particular disposition of its posterior extremity, which is furnished with tentacular papillæ; a large fleshy abdominal mass for locomotion, without byssus at its base; two distinct muscular impressions.

Shell free, subnacreous, regular, equivalve; dorsal hinge lamellar, ligament external; two muscular impressions with the pallial impression which unites them not excavated backwards.

M. De Blainville remarks that this family are more or less inhabitants of mud, and are locomotive by means of their foot.

He divides them into two sections:—

1. The *Limnoconchs* (*Limnoderma*, Poli).

All these have an epidermis, are nacreous, and are inhabitants of fresh waters. [NAIADÆ.]

2. Species without any evident epidermis, not nacreous, and more or less pectinated.

These are marine.

Under this section M. De Blainville arranges but one genus, *Cardita*. Animal resembling that of the Fresh-Water *Musclea*. [NAIADÆ.]

Shell very thick, solid, equivalve, often very inequilateral; umbones recurved forwards; hinge with two unequal oblique teeth, one short and cardinal, the other long, lamellar, bent, and placed much more backwards; ligament elongated, subexternal, and sunk into the shell; muscular impressions rather large and very distinct; pallial impression narrow.

M. De Blainville divides the genus into the following sections:—

A. Elongated species, a little notched or gaping at the inferior border; umbo nearly cephalic; ligament hidden. (The *Mytilicardia*.)

Examples, *Cardita crassicosta*, Adans., 'Seneg.' pl. 15, f. 8; *Cardita calyculata*, 'Malacol.' pl. 69, fig. 1.

B. Oval species, with the inferior border nearly straight or a little convex, crenulated and completely closed. (The *Cardiocardia*.)

Ex. *Cardita Ajar*, Adans., 'Seneg.' pl. 16, f. 2.

C. Species nearly round or suborbicular, with the inferior border rounded, denticulated, and more and more equilateral; the two teeth shorter and more oblique. (Genus *Venericardia*, Lam.)

Ex. *Venericardia imbricata*, 'Malacol.' pl. 68, f. 3.

D. Elongated and very inequilateral species; the umbo nearly cephalic and recurved forwards; two short cardinal diverging teeth besides the lamellar tooth; ligament very long, little or not at all projecting; abdominal impression sometimes a little directed backwards. (Genus *Cypriocardia*, Lam.)

Cardita calyculata has the shell oblong, white, painted with lunate brown spots; the ribs imbricate-squamous; the scales arched and incumbent.

Cardita calyculata.

a, with the umbones turned towards the spectator, showing the lunule.

Species of *Cypriocardia*, *Venericardia*, and *Cardita* occur fossil from the Lower Silurian upwards. [VENERIDÆ.]

Venericardia (Cardita) imbricata.

Fossil from Grignon. A variety found at Courtagnon.

SUBOSTRACEA, M. De Blainville's name for his second family of *Lamellibranchiata*. [PECTINIDÆ; SPONDYLIDÆ.]

SUBULA. [ENTOMOSTOMATA.]

SUBULARIA (from 'subula,' an awl, from the form of the leaves), a genus of Plants belonging to the natural order *Crucifera*, and the tribe *Subularicea*. It has an oval-oblong laterally compressed pouch, with boat-shaped valves.

S. aquatica, Awl-Wort, is a little aquatic stemless herb, with fascicular simple white fibrous roots. The radical leaves are linear and awl-shaped, the scapes naked and few-flowered, the pedicels filiform and bractless. It is a native of the colder parts of Europe, in ditches, lakes, and rivulets with a sandy or gravelly bottom. It is also found plentifully in the north of England, Scotland, and Ireland. Sir W. Hooker and Sir J. E. Smith agree in stating that the flowers always remain several feet under water, even during the time they are expanded, so that, contrary to the general rule, fertilisation must take place in that element.

(Babington, *Manual of British Botany*; Burnett, *Outlines of Botany*.)

SUBULICORNES. [NEUROPTERA.]

SUCCINEA, a genus of Pulmoniferous Gasteropodous *Mollusca*, belonging to the *Colimacea* of Lamarck and the *Limacinea* of De Blainville. It is the sub-genus *Cochlohydra* of Férussac.

The shell is ovate, rather elongated, with a large entire longitudinal aperture, and a short spire; the outer lip is thin, and continuous with the delicate sharp-edged columella; the inner lip is spread over a part of the body-whorl.

Cuvier, who places the genus between *Chondrus* and *Clavilia*, remarks that the animal cannot withdraw itself into the shell entirely, and that it may be regarded almost as a *Testacella*, with a large shell. It has, he remarks, the lower tentacula very small, and lives on the herbage and plants on the brinks of streams, whence it has been considered as amphibious. [HELICIDÆ.]

The most familiar species is *Succinea putris*, *Helix putris* of Linnæus, which is common in moist places, on the banks of fresh waters.

SUCCINITE. [GARNET.]

SUCCORY. [CICHORIUM.]

SUCCULATÆ, the name of a natural order of Plants in the 'Fragments of a Natural System' of Linnæus, adopted by Bartling

It includes those families which are remarkable for the succulent character of their leaves, as *Saxifragaceæ*, *Crassulacæ*, *Ficoidaceæ*, &c.

SUCHOSAURUS, a genus of Fossil Saurians of the Wealden Formation of Tilgate.

SUCKING-FISH. [DISCOBOLI; ECHINEIS.]

SUCTORIA. [PULEX.]

SUCTORIA. [ANNELIDA.]

SUCTORIAL CRUSTACEANS. [SIPHONOSTOMATA.]

SUGAR is a sweet soluble crystallisable substance found very generally in plants. It differs from the other assimilable secretions of plants in its solubility, its sweet taste, and the readiness with which it enters into fermentation. Chemists have detected different kinds of this substance. Thus there is Cane-Sugar, Grape-Sugar, Eucalyptus-Sugar, Milk-Sugar, &c. There are other sweet secretions of plants as Mannite and Glycyrrhizin, which seem to be modifications of some common form.

The physiological action of Sugar seems to be indicated by its ready solubility, a property which renders it easily conveyable from one part of the plant to another.

Sugar is found under all circumstances in some plants, but in the great mass of the vegetable kingdom it presents itself at particular seasons. It is found very generally in the seed during germination. It appears that the starch of the albumen of the seed is converted first into dextrine and then into sugar, whilst the embryo is growing. Here it seems a provision for assisting the growth of the tender tissue of the germ. In this stage it is obtained for the purposes of fermentation, as in the brewing of beer, where germinating barley is converted into malt for the sake of the sugar.

Sugar is frequently found in considerable quantities in the sap of trees previous to their budding. It is found in sufficient quantities in the sap of *Acer saccharinum*, to be separated for dietetical purposes in North America. The Common Birch (*Betula alba*) contains so large a quantity of sugar in its sap that it is employed in the north of England and Scotland for making an effervescing wine in considerable repute. Many other trees yield sugar in their sap.
